An actual working design of a collinear array is presented here. It has two identical dipoles fed with a coaxial phasing line or 'harness'. Each dipole element is tuned by a gamma matching system similar to that described in chapter 6. In fact, it is the same design of dipole just 'doubled' and fed simultaneously. This configuration gives a gain of 3 dB compared to a single dipole.

This model is dimensioned to operate in the frequencies of 140-150 MHz band. It has an SWR response of less than 1.5:1 over the entire band. Tuning procedure is similar to that described for dipole model DP-2.

Materials needed

Most of the materials needed to build the antenna model SD-22 are the same with those needed for antenna model DP-2 except for the mounting channel. The mounting channel for SD-22 is shorter being only 8 inches long and has slits on two sides instead of two holes.

Additionally, another long square channel is needed to mount the two dipole elements into a single mast. Also, a system of phasing harness made of coax cable is required to feed the two dipoles simultaneously. In short the additional materials needed for SD-22 are as follows:

Quantity	Description	Dimensions
2 pcs.	Square aluminum channel	1" x 1" x 8"
1 pc.	Square aluminum channel	1" x 1" x 115"
2 pcs.	Hose clamp	2 - 1/2" clamping capacity
6 pcs.	BNC VHF male connector	
2 pcs.	BNC 'T' connector	

Construction

Follow the procedures for constructing the dipole antenna model DP-2 and make two identical dipoles. The mounting channel for model SD-22 is slightly different and is described in the following illustration (see Figure 14.2).

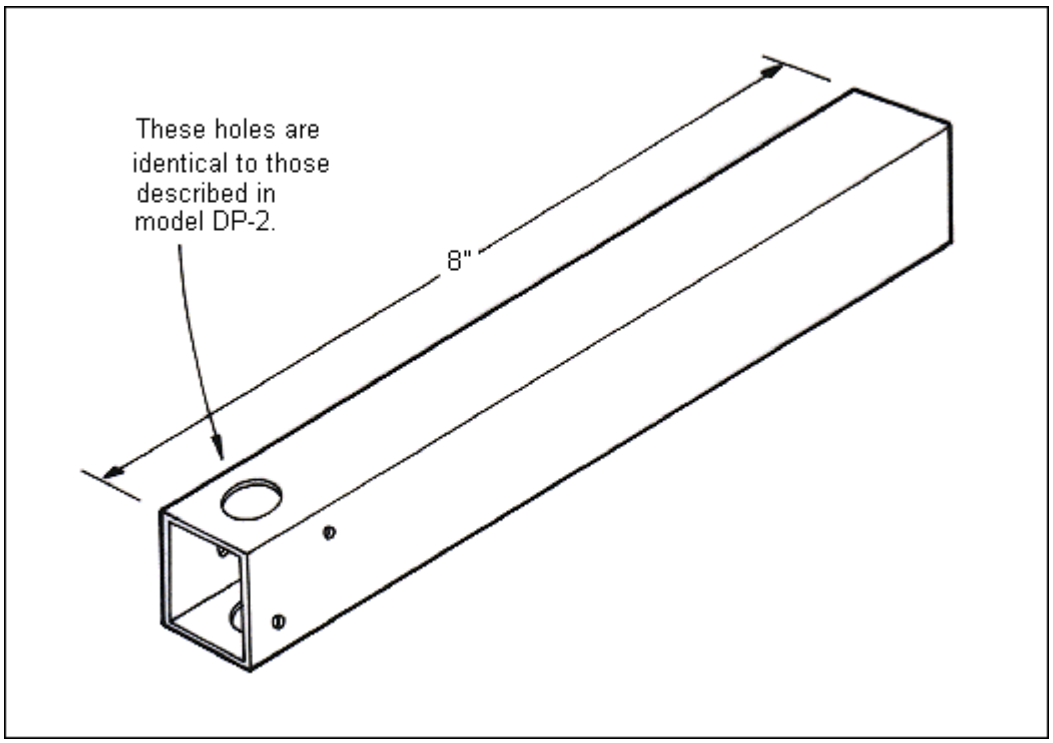

Figure 14.2 Mounting channel dimensions.

Saw shallow slits at two sides of the channel using a hacksaw. A hose clamp will be inserted into these slits for the purpose of mounting the channel to the supporting mast (see Figure 14.3).

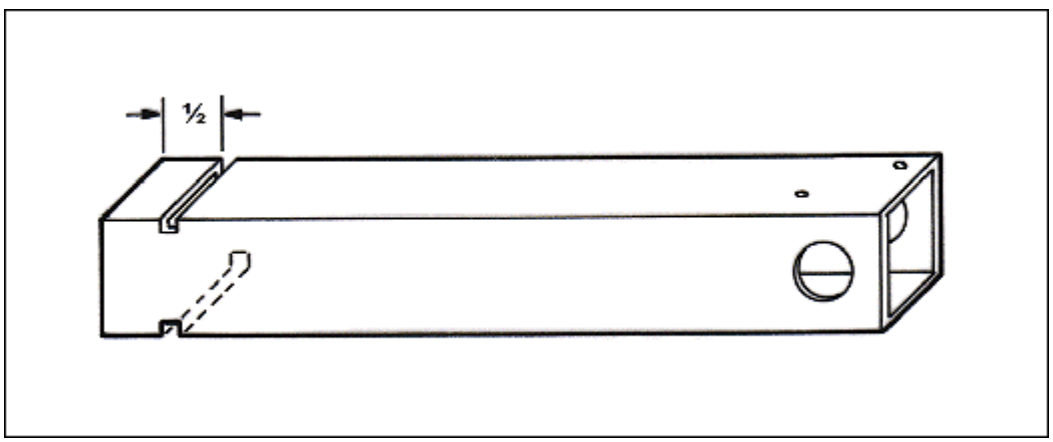

Figure 14.3 Saw slits at two sides of the channel.

Assemble the two dipole elements following the procedures described for antenna model DP-2. After the dipoles are completed, insert the hose clamps through the slits in the channel (see Figure 14.4).

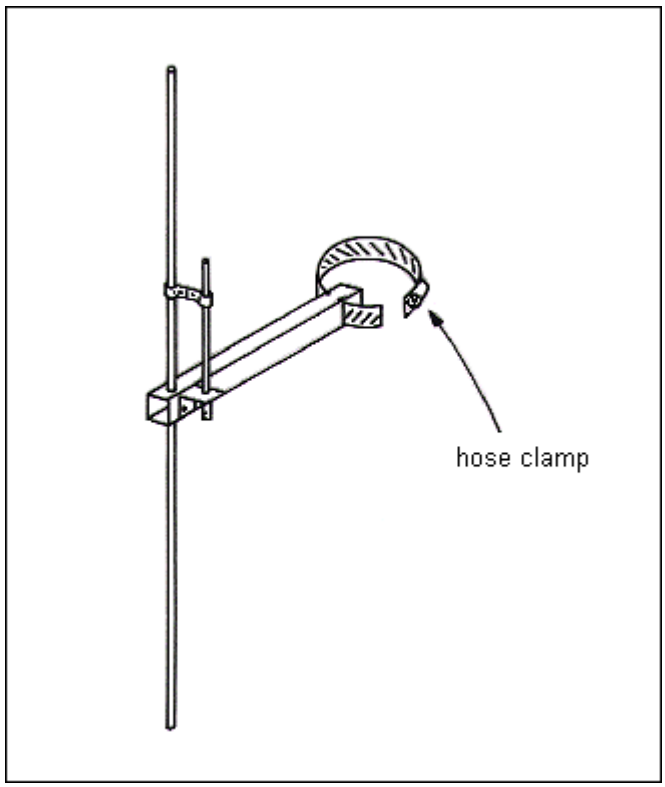

Figure 14.4 Assembled dipole element with hose clamp.

Mount the two dipoles to the aluminum supporting mast following the dimensions shown in Figure 14.5. Wrap the two hose clamps around the body of square channel mast and tighten the clamps to hold the dipole elements rigidly.

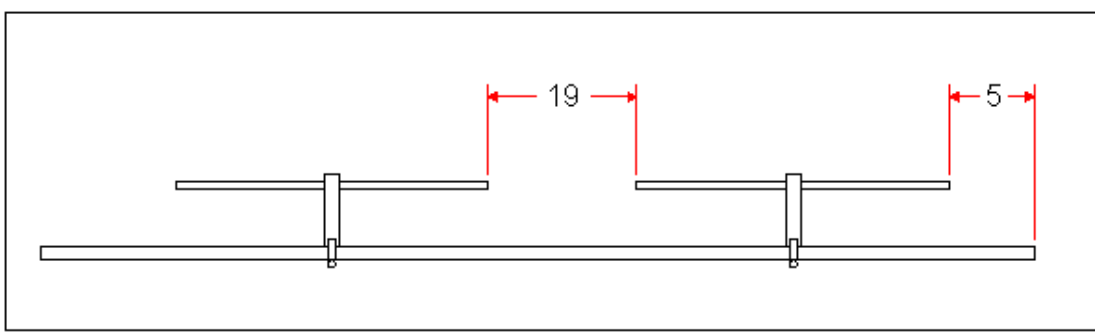

Figure 14.5 Mounting the dipoles to the aluminum mast.

Next, construct the phasing harness using RG-58/U coaxial cables and the appropriate connectors (see Figure 14.6).

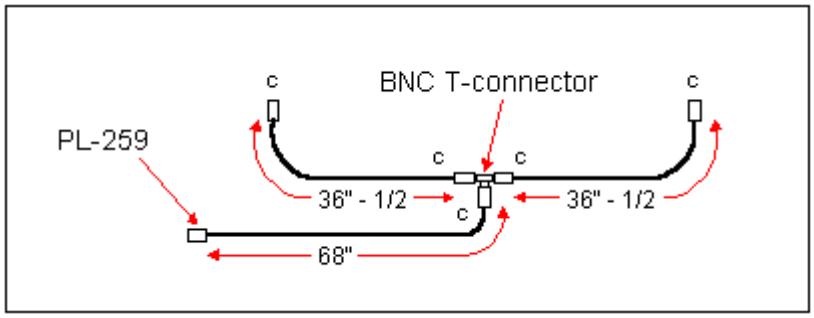

Figure 14.6 Constructing the phasing harness.

Finally connect the phasing harness to the two dipole elements and secure it to the support mast with plastic binders (see Figure 14.7).

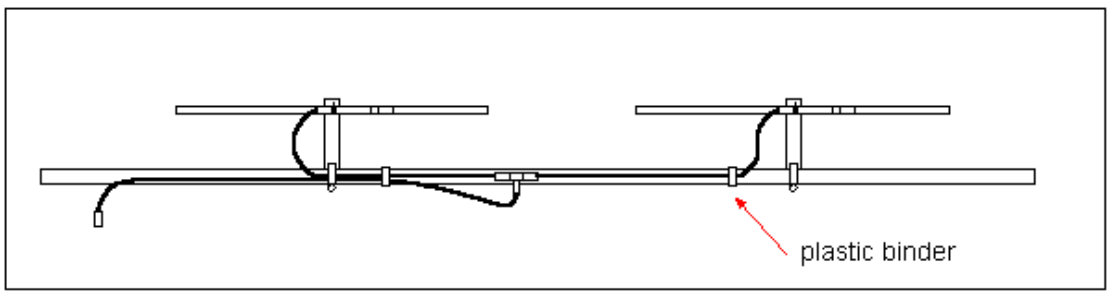

Figure 14.7 Connecting the phasing harness to the antenna.

Tuning the antenna

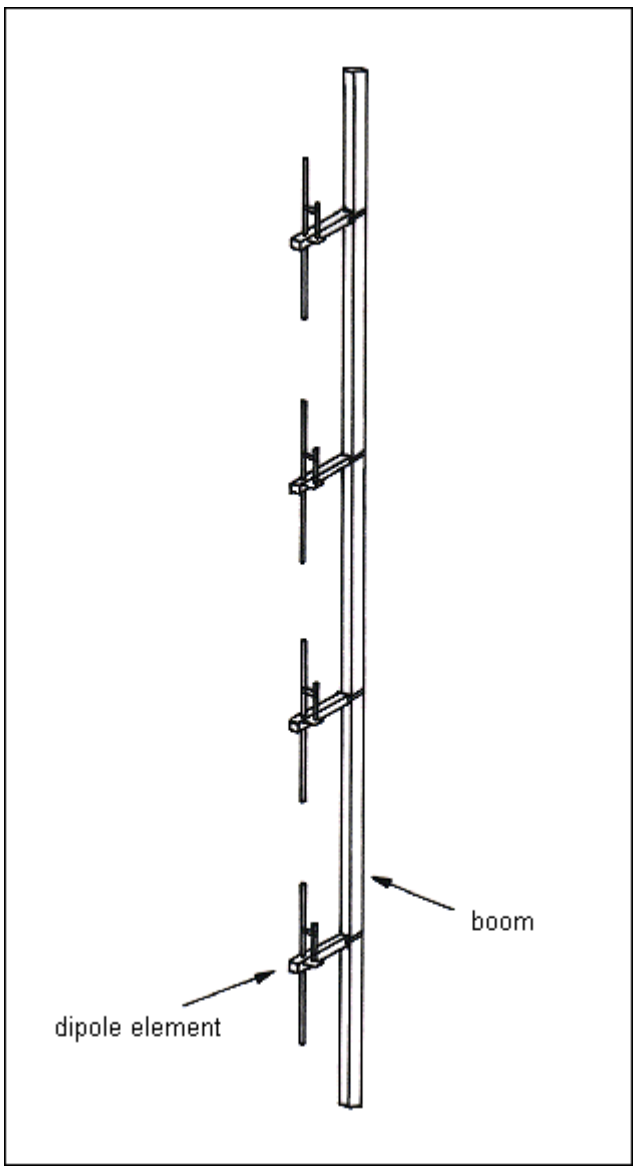
The tuning procedure for the antenna model SD-22 is similar to the procedure for tuning the antenna model DP-2. In tuning the SD-22 however, the two dipoles have to be tuned simultaneously. You have to do a lot of shuttling back and forth between the two dipoles before you can achieve a good match. If it is not practical to tune the antenna right in the main mast, then it can be tuned on the ground by placing it in a horizontal position with the dipoles facing upward. The antenna must be elevated to not less than 1 meter above the ground supported by non-metallic materials like wooden benches for example.

15 STACKED DIPOLE ARRAY

Model SD-24 (four stacked dipole)

This model demonstrates the capability of a simple dipole to attain high power gain by simply stacking identical units into a single structure and feeding them all simultaneously with a phasing harness. This arrangement is also called collinear array.

As stated earlier in chapter 14, power gain in a collinear array increases in direct proportion to the number of dipole elements used. However, in order to construct a practical phasing harness, the number of dipole elements installed cannot be simply dictated by personal choice. The correct method is to double the original number of dipole units - meaning, it the original array has two dipole elements installed, then the next array must have four dipoles and the next must have eight dipoles and so on. Everytime the number of dipole elements used is doubled, the power ratio is also doubled.



NOTE:
The power ratio is not numerically the same with the dB figure. For accurate computations refer to Appendix.

The particular four-element array presented here has a power gain of 6 dB. A collinear array having eight dipole elements will have a power gain of 9 dB. An array with elements in excess of eight is rarely constructed because of the inherent mechanical problems encountered in erecting structures of this size. Most collinear antennas are mounted vertically to effect an omni-directional pattern of radiation.

The model SD-24 is specifically dimensioned to operate in the frequencies of 140-150 MHz band. If properly tuned, this array exhibits an SWR of less then 1.5:1 over the entire band. The procedure for tuning this antenna to resonance is similar to the procedure for model SD-22.

Materials List

The necessary materials in building this antenna are the same with those needed for SD-22 being its extended version. The square channel used to mount the four dipoles is larger and twice longer than the one used for SD-22. Additional set of phasing harness is also needed to feed the four dipole elements simultaneously.

Additional materials for Model SD-24 are as follows:

1 pc.	**Square aluminum channel**	**1-1/2" x 1-1/2" x 235"**
4 pcs.	**BNC male connectors**	
2 pcs.	**BNC 'T' connectors**	

Construction

Construct the four dipoles following the procedures described for models DP-2 and SD-22. Mount the four dipoles to the aluminum supporting channel by using hose clamps. The antenna elements must be attached to the mast with the proper distances from each other (see Figure 15.2).

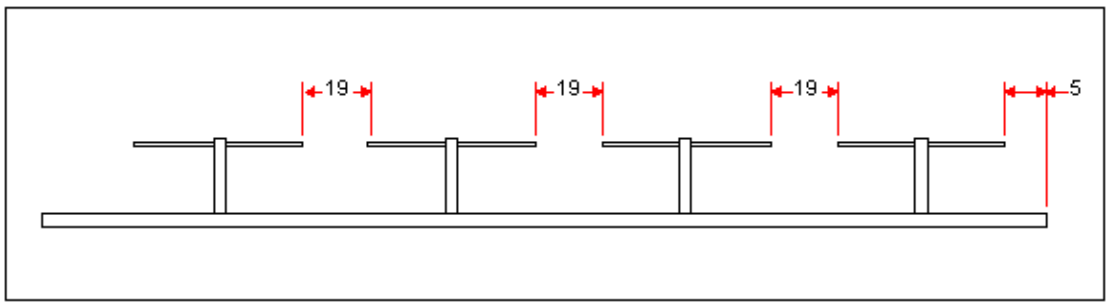


Figure 15.2 Mounting the four dipole elements on the mast.

Construct the phasing harness as shown and attach it to the four dipoles in similar fashion to model SD-22 antenna (see Figure 15.3).

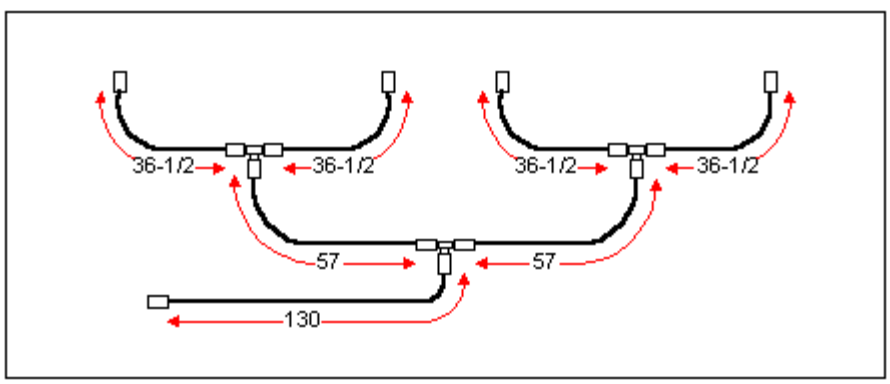

Figure 15.3 Constructing the phasing harness.

Tuning SD-24 to resonance

Tuning the antenna model SD-24 to get a good match is similar to procedures for tuning antenna model SD-22.

16 YAGI-UDA ANTENNA

Model YG-23 (3 element beam)

A yagi-uda antenna is a type of an array having one active dipole and two or more parasitic elements. It was named after the two Japanese physicists who invented it. The basic yagi is one of the highest gain antennas yet developed. Several factors affect the performance of a Yagi. Among these are the number of elements used, their diameter, and the spacing between them.

A basic hafwave dipole is cut to resonance at the center of the frequency band and is utilized as the driven element. High gain is attained by the addition of parasitic elements positioned either in front or behind the driven element. These parasitic elements are called directors and reflectors depending on their length and positioning with respect to the drive element. The reflector is longer by approximately 5 % and is positioned behind the driven element. The director on the other hand is cut shorter by approximately 5% and is positioned at the front of the driven element. The combination of these elements produce the directivity of the radiated signal thus resulting to higher power gain. However, the radiation pattern becomes uni-directional and the much desired omni-pattern is completely lost.

Maximum radiation of signal is now concentrated at the front of the antenna and there is only minimum radiation at the back. The ratio between the radiated signal at the front and the radiated signal behind it is called 'front to back ratio'. Radiation is weakest at the sides of the yagi and these points are called 'null points'. The ratio between the radiated signal at the front and the radiated signal at the sides is called 'front to side ratio'.

This highly directive and uni-directional characteristics of a yagi antenna necessitates the use of a rotator device in order to beam it to the direction of the station in contact. If a rotator device is not used, the high gain character of a yagi becomes useless unless the antenna is intended to be permanently beamed to a single direction such as in the case of fixed point-to-point communication.

The dimension of model YG-23 is specially cut to resonate in the frequency band of 140-150 MHz. If properly tuned, it exhibits an SWR of less than 1.5:1 over the entire band. It has a gain of approximately 7.3 dB compared to a standard dipole reference. This is only a basic configuration of a yagi and its gain and directivity can be increased by adding more directors at the front. Detailed information for the exact dimensions of additional director elements and their spacing is given in chapter 17. These yagi dimensions are based on the information published by the National Bureau of Standards.

Scaled down Appearance

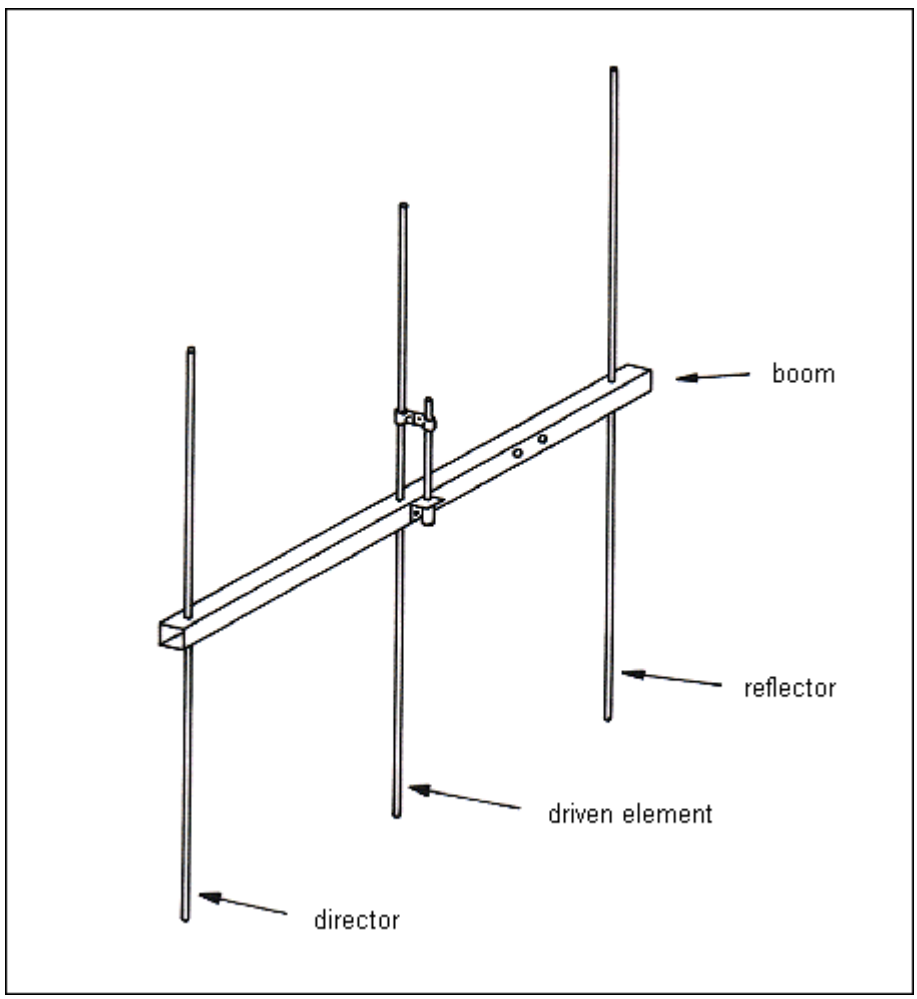

Figure 16.1 Yagi antenna model YG-23

Materials List

Quantity	Specification/Description	Dimensions
1	Aluminum tube 3/8" od*	3 feet 4"
1	Aluminum tube 3/8" od*	3 feet 2-3/16"
1	Aluminum tube 3/8" od*	3 feet 7/8"
1	Aluminum square channel	1" x 1" x 2 feet and 32-1/4"

Other materials used in constructing the antenna DP-2 are also needed for this yagi antenna except for the mounting channel.

* od - outside diameter

Construction

Cut the three tubes to their exact lengths and drill a hole (1/8" diameter) thru and thru at its middle length. The shortest tube will be used as a **director** element, the longest tube will the **reflector** element and the medium length will be the **driven** element (see Figure 16.2).

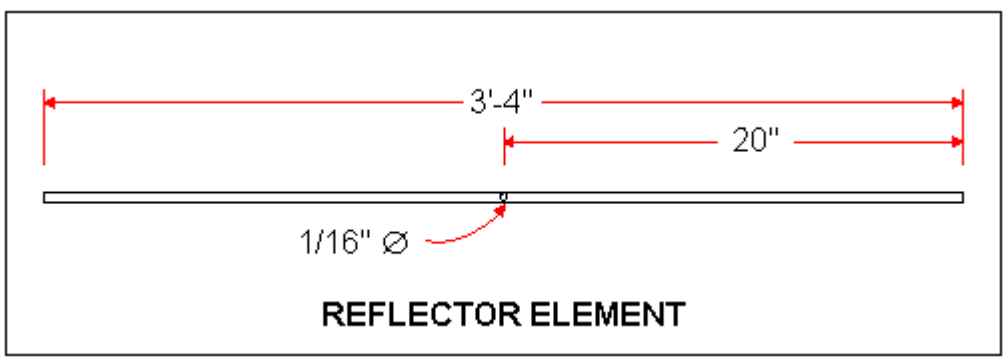

Figure 16.2 Preparing the reflector element.

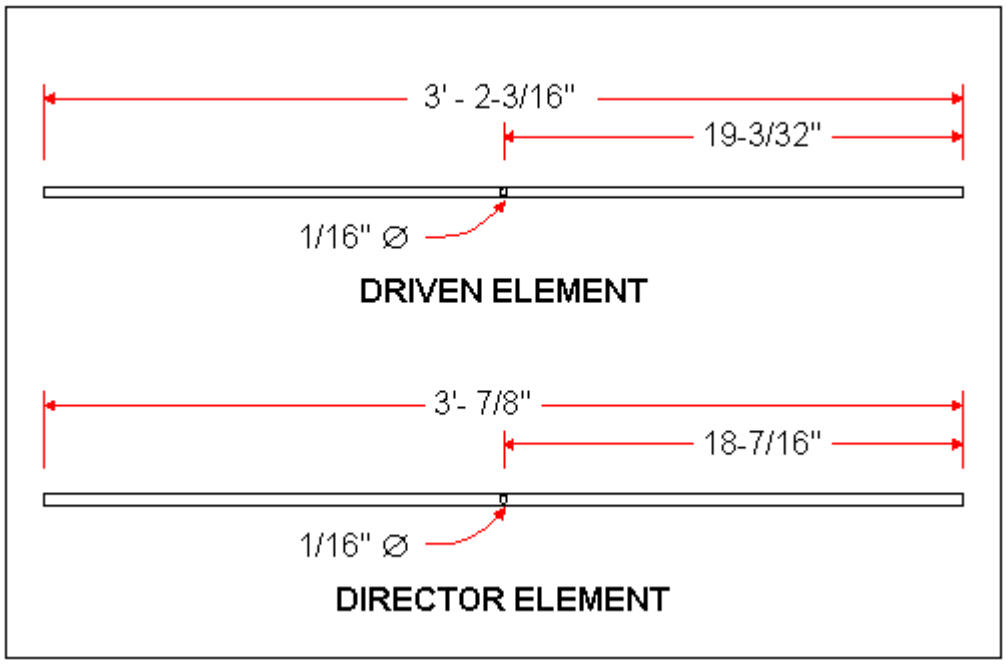

Figure 16.3 Preparing the driven and director elements.

Cut the aluminum mounting tube or boom to 2 feet and 11 inches long and drill three holes thru and thru at one side. The holes must have a diameter of 3/8" or enough to accomodate the diameter of the tube that will be inserted into it. Follow the dimensions shown. Drill also three 3/8" diameter holes at the same point where the larger holes are but at one side. The axis of the smaller holes must cross the axis of the larger holes (see Figure 16.4).

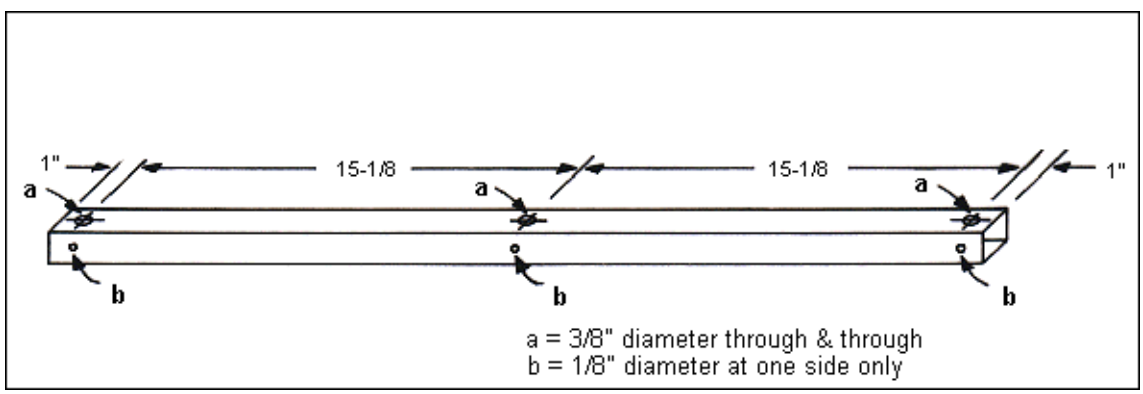

Figure 16.4 Preparing the boom.

Insert the aluminum tubes to the boom following the illustration for the proper arrangement of the elements. Secure the tube to the boom by placing the screws through the holes at the sides similar to the method of attaching the dipole element of the antenna model DP-2 (see Figure 16.5).

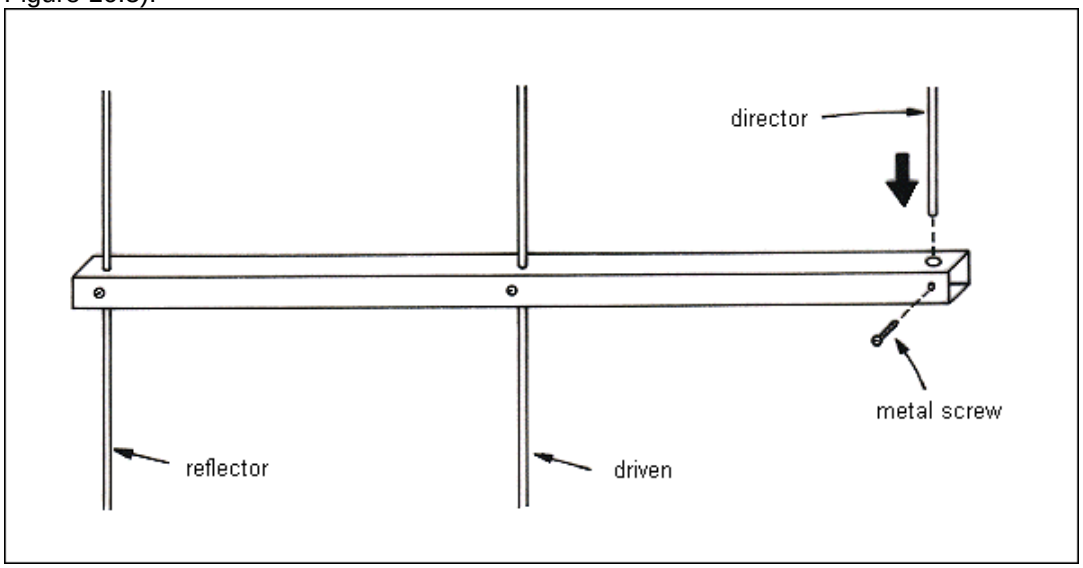

Figure 16.5 Assembling the antenna elements to the boom.

Complete the attachments of the **driven** element following the procedures described for model DP-2. All other materials and dimensions (e.g. gamma, bracket, connector, clamp, etc.) are similar to those used for the dipole elements of DP-2 (see Figure 16.6).

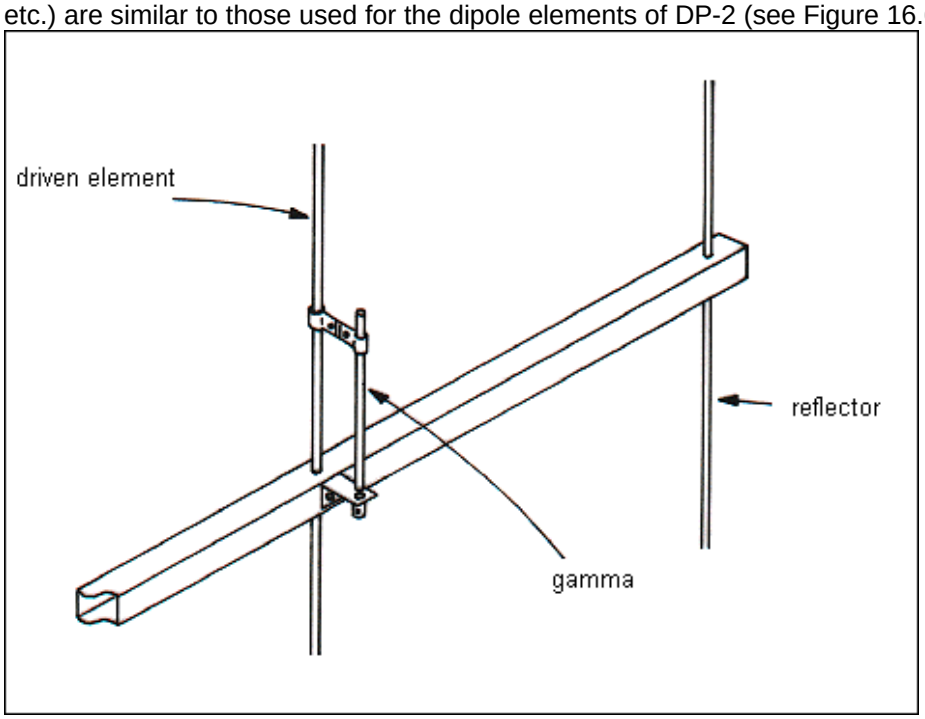

Figure 16.6 Complete assembly of the driven element.

Installation of YG-23

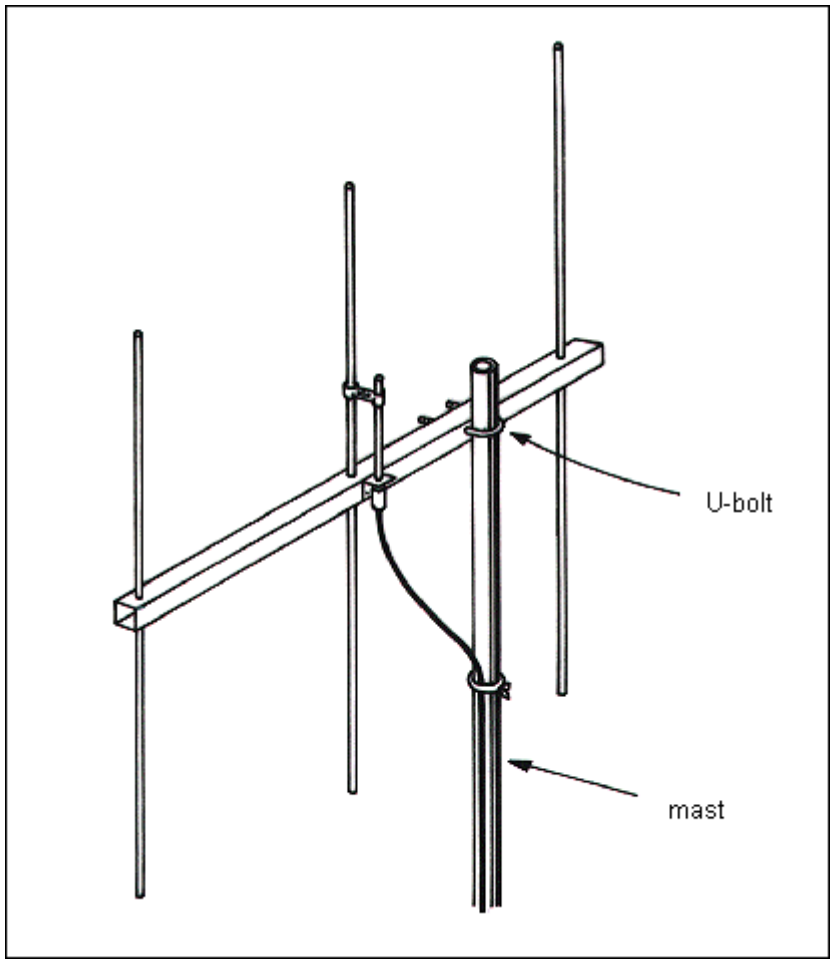

Figure 16.7 Installing the YG-23 to the mast.

Tuning YG-23 to resonance

The tuning procedure for the antenna model YG-23 is similar to the procedure for tuning antennas model DP-2, SD-22 or SD-24. The most important instruction to keep in mind is to tune the antenna while directly attached to the mast where it will be permanently installed whenever practical.

17 MULTI-ELEMENT YAGI-UDA ANTENNA ARRAY

The Yagi-Uda antenna or simply 'yagi' model YG-23 described in the preceeding chapter gives a fairly high gain figure in a very compact and easy to construct antenna. By adding more director elements at the front and extending the boom length of the yagi, you can achieve a very high gain figure from this type of antenna.

The following table shows the exact element lengths and dimensions for various yagi antennas based on the NBS standard. Two sets of dimensions are given, one set for the type of yagi antenna with elements that are insulated from the boom and another set for the yagi antenna with elements directly attached to the metal boom. The latter is widely popular among the antenna constructors because it is easier to construct and eliminates the need for individual insulators.

The construction of the reflector, driven element, gamma match, director elements, assembly of the whole antenna and tuning procedures are basically the same with the model YG-23.

NBS YAGI STANDARD DIMENSIONS

Boom Length	Boom Diameter	Element Diameter	Insulated Elements	Reflector	Driven	Dir.1	Dir.2	Dir.3	Dir.4	Dir.5

ELEMENT SPACING WITH RESPECT TO BOOM LENGTH

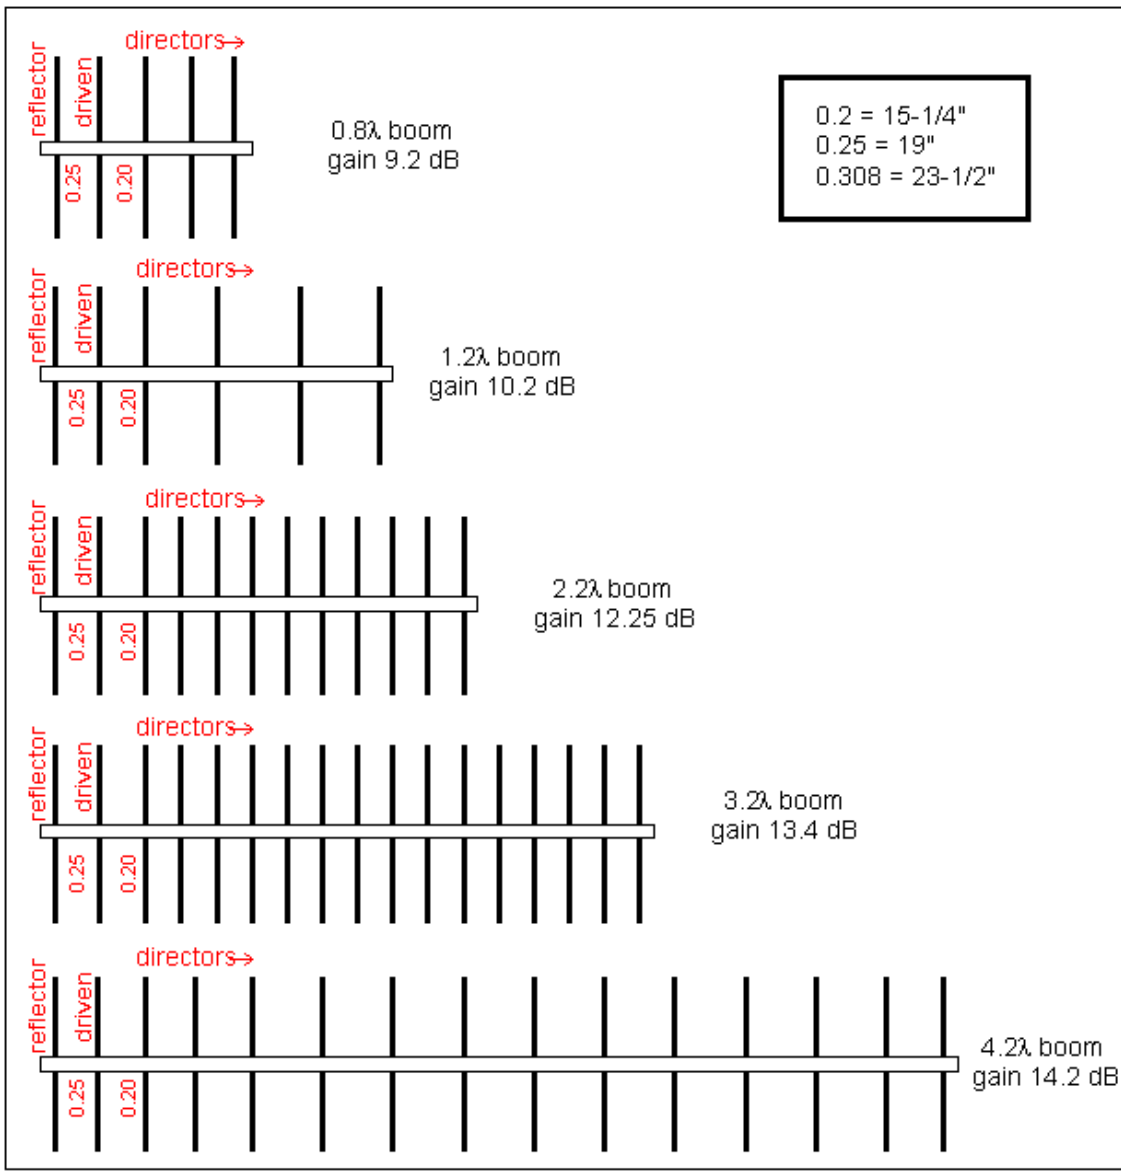

Figure 17.1 Element spacing of a Yagi antenna with respect to its boom length.

18 STACKING YAGI ANTENNAS

Stacking yagi antennas means multiplying the number of yagi antennas and feeding them all simultaneously. If a number of the yagi antennas is doubled, it will add an additional 3 dB to the original gain figure of the yagi. For example, if you feed two identical 3-element yagi which has a gain of 7.3 dB, it will give you a total gain figure of 10.3 dB. Similarly, a 17-element yagi with a gain of 13.4 dB will give a whooping 19.4 dB if stacked to four identical pieces!

In stacking yagis, the spacing between the antennas is important. The distance between two yagis stacked side by side must not be less than 1 wavelength or it must be approximately 77 inches. The distance between the tips of the elements in vertically stacked yagis must not be less than one-half wavelength or it must be approximately 38 inches (see Figures 18.1 and 18.2).

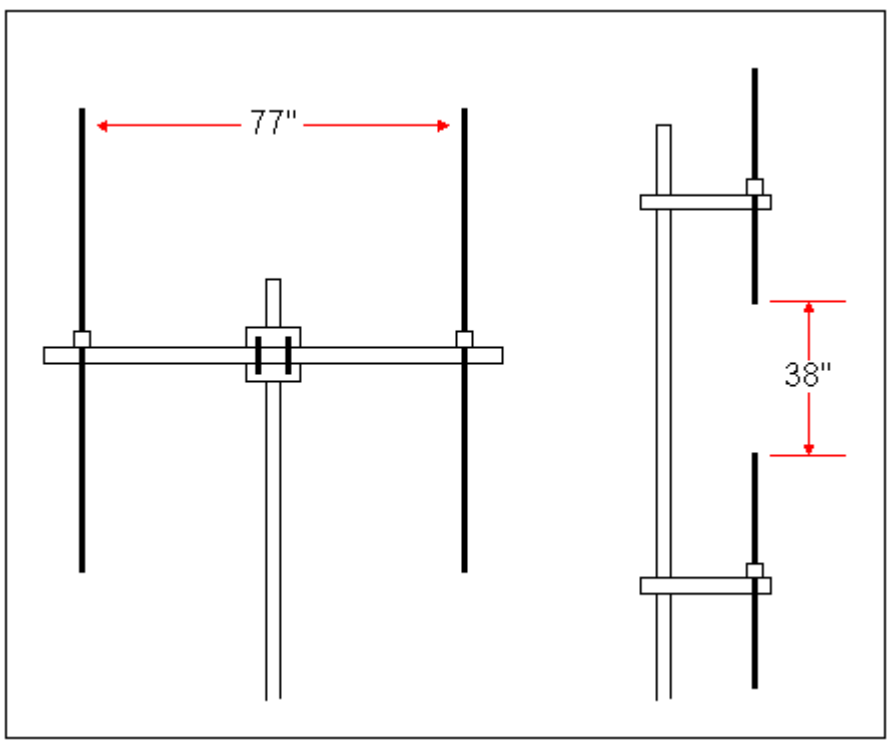

Figure 18.1 2 stacked yagis viewed at their boom ends.

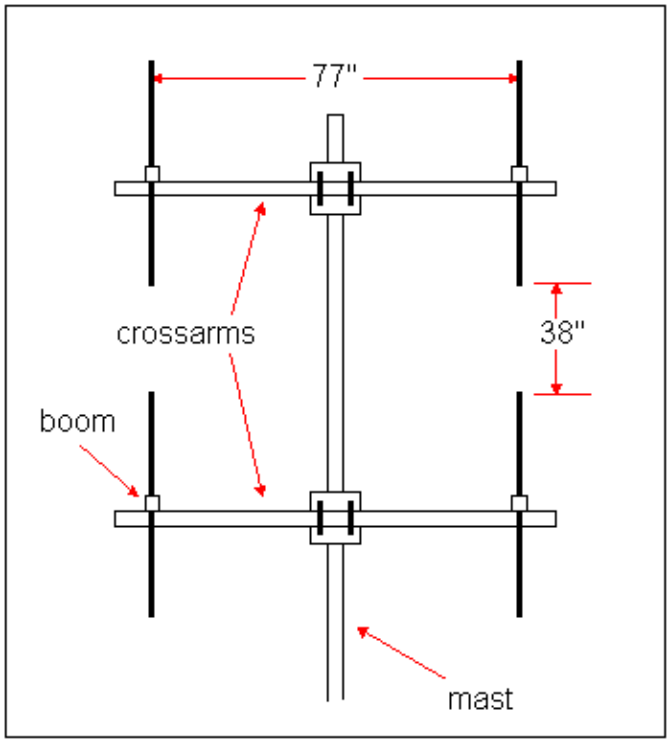

Figure 18.2 4 stacked yagis viewed at their boom ends.

All the yagis must be fed in phase with a phasing harness. For example, the configuration of a phasing harness for the 4 stacked yagis shown above is described in the following illustration.

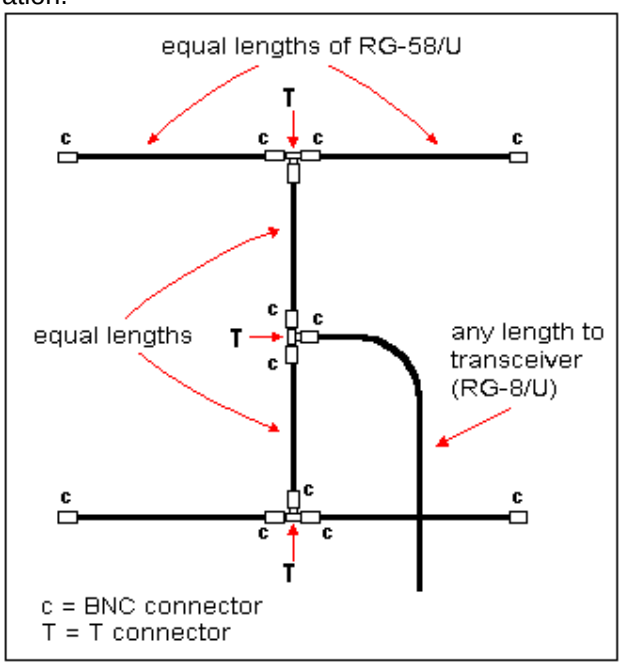

Figure 18.3 Phasing harness for a 4-stacked yagi antenna.

Mechanical Construction

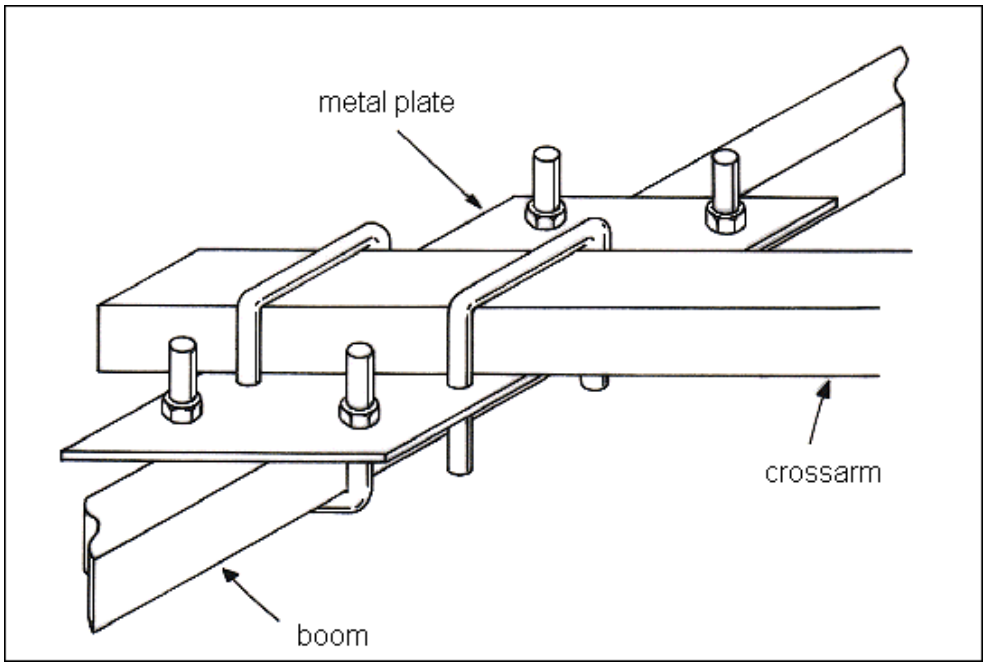

Figure 18.4 Attachment of the boom to cross-arm.

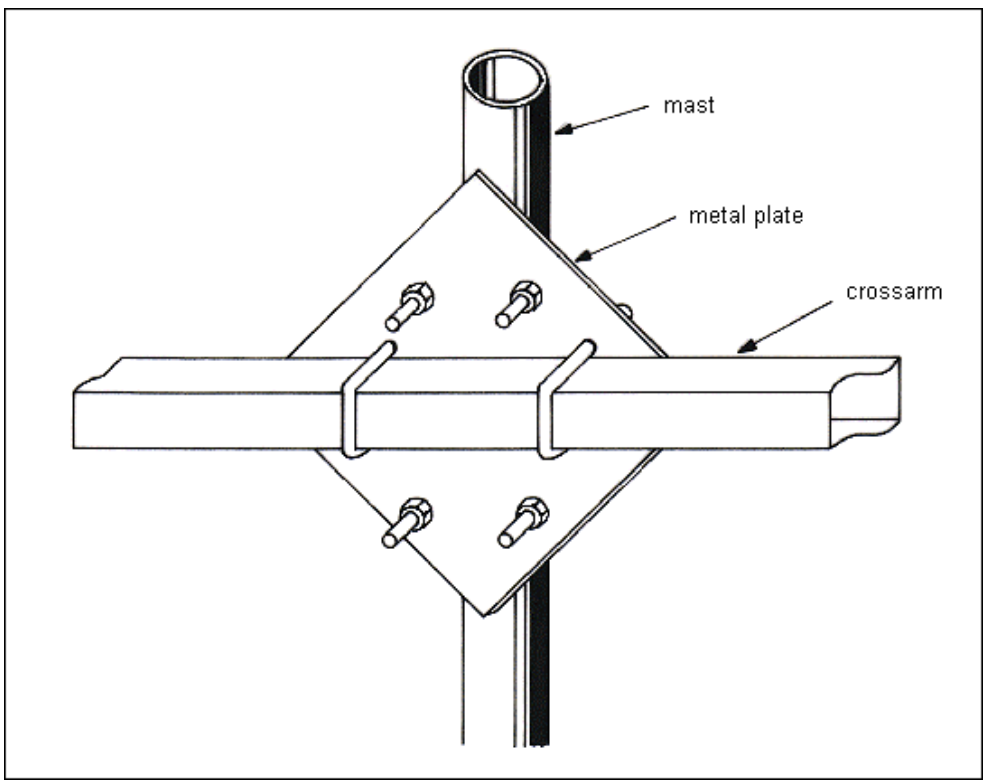

Figure 18.5 Attachment of the cross-arm to mast.

19 FORMULAS FOR CONVERTING ANTENNA DESIGNS FOR OTHER FREQUENCY BANDS

The dimensions of the antenna elements are generally derived from the antenna's electrical wavelength. **The electical wavelength of a certain frequency is slightly different from its wavelength in free space**, where the former is the wavelength of the signal present in the **physical** conductor of the antenna and is somewhat shorter.

The formula to get the electrical wavelength of a frequency is:

In feet:

$$\frac{936}{F_C \text{ (MHz)}} = \lambda \text{ (feet)}$$

In meters:

$$\frac{286}{F_C \text{ (MHz)}} = \lambda \text{ (meters)}$$

- F_C is the center frequency of the band expressed in Megahertz.
- Lambda λ is the symbol for the wavelength expressed either in feet or meters depending on the particular units used.

■ For example, the wavelength of 145 MHz is:

$$\frac{936}{145} = 6.46 \text{ feet or } 77.52 \text{ inches}$$

Other symbols of wavelength:

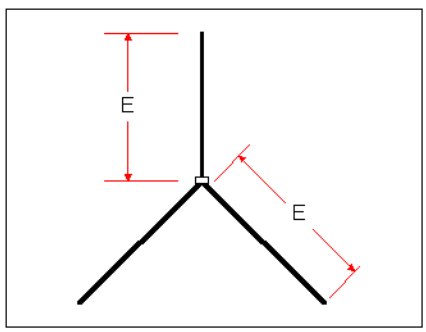
$\lambda/2$ or $(0.5)\lambda$ = halfwavelength
$\lambda/4$ or $(0.25)\lambda$ = quarterwavelength

Groundplane elements

The formula to get the length of each element of a groundplane antenna is:

$$\mathbf{E}\ (\text{feet}) = \frac{468}{Fc} \qquad \text{or} \qquad \mathbf{E}\ (\text{feet}) = 0.25\ \lambda$$

- To convert **E** (feet) to inches multiply it with 12.



- **Example:** Find the length of one groundplane element intended for 220 MHz.

Solution:

$$\mathbf{E}\ (\text{feet}) = \frac{468}{220} \qquad \textit{substituting the value of frequency}$$

$$\mathbf{E}\ (\text{feet}) = \frac{2.127}{2}$$

$$\mathbf{E}\ (\text{feet}) = 1.06 \qquad \textit{this is the length of the element expressed in feet}$$

To convert the result to inches:

$$\mathbf{E}\ (\text{feet}) \times 12 = \mathbf{E}\ (\text{inches})$$

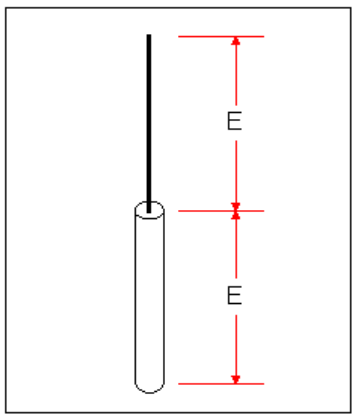
$$1.06 \times 12 = 12.72$$

$$\mathbf{E} = \mathbf{12.72\ inches} \qquad \textit{this is the length of the element expressed in inches}$$

Coaxial dipole elements

Formulas to find the elements of a coaxial dipole:

$$\mathbf{E}\ (\text{feet}) = \frac{468}{Fc} \qquad \text{or} \qquad \mathbf{E}\ (\text{feet}) = 0.25\ \lambda$$



- **Example:** Find the length of the element for a coaxial dipole intended for 110 MHz (also known as aircraft band).

Solution:

$$\mathbf{E}\ (\text{feet}) = \frac{468}{Fc}$$

$$\mathbf{E}\ (\text{feet}) = \frac{468}{110}$$

substituting the value of frequency

$$\mathbf{E} = 2.125 \text{ feet}$$

this is the length of the coaxial element expressed in feet

Convert the result to inches:

$$\mathbf{E}\ (\text{feet}) \times 12 = \mathbf{E}\ (\text{inches})$$

$$2.125 \times 12 = 25.5$$

$$\mathbf{E} = \mathbf{25.5\ inches}$$

this is the final value expressed in inches

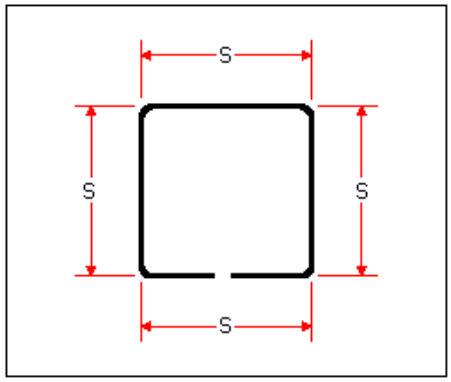
Quad loop antenna element

The formula to get the length of each side of the loop element for the Quad loop antenna:

$$\mathbf{S}\ (\text{feet}) = \frac{486}{Fc}$$

or

$$\mathbf{S}\ (\text{feet}) = \frac{0.25\ \lambda}{2}$$



■ **Example:** Find the length of one side of the quad loop intended for 155 MHz (VHF commercial band).

Solution:

$$\mathbf{S}\ (\text{feet}) = \frac{468}{Fc}$$

$$\mathbf{S}\ (\text{feet}) = \frac{468}{155} \qquad \textit{substituting the value of frequency}$$

$$\mathbf{S}\ (\text{feet}) = \frac{3.02}{2}$$

$$\mathbf{S} = 1.51 \text{ feet} \qquad \textit{this is the length of one side of the loop element expressed in feet}$$

Convert the result to inches:

S (feet) x 12 = **S** (inches)

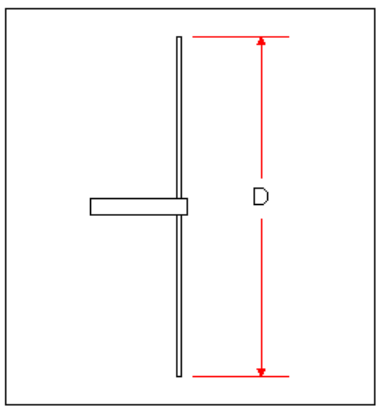
1.51 x 12 = 18.12

S = **18.12 inches** *this is the final value expressed in inches*

Dipole element

The formula to get the length of the dipole element for the antennas DP-22, SD-22, and SD-24:

$$\textbf{D}\ (\text{feet}) = \frac{486}{Fc} \qquad \text{or} \qquad \textbf{D}\ (\text{feet}) = 0.5\ \lambda$$



■ **Example:** Find the length of the dipole element intended for 195 MHz.

Solution:

$$\textbf{D}\ (\text{feet}) = \frac{468}{Fc}$$

$$\textbf{D}\ (\text{feet}) = \frac{468}{195}$$

D (feet) = 2.4 feet — *this is the length of the dipole element expressed in feet*

Convert the result to inches:

D (feet) x 12 = **D** (inches)

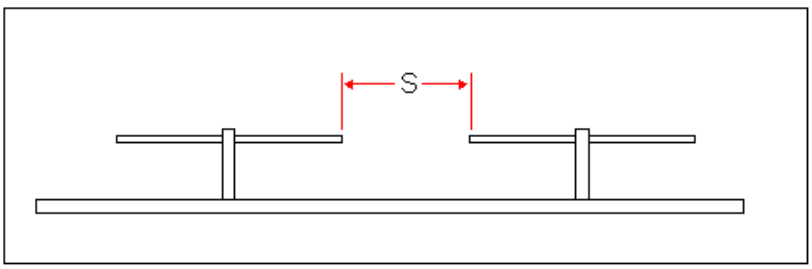
2.4 x 12 = 28.8

D = **28.8 inches** — *this is the final value expressed in inches*

Spacing between dipoles' ends

The formula to get the correct spacing between the ends of two dipoles in a collinear array such as SD-22 or SD-24:

$$\mathbf{S}\ (\text{feet}) = \frac{468}{Fc \quad 2} \qquad \text{or} \qquad \mathbf{S}\ (\text{feet}) = 0.25\ \lambda$$



■ **Example:** Find the spacing between two dipoles designed for 220 MHz.

Solution:

$$\mathbf{S}\ (\text{feet}) = \frac{468}{Fc \quad 2}$$

$$\mathbf{S}\ (\text{feet}) = \frac{468}{220 \quad 2}$$

$$\mathbf{S}\ (\text{feet}) = \frac{2.127}{2}$$

S = 1.053 feet *this is the length of the dipole element expressed in feet*

Convert the result to inches:

S (feet) x 12 = **S** (inches)

1.053 x 12 = 12.45

S = 12.45 inches *this is the final value expressed in inches*

NOTE:

This spacing is only for the minimum allowable between the ends of the dipole elements in a collinear antenna. Optimum spacing is within 0.25λ and 0.5λ.

Discone dimensions

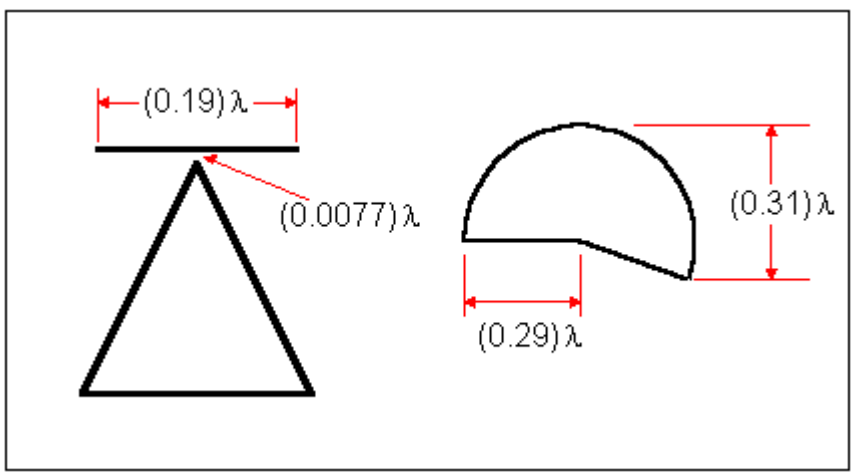
To get the exact lengths and dimensions of the discone antenna, first compute the wavelength of the lowest targeted frequency by using this formula:

$$\lambda \text{ (wavelength in feet)} = \frac{936}{Fc}$$

Formulas for dimensions:

The disc element diameter is **0.19** of the wavelength.
The cone element length is **0.29** of the wavelength.
The spacing between the disc element and the apex of the cone element is **0.0077** of the wavelength.

The diameter of the mounting tube is not critical.



■ **Example:** Find the dimensions of a discone antenna with a cut-off frequency of 120 MHz (upper portion of the aircraft band).

Solution:

First find the wavelength of the frequency by using the formula below and convert the result to inches.

$\frac{936}{Fc} = \lambda$ (wavelength in feet)

$\frac{936}{120} = 7.8$

7.8 feet = λ *this is the wavelength of the frequency in feet*

Convert it to inches:

7.8 x 12 = 83.6

λ (inch) = **83.6 inches** *wavelength of the frequency in inches*

From the result above you can proceed to compute the dimensions:

DISC ELEMENT DIAMETER:

Formula: 0.19 x λ (inch) = disc diameter

(substitute value of λ)

0.19 x 83.6 = 15.384

15.382 inches *diameter of the disc*

LENGTH OF CONE ELEMENT:

Formula: 0.29 x λ (inch) = length of cone element

(substitute value of λ)

0.29 x 83.6 = 24.44

24.44 inches *length of the cone element*

SPACING BETWEEN DISC AND CONE'S APEX:

Formula: 0.0077 x λ (inch) = spacing

(substitute value of λ)

0.0077 x 83.6 = 0.64

0.64 inches *spacing between disc and cone's apex*

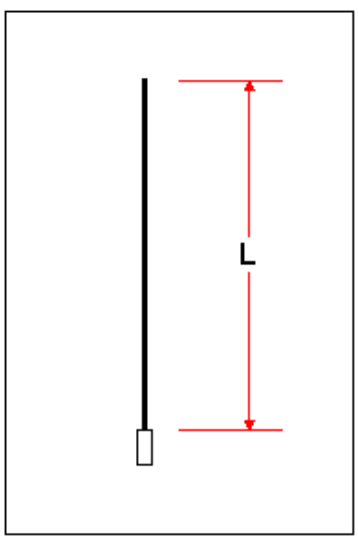
NOTE:

In calculating the dimensions of a discone, you must always use the value of the lowest frequency you intend to operate (cut-off frequency).

5/8 Wave radiator element

The formula to get the length of the radiator element of a 5/8 element wavelength antenna such as in WA-2 and PF-2C:

L (feet) = 0.65 x λ or **L** (feet) = $\frac{(5 \times \lambda)}{8}$



■ **Example:** Find the length of the radiator element intended for 160 MHz (VHF commercial band).

Solution:

First find the wavelength of the center frequency by using the formula below and convert the result to inches.

$$\frac{936}{Fc} = \lambda \text{ (wavelength in feet)}$$

$$\frac{936}{160} = 5.85$$

5.85 feet = λ *this is the wavelength of the frequency in feet*

Convert it to inches:

5.85 x 12 = 70.2

λ (inch) = **70.2 inches** *wavelength of the frequency in inches*

Finally, find the length of the 5/8 radiator element by using the following formula:

L (inch) = 0.65 x λ (inch)

L (inch) = 0.65 x 70.2

L = 45.6 inches *length of the radiator element*

APPENDIX

POWER RATIO TO DECIBEL CONVERSION

	Decimal Increments									
Ratio	0.0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9

x10	+10									
x100	+20									
x1000	+30									
x10,000	+40									
x100,000	+50									

How to use this chart:

The decibel value is read from the body of the table for the desired ratio, including the decimal increment. For example, a power ratio of 1.8 is equivalent to 2.55 dB. Value from the table may be extended as indicated at the lower left in each section. For example, a power ratio of 16 which is the same as 10 x 1.6 is equivalent to 10 + 2.04 = 12.04 dB.

Power loss in relation to the SWR figure in the transmission line:

SWR	Power lost in %
1 :1	0 %
1,3 :1	2 %
1,5 :1	3 %
1,7 :1	6 %
2 :1	11 %
3 :1	25 %
4 :1	38 %
5 :1	48 %
6 :1	55 %
10 :1	70 %

METRIC EQUIVALENTS

Most of the antenna dimensions described in this book are in English units. If the constructor wants to use the metric system, he can convert all the dimensions by using the following conversion guide:

English to Metric

Inch = 25.4 millimeters
Inch = 2.54 centimeters
Foot = 0.305 meter
Yard = 0.914 meter

Metric to English

Centimeter = 0.3937 inches
Meter = 39.37 inches
Meter = 3.28 feet
Meter = 1.094 yards

GLOSSARY OF ANTENNA TERMS

Actual ground The point within the earth's surface where effective ground conductivity exists. The depth of this point varies with the frequency, the condition of the soil and the geographical region.

Antenna An electrical conductor or array of conductors that radiates signal energy (transmitting) or collects signal energy (receiving).

Apex The feedpoint region of a discone antenna.

Apex angle The enclosed angle in degrees inside the cone element of a discone antenna and similar antennas.

Bandwidth The group of frequencies where the antenna functions efficiently.

Band A group of frequencies.

Coaxial cable Any of the coaxial transmission lines that has the outer shield (either solid or braided) in the same axis as the inner or center conductor. The insulating material can be air, helium, or solid dielectric compounds.

Collinear array A linear array of radiating elements (usually dipoles) with their axis arranged in a straight line. Popular in VHF and higher frequencies.

Conductor A metal body such as tubing, rod or wires that permits current to travel continously along its length.

Counterpoise A wire or group of wires mounted close to ground, but insulated from ground, to form a low impedance, high capacitance path to ground. Commonly used at medium frequency and high frequency to provide an effective ground for an antenna.

Dielectrics Various insulating materials used in antenna systems, such as found in insulators and transmission lines.

Dipole An antenna that is split exactly at the middle for connection to a feedline. Usually a halfwavelength in dimension. Also called a doublet.

Directivity The property of an antenna that concentrates the radiated energy to form one or more major lobes.

Director A conductor placed in front of a driven element to cause directivity. Frequently used singly or in multiples with Yagi or cubical quad beam antennas.

Direct ray Transmitted signal energy that arrives at the receiving antenna directly rather than being reflected from the ionosphere, ground or man made reflector.

Doublet see Dipole

Driven array An array of antenna elements which are all driven or excited by means of a transmission line.

Driven element The radiator element of an antenna system. The element to which the transmission line is connected.

Efficiency The ratio of useful output power to input power, determined in antenna systems by losses in the system, including in nearby objects.

Feeders Transmission lines of assorted type that are used to route RF power from a transmitter to an antenna, or from an antenna to a receiver.

Feedline see Feeders

Front to back The ratio of radiated power off the front to the back of a directive antenna. A dipole would have a ratio of 1 for example.

Front to side The ratio of radiated power between the major lobe and the null side of a directive antenna.

Gain Increase in effective radiated power in the desired direction of the major lobe.

Gamma match A matching system used with driven antenna elements to effect a match between the transmission line and the feed-point of the antenna. It consists of an adjustable arm that is mounted close to the driven element and in parallel with it near the feedpoint.

Groundplane A man made system of conductors placed below an antenna to serve as an earth ground.

Groundscreen A wire mesh groundplane.

Impedance The ohmic value of an antenna feedpoint, matching section or a transmission line. An impedance may contain reactance as well as resistance components.

Lambda Greek symbol for L used to represent a wavelength with reference to electrical dimensions in antenna work.

Line loss The power lost in a transmission line, usually expressed in decibels.

Line of sight Transmission path of a wave that travels directly from the transmitting antenna to the receiving antenna.

Load The electrical entity to which the power is delivered. The antenna is a load for a transmitter. A dummy load is a nonradiating substitute for an antenna.

Loading The process of transferring power from its source to a load. The effect of a load has on a power source.

Lobe A defined field of energy that radiates from a directive antenna.

Matching The process of effecting an impedance match between two electrical circuits of unlike impedance. One example is matching a transmission line to the feedpoint of an antenna. Maximum power transfer to the load (antenna system) will occur when a matched condition exists.

Null A condition during which an electrical property is at minimum. The null in an antenna radiation pattern is that point in the 360 degree pattern where minimum field intensity is observed. An impedance bridge is said to be 'nulled' when it has been brought into balance.

Parasitic array A directive antenna that has a driven element and independent directors or reflectors or both. The directors and reflectors are not connected to the feedline. A yagi antenna is one example. See also driven array.

Phasing lines Sections of transmission line that are used to ensure correct phase relationship between the bays of an array of antenna. Also used to effect impedance transformations while maintaining the desired array phase.

Quad Rectangular or diamond shaped fullwave loop antenna. Most often used with a parasitic loop director and a parasitic loop

reflector to provide approximately 8 dB of gain and good directivity. Often called the 'cubical quad'.

Radiation pattern The radiation characteristics of an antenna as a function of space coordinates. Normally, the pattern is measured in the far field region and is represented graphically.

Radiator A discrete conductor in an antenna system that radiates RF energy. The element to which the feedline is attached.

Reflector A parasitic antenna element or a metal assembly that is located behind the driven element to enhance forward directivity. Large man made structures may reflect radio signals.

Source The point of origination (transmitter or generator) of RF power supplied to an antenna system.

Stacking The process of placing similar directive antennas atop or beside one another forming a 'stacked array'.

SWR Standing wave ratio on a transmission line in an antenna system. More correctly, 'VSWR' or voltage standing wave ratio. The ratio of the forward to reflected voltage on the line and not the power ratio. A VSWR of 1:1 occurs when all parts of the antenna system are matched correctly to one another.

Velocity factor That which affects the speed of radio waves in accordance to the dielectric medium they are in. A factor of 1 is applied to the speed of light and radio waves in free space, but the velocity is reduced in various dielectric mediums such as transmission lines. When cutting a transmission line to a specific electrical wavelength, the velocity factor of the particular line must be taken into account.

VSWR Voltage standing wave ratio. See SWR.

Wave A disturbance that is a function of time or space or both.
A radio wave for example.

Wave front A continous surface that is the locus of points having the same phase at the same instant.

Yagi A directive, gain type of antenna that utilizes a number of parasitic directors and a reflector. Named after one of the inventors (Yagi and Uda).

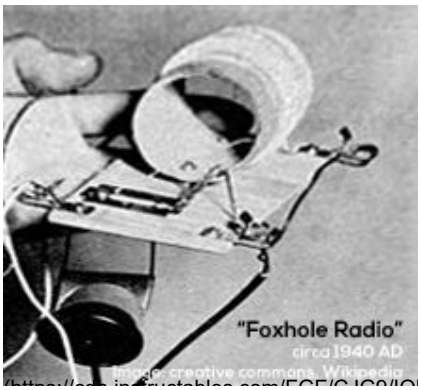
Bio: I am a tech maniac; from media, marketing and design to alternative energy and more. Check out my website for links to all my projects.

More by DrewPaulDesigns:

(/id/TRIPLE-YOUR-SOLAR-ARRAYS-OUTPUT/)

(/id/Free-Energy-From-Thin-Air/)

(/id/DIY-Electro-Magnetic-Levitation/)



"Free energy from the air?, Yea, right!" Sardonic skepticism was my first reaction to this unusual concept, as well.

Though, its not so far out there, in fact. Light can be converted to DC current with solar panels, electricity can be converted to magnetism as I did in my last article (https://www.instructables.com/id/DIY-Electro-Magnetic-Levitation/), in a microphone sound waves are converted to an electrical signal (by vibrating a magnet near a coil (http://hyperphysics.phy-astr.gsu.edu/hbase/audio/mic.html)), solar rays can even be focused and converted to heat in awesome devices like this! (http://www.gosunstove.com/) When we think about it, energy is all around us and can be harvested in an enumerable many of ways.

Today, we are going to take a rather novel approach. We are going to build a device specifically designed to sense and capture a particular band of energy which is all around us.

The earth is magnetic and anyone who has ever used a compass knows this. Magnetic bodies in motion produce electricity, we can see this in any alternator, like the one in your car. So, therefore the earth is electric as well as magnetic, by definition.

Can we detect this energy? Yes, we sure can! Ever turn on a radio in the middle of nowhere and heard static? That is your radio picking up naturally occurring energy in the RF spectrum!

Can we use this energy to do work? Absolutely! This has been known for a long time. Crystal radios (https://en.wikipedia.org/wiki/Crystal_radio) have been around since before the 1930's and can run with no input energy other than the radio signal. Even when completely isolated, but from the atmosphere, a crystal radio will produce a voltage in the earpiece resulting in a sound (albeit and undesirable one).

Well, this is where it gets interesting...

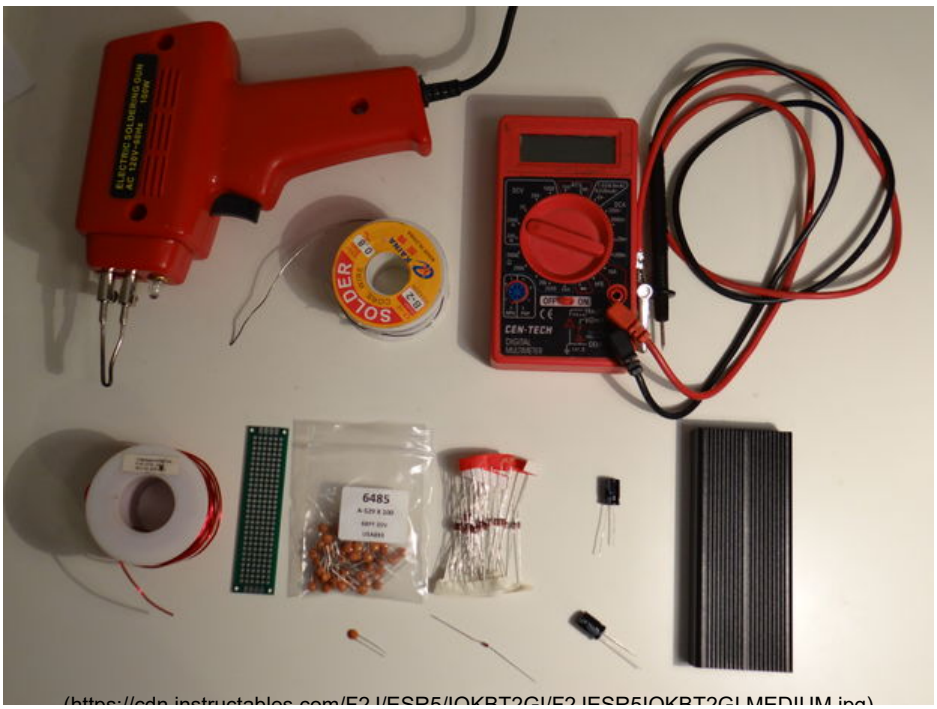
Can we replicate this effect? Yea, and with modern components like the high quality crystals found in germanium diodes, we can even increase efficiency. By applying this concept as a Crystal Energy Receiver we can take advantage of a wide range of energetic frequencies rather than tuning in to just one.

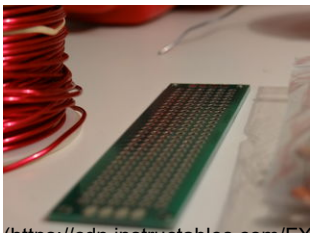
Can we scale it up? Definitely. Things like micro germanium diodes, high efficiency antennas and compact contemporary capacitors make the components that are required to build a crystal receiver fit in the palm of your hand. While there may or may not be a more efficient way, this renewable

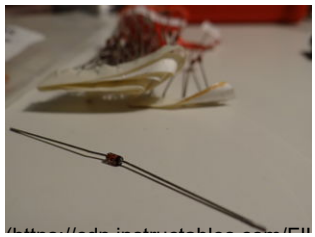
energy solution is simple to employ and can be scaled up, or down, indefinitely.

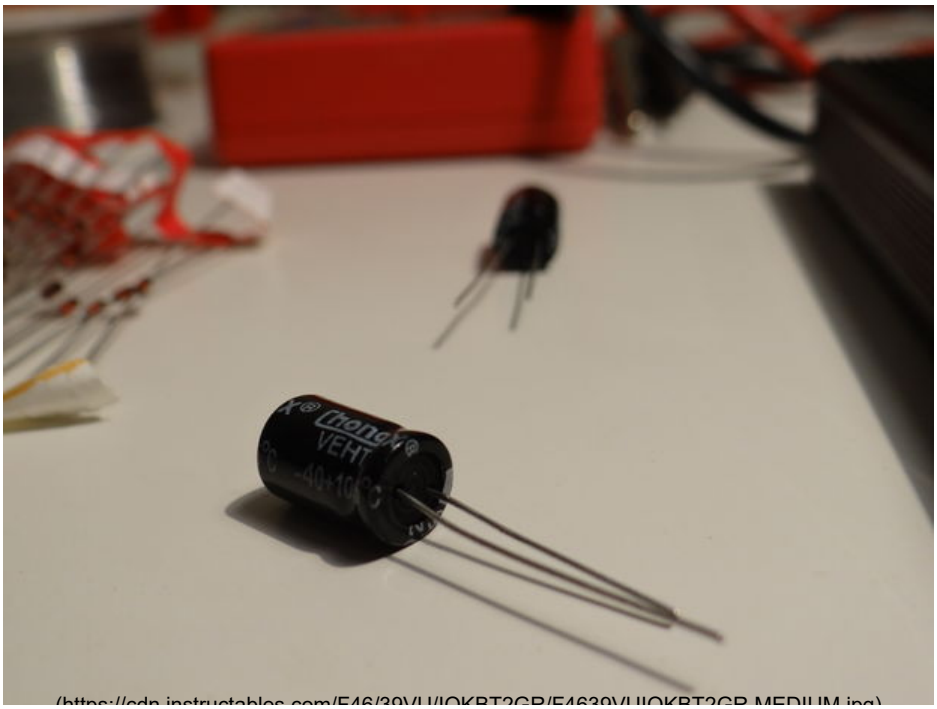
It sounds like we can build a Crystal Energy Receiver. Let's give it a shot...

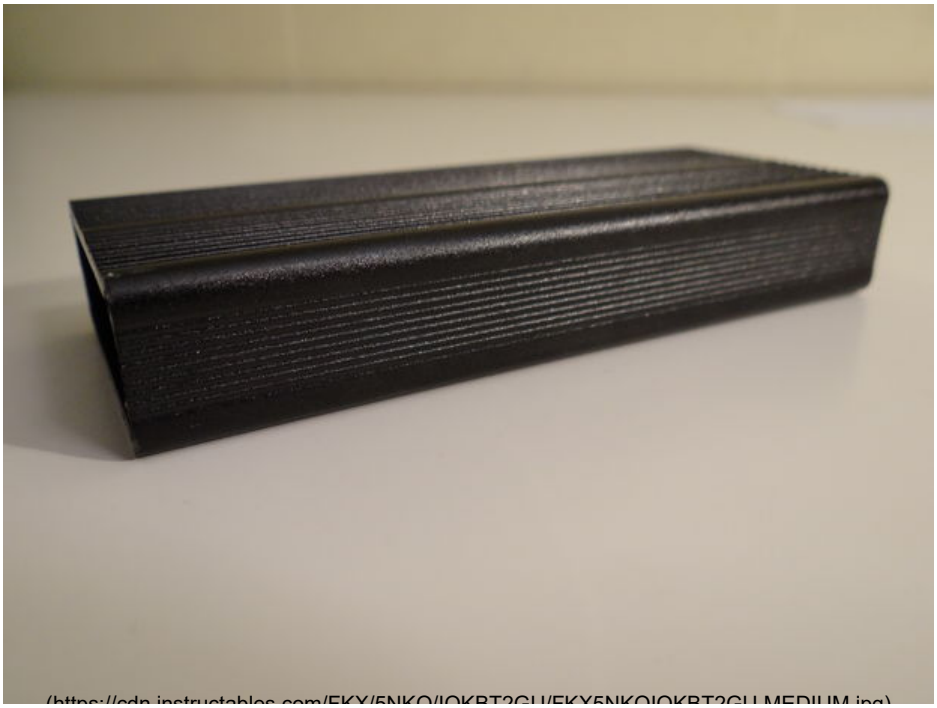
Step 1: What You'll Need











One of the reasons this particular renewable energy harvesting method is so viable is the relatively few and easy to obtain materials required.

The simplest crystal receiver design needs no power and can be built with only three parts: a coil, a crystal and a resistor. We're going to optimize that design in order to produce a cleaner and more reliable output signal by first polarizing the input amplitude, then rectifying and filtering the signal. Then we'll add an antenna, case and connections.

Get the circuit diagram here (http://www.drewpauldesigns.com/crystal-energy-receiver-kit.html)
Get the kit here (http://www.drewpauldesigns.com/crystal-energy-receiver-kit.html)

The parts for the circuit include:
(1) Circuit Board (http://www.drewpauldesigns.com/crystal-energy-receiver-kit.html)
(1) 10-18 gauge Copper Wire
(2-12+) Ceramic Capacitors (matched)
(2-6+) Electrolytic Capacitors (matched)
*note various types of capacitors can be used
(4) Germanium Crystal Diodes (1A+)

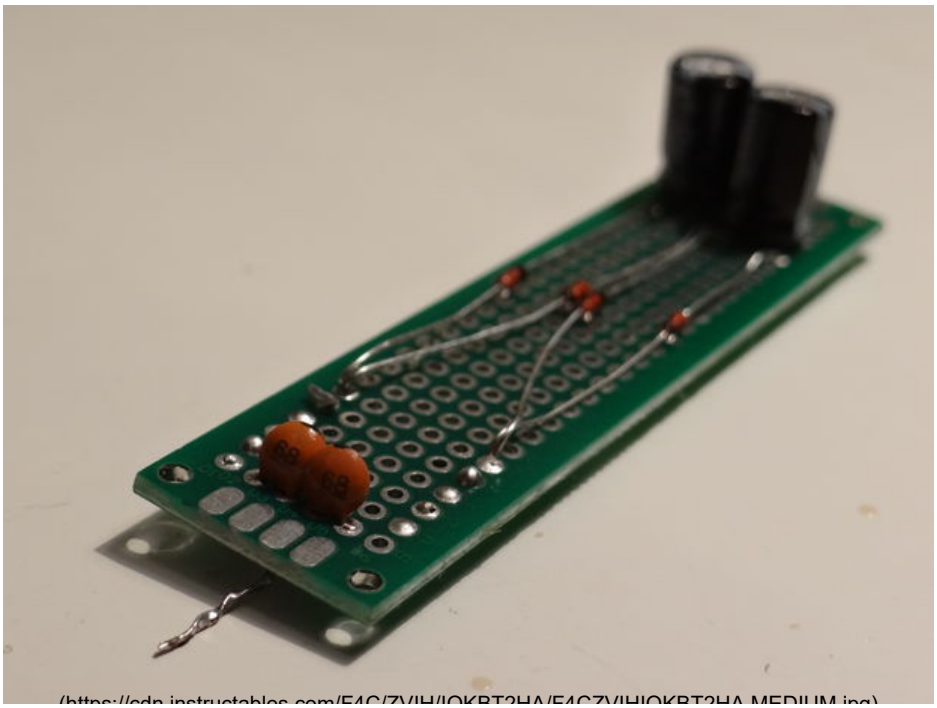
Total Unit Cost: +/- **$0.40** (USD, scaled for volume of 1,000+ units)

In addition, you'll probably want to get:
(1) Project box (optional)
(1) Antenna (a loop antenna or elevated antenna is recommended and can be made with copper wire)

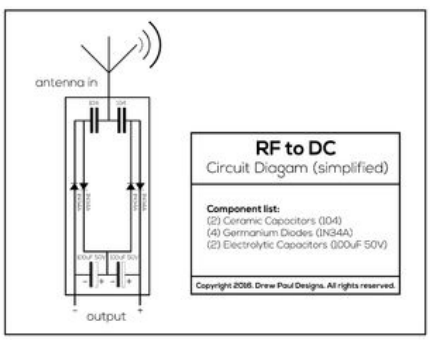
The tools you'll need are:
Soldering Iron/ Solder (optional)
Multimeter
Oscilloscope (http://www.seeedstudio.com/depot/DSO-Nano-v3-p-1358.html?cPath=63_65) (optional)

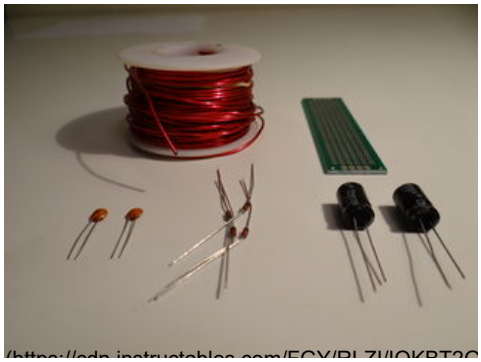
That's it. Yup, that's all. Once we've got it all, let's begin.

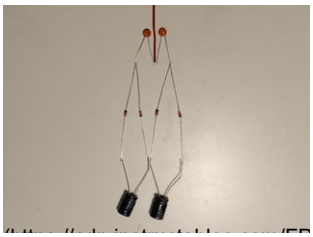
Step 2: Build the Circuit

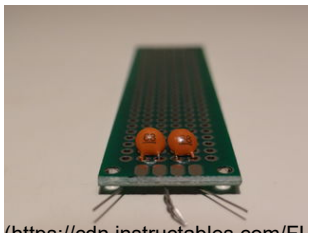


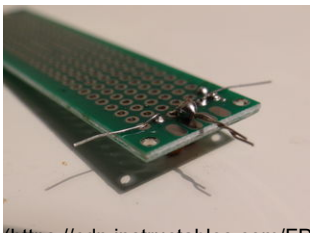
(https://cdn.instructables.com/F4C/ZVIH/IQKBT2HA/F4CZVIHIQKBT2HA.MEDIUM.jpg)

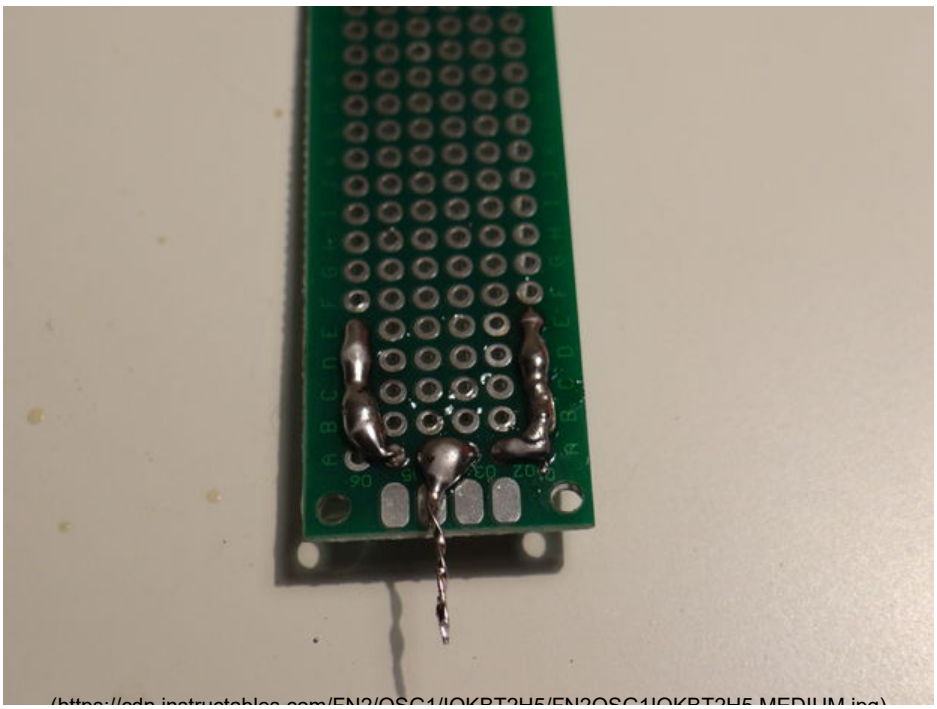


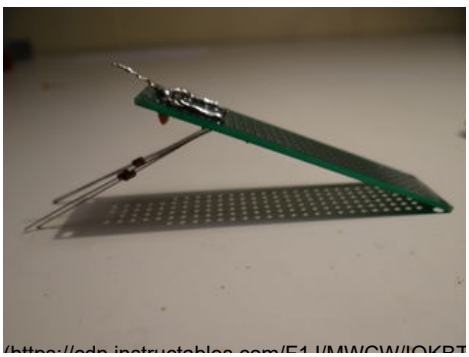


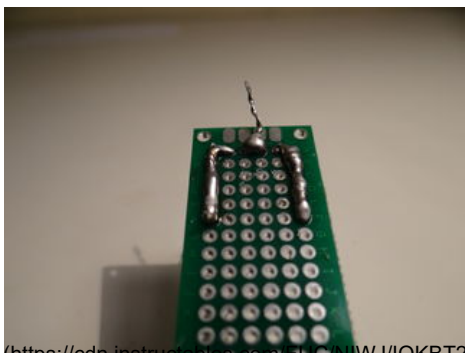


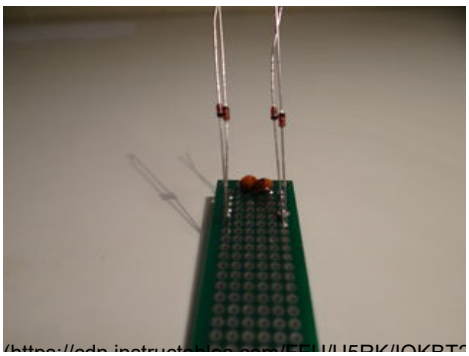


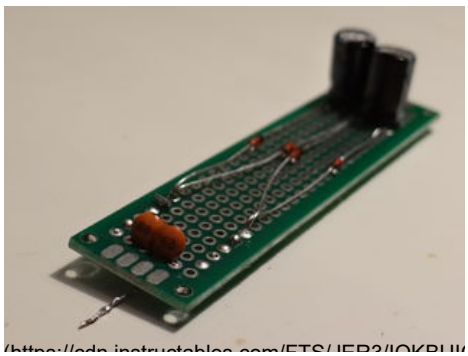












We're going to build the simplest version of this circuit variation in order to understand how each component interacts and as a proof of concept.

There are three simple systems at work in the circuit that are composed of capacitors, which store energy, and diodes that direct it.

Energy in the band of radio waves, among others, will vibrate a wire antenna on an atomic level, sending a discernible signal to its lead. This signal will then

meet the junction between two ceramic capacitors wired in series. This junction will force positive charge from the wave to travel in one direction and negative charge in the other direction which, when collected again, makes the signal uniform and polar. Connecting the two capacitors in series creates leads on each end; the now positively charged side of one and the now negatively charged side of the other creates a two cell battery.

This next stage of the circuit takes a signal with a net value of zero, adds the absolute values of the positive and negative amplitudes with respect to the origin and produces a positive integer. This concept can be thought of as taking:

(+1) + (-1) + (+1) + (-1) = **0**

and converting it to:

| [(+1) + (+1)] | = **2**
+
| [(-1) + (-1)] | = **2**
= 4

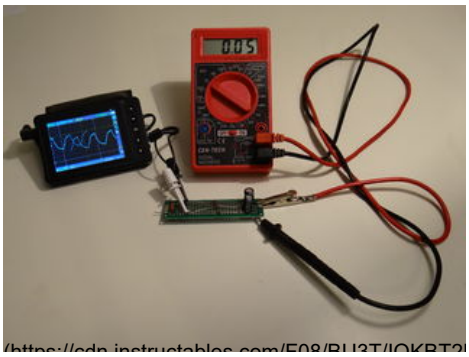
Isn't math fun?

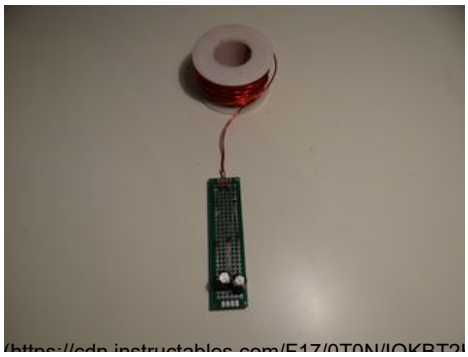
To each of these leads from our two capacitors in series, we will connect two crystal diodes, one facing each direction, to form what is called a bridge rectifier. A bridge rectifier is a configuration which will convert an alternating current to a direct one by cleverly rerouting the signal.

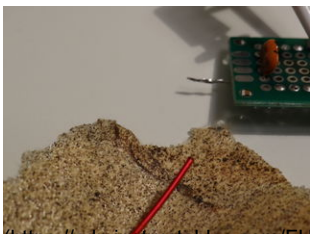
By connecting the bridge rectifier as shown in the circuit diagram, this direct current from the diodes then charges the electrolytic capacitors. This stage normalizes the amplitude, making the current constant and usable.

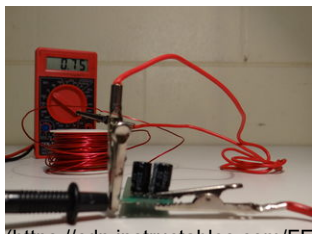
Components can easily be twisted together for testing and then soldered to a circuit board to secure.

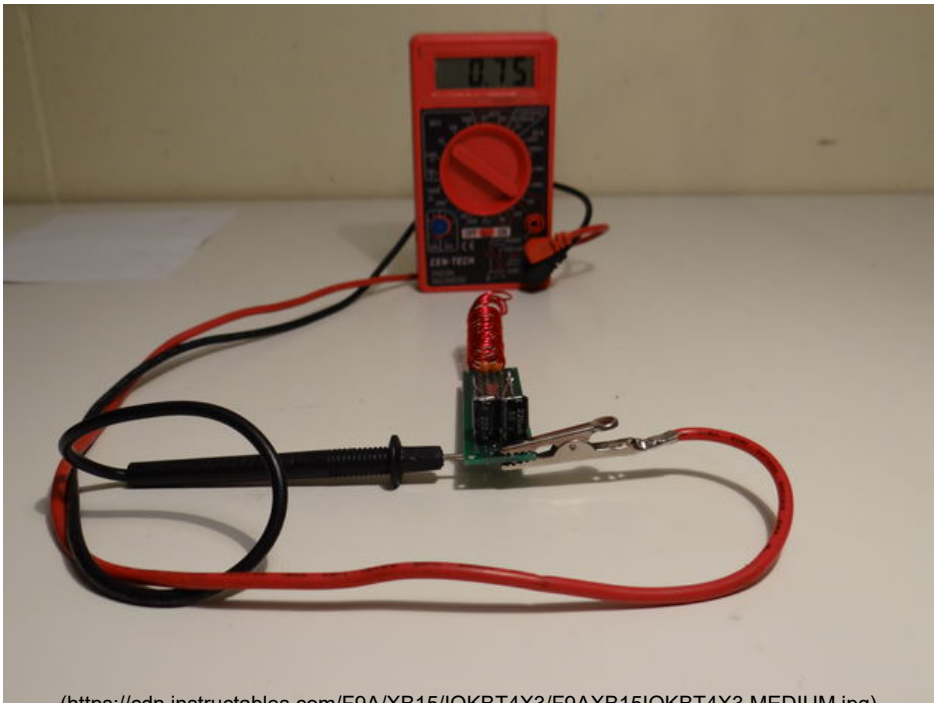
Step 3: Test and Optimize Your Circuit











To test and analyze our circuit, we'll be using a digital voltmeter and oscilloscope.

By connecting a voltmeter to the output, we'll immediately begin to see a small voltage climbing in the 10-100mV range. If not, we'll want to check our connections and make sure the circuit is not isolated from the environment by taking it outside to a clear area.

Then, by connecting an oscilloscope to the outside leads of our two ceramic capacitor bank, we will see the the polarized signal being captured from the air around us. We can then connect after the diodes to see our varying direct current and then to after the electrolytic capacitors to see a normalized, usable direct current at our output.

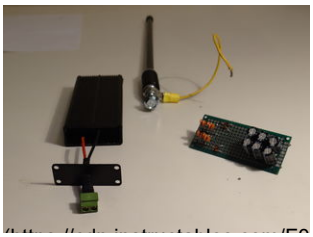
We can then optimize the input resistance in two ways. Firstly, we can add additional ceramic capacitors in parallel to our original two and make sure our soldered connections are consistent and thick in this area.

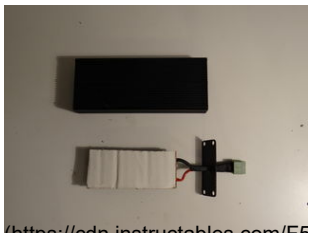
We can optimize the circuit's capacity by adding electrolytic capacitors in parallel to our original two which will allow this circuit to charge slightly when not in use. For this purpose, a charging circuit can also be added here in order to incorporate an optional battery bank.

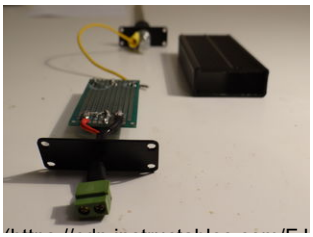
We can optimize the antenna by attaching loops and coils of copper wire in various positions, store-bought antennas or by stringing some wire up to the highest point you can reach.

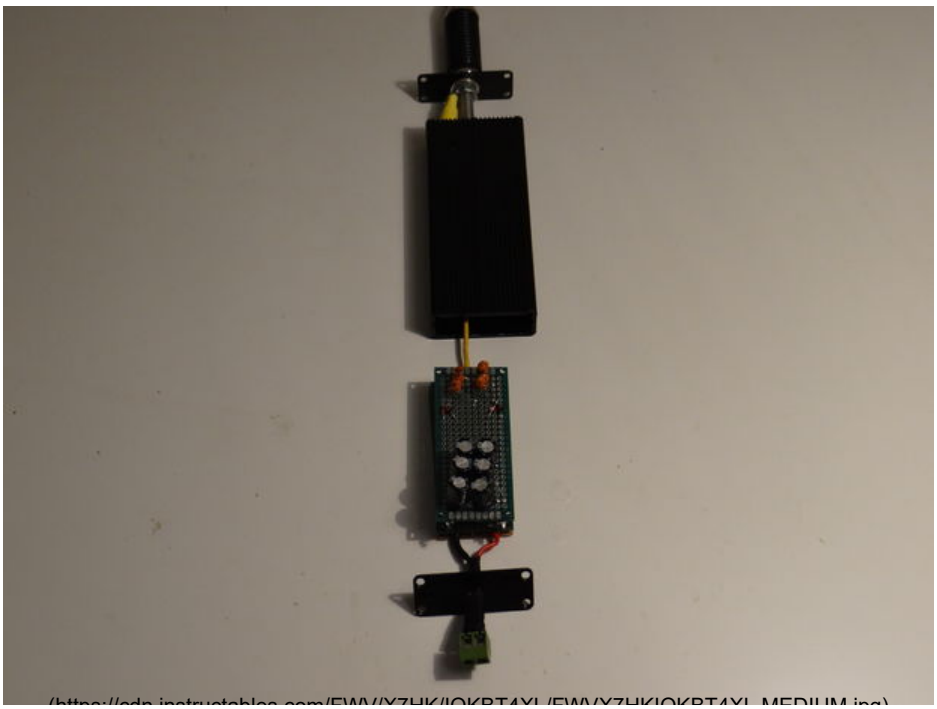
We don't have to stop there, either. We can now connect multiple circuits in series to increase voltage or in parallel to increase current. This can be done indefinitely.

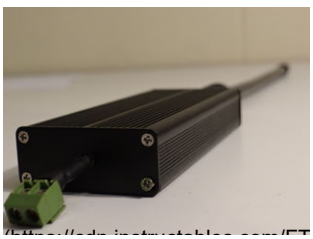
Step 4: Add a Case and Antenna









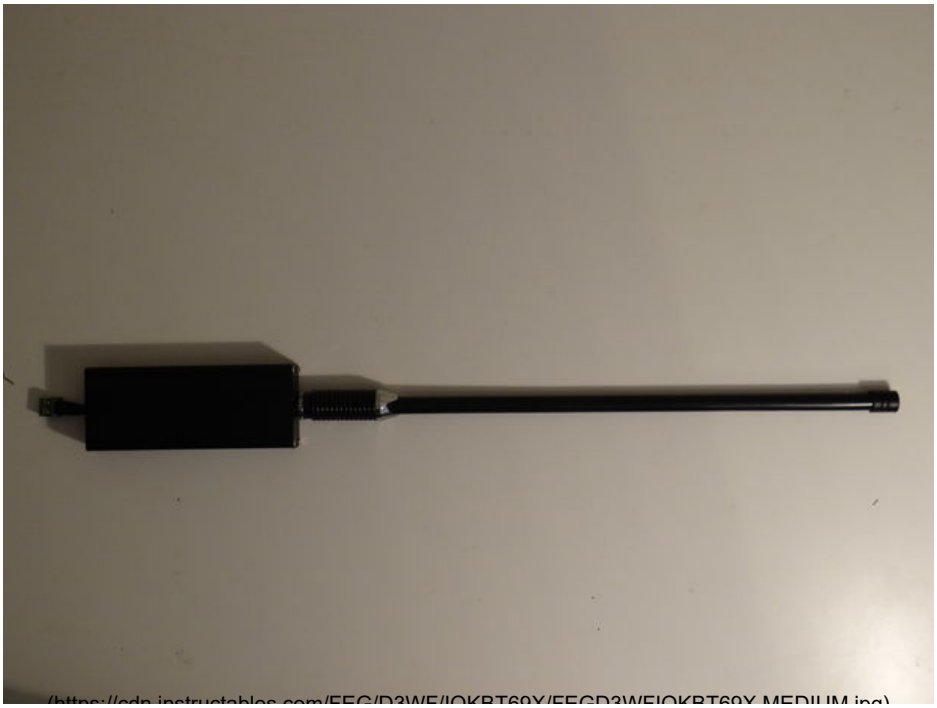


After choosing an antenna in the last step we'll now want to permanently wire it. Whether you choose a compact antenna for portability or a tall fixed antenna for power and range, we will wire it in the same manner according to the diagram in the previous step. Note that the input on the configuration here is grounded to the metallic case, and thus the users hand, and incorporation of longer antennas will require proportionally more substantial grounding.

We will then attach a terminal to the output to allow us to connect this circuit to an electrical device or charging circuit and battery bank.

Next, we will add a case, making sure to isolate exposed leads with non-conductive material especially if mounting in a conductive case. A piece of cardboard secured with glue is sufficient for the circuit's bottom and shrink wrap or electrical tape can be used in the case of any additional exposed leads. Drill two holes in your enclosure, one for the antenna or antenna lead and another for your output terminals. You can then insert your components, fasten the enclosure and your device is ready to use!

Step 5: Your Crystal Energy Receiver Is Complete!



Your Crystal Energy Receiver is now complete and ready to use!

I built a portable version, for proof of concept and demonstration purposes. However, you can go as big as you want- to passively charge batteries or run equipment remotely; or go as small as you want- to power sensors, RFID devices, small electronics and more.

I used this harvested energy to easily power a low-consumption quartz clock, a digital chronograph with integrated circuits and LCD and was even able to momentarily rotate a small dc motor.

Because of its simplicity this device is a durable, efficient and reasonably effective method of harvesting radiant energy in a simple, replicable and sustainable way. I humbly hope that the contributions made here, and by those

reading, can be one day used by people worldwide to conveniently capture free energy.

Thanks for checking out my project and I look forward to seeing everyone's variations, suggestions and improvements!

2017-07-29 Reply

Thanks for checking out my project. A lot of these questions are covered in the Instructable but I will answer them briefly for you.
The ceramic capacitors used are 104s and their purpose is to polarize the charge. Electrolytic caps are 50v rated and are used to hold the charge in order to provide a usable current. In this example the ground is connected to the case, and thus grounded through the users hand. Scaling this up for that purpose will require a more significant antennae, ground and wiring up multiple circuits in series which is covered in more detail in the article. Let me know if you have any other questions and be sure to post your project pictures here when you're done for everyone to see!

Loveforcats (/member/Loveforcats/) 2017-07-17 Reply

Hey,how much maximum voltage can be obtained at the output by adiing capacitors in parallel....????

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ Loveforcats (/member/Loveforcats/) 2017-07-17 Reply

Thanks for checking out the project. Great question. Adding capacitors will only increase the capacity (mAh). If you want to increase voltage you can build multiple circuits in parallel and make sure your antennae is as tall as possible.

Loveforcats (/member/Loveforcats/) ▸ DrewPaulDesigns (/member/DrewPaulDesigns/) 2017-07-26 Reply

I dont want to place my antenna on roof top.I want a min of 5 volt and max of 20 volts and a portable circuit.So what shud i add to the circuit for getting it.??? and what kind of antenna shud i make..??

galihprog (/member/galihprog/) 2017-07-14 Reply

sir, why the first kit show value 0.75v and the second kit show value 3.50v,

what is different make? (coil turn, coil component, total component, etc..)

Raghdado (/member/Raghdado/) 2017-07-04 Reply

What a nice instructable! But I have few questions though, if you don't mind.
How long did it take you to complete the project?
How much did it cost you?
Would it be realizable for the duration of one month only (for a beginner)?
And most of all, Could you tell me about the output (after testing)?

Thank you :)

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ Raghdado (/member/Raghdado/)

2017-07-04 Reply

Thank for checking out my instructable! This project can be done in an afternoon and the kit can be found here: http://www.drewpauldesigns.com/crystal-energy-receiver-kit.html

Before getting started you will also want to get a soldering iron and take some time to practice with it.

Just follow the instructable carefully and you will have no problem.

You can get everything you need here: http://www.drewpauldesigns.com/crystal-energy-receiver-kit.html

frisbrob (/member/frisbrob/) 2017-03-30 Reply

I am always looking for ways to generate power, mostly because it's fun but most of our renewable energies have their down sides. Solar only works while it's day time, wind only works while there is wind. I don't know about where you live but here in Sandy Utah there is no sun at night and at night during winter or summer there is no wind at night, so that takes care of generating power at night. I have looked at several of these pulling power out of the air things, I have even looked at finding Tesla's plans and there is nothing usable. I don't know how to do the math to figure out what parts are needed to build these diy collectors and generators. To me it sounds like you would need an entire back yard to hold anything big enough to do any good, most of the things people build might charge a cell phone but that's about it. If I was to build this unit but big enough to constantly run an 800 watt unit, how big would the antenna need to be and what parts would I need? Just curious.

PhillipH50 (/member/PhillipH50/) 2017-03-12 Reply

I think what you should look into is tuning this simular curcuit to recieve in the frequency range of 7.83hz to 8.4hz. Because this is the earths magnetical resonance frequency. Tesla's paper state that 1 meter = 100v on a horizontal wire. So at 3 feet tuned into this frequency can produce 100v and at 6 feet produce 200v, ect..
About 10 years ago there was a video that was taken down of a Russian man who was demostrating his setup with a hand full of scientists. I don't remember all the details but one thing I do remember was that his antenna was 68 feet of 14 gauge copper wire hanging 6 feet above the ground horizontally. The ground stake was 1/2" rebar 6' into the ground.

You can look into these frequencies by searching "Schumann resonances are global electromagnetic resonances in the cavity formed between the earth’s surface and the ionosphere. "

Just some of my thoughts..

---

tatebullrider (/member/tatebullrider/) 2017-02-09 Reply

Great instructable!! Just a quick question though. So the higher the antenna is in the atmosphere the better? And if so, you could (in theory) use a long thin wire attached to a kite or a weather balloon to temporarily generate more power, correct?

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ tatebullrider (/member/tatebullrider/) 2017-02-09 Reply

You got it. You could use a kite or even a drone or quadcopter to take measurements at different altitudes. Post your data for us to see!

SHOE0007 (/member/SHOE0007/) 2016-11-07 Reply

I not trying to be rude but how do you get free energy from nothing? Unless you do this under a high voltage power line (very dangerous) i am not sure if this would work?

In state matter is neither created or destroyed so were is this energy coming from??

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ SHOE0007 (/member/SHOE0007/) 2016-11-07 Reply

Not at all and this is a very good question.

As Faraday and others have demonstrated, magnetic bodies in motion produce an electric charge. If you've ever used a magnetic compass, you know that the earth, along with orbiting bodies, are magnetic with a north and south pole. These moving bodies induce a charge in our atmosphere. This charge, with our new Crystal Energy Receiver, can be captured and harvested as usable energy.

Thanks for reading. Give it a try and be sure to follow and visit www.DrewPaulDesigns.com for more projects.

Brandonoutdoors (/member/Brandonoutdoors/) 2016-11-04 Reply

i like this "ible". I'm seeing a lot of negative comments though so I want lend my support to the author.
In no way is converting radio waves into electricity stealing. I mean think about it. When you turn on a radio to listen to music nobody bills you for the radio waves. They are paid for by ads.
With a homesteader in mind who may not live anywhere near transmission lines could use somthing like this at a larger scale (our planet is saturated in rf). when radio waves cross your property line they become yours to do with what you will (in my opinion). I say build (or buy) a large antenna and start experimenting with a larger scale.

cloethix (/member/cloethix/) 2016-08-02 Reply

good project

rah187 (/member/rah187/) 2016-07-22 Reply

Cool project! I have favorited this instructable and it is possible that I will eventually construct it. This circuit is actually very simaller to a few others I have seen on the internet, all of which produce around three volts. I have even seen people use crystal radio sets to generate electricity for LEDs. Of course, there are limitations to this setup, including the very low current and the fact that making this unit much larger than it already is may be considered illegal. The truth is, nobody would probably care about one device running off of the RF, seeing as seemingly innoccuous grounded objects such as flagpoles can also "steal" radio waves. However, I am glad I read through the comments before making a gigantic fractal antennae and getting myself in trouble.

İlhamiA1 (/member/%C4%B0lhamiA1/) 2016-07-18 Reply

Lolz its ??? Nano amperes and 0.06 v

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ İlhamiA1 (/member/%C4%B0lhamiA1/) 2016-07-18 Reply

Eureka! You got it working! You now have proof of concept. Now it's time to increase your current.

First, try extending the antennae all the way to the highest point you can find (try your roof). Then connect a ground lead to the junction between your output terminals (between the two electrolytic caps in series) and run that to a piece of steel rod pressed into the dirt.

Once that is complete, you can optimize it even further! Now, with your antennae and ground set up start wiring in more circuits. Wire them in series, parallel or both according to your needs. Put all of the components on the same circuit board for a supersized version.

Thanks for checking out my 'ible! I hope this helps!

unbottled19208306 (/member/unbottled19208306/) 2016-07-10 Reply

When you say the 2 12 and 6 matched caps, do you mean 12 and 6 volt caps?

DrewPaulDesigns (/member/DrewPaulDesigns/) ▸ unbottled19208306 (/member/unbottled19208306/) 2016-07-11 Reply

The voltage capacity is variable, however it is important to use matching pairs of both ceramic and electrolytic capacitors. Thanks for checking out my project and let us know how yours comes out!

Arghus (/member/Arghus/) 2016-06-23 Reply

can u get it to 5v? for a usb port?

RowanS1 (/member/RowanS1/) ▸ Arghus (/member/Arghus/) 2016-07-01 Reply

yes its possible but current would be too low to be usable

RobertH7 (/member/RobertH7/) 2016-06-13 Reply

Congratulations! You built a full-wave rectifier! You passed the first chapter of basic electronics.

Unfortunately, this particular rectifier is an extraordinary waste of time. It produces a negligible amount of power. Your oscilloscope voltage reading is meaningless. Power is voltage TIMES current, and something like this will produce current in the range of nano-Amperes.

Just get some solar cells and call it a day. They absorb energy from the peak of the sun's blackbody radiation spectrum (which happens to be visible light), not in the negligible radio frequency range. The cheapest, least efficient solar cells out there will produce orders of magnitude more power.

You will need:

A diode. Germanium point contact, OA79 or 1N34 is the preferred and traditional choice. But a modern substitute will be a schottky (gold bonded) diode. These have a low forward voltage, below 250 millivolts or so, versus the 600 or so of the silicon diode.

A few capacitors, chip type, value not critical, around 1 nf to 100 nf. (or 1000 pf to 0.1 microfarad)

One resistor, 1 Megohm.

One stereo earphone jack.

One pin from a turned pin IC socket. This forms the 'hot' end of the probe, so that various pins can be inserted for probing. A short piece from a needle for exploratory work. A piece of wire soldered to the circuit board when using it for a tuning up session, requiring it to be in place for a long time.

The circuit is traditional, as below:

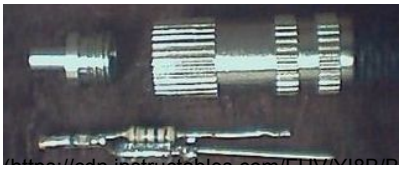
```
   C1          R<--||-------/\/\/\/\-------------o +      |               |
---              |      ^               |     /-\ diode        === C2      |
             |      |               |<--------------------------------o -
```

Step 2: Connect It Up

I used a small sliver of circuit board to hold C1. The turned pin socket was fitted to one end, the capacitor C1 soldered to it and then the resistor and diode leads formed to shape and soldered to the capacitor. It is shown next to the stereo earphone jack in order to see whether it will fit. Adjust sizes, get a smaller capacitor etc until it does.

The socket, capacitor and supporting board will go inside the barrel of the jack.

Step 3: Take the Jack Apart



A bit of filing, twisting and pulling will result in the jack coming to pieces. It is composed of a large number of precision formed metal and plastic pieces.

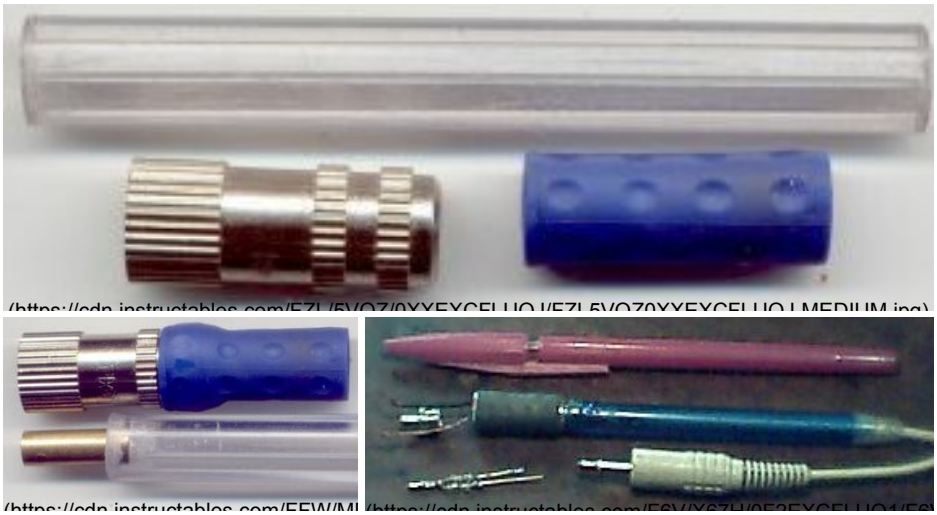
KQED
KQED - Sundays at 6:30
KQED World - Sundays at 6:30 beginning November 12

We need just the outer shell and the cover - It is best that the cover of the jack is metal, otherwise the shielding will not be perfect.

Step 4: Form the Body



The body of the probe is made from an old ball point pen. A piece of brass tube was found to serve as a join between the shell of the stereo jack and the ball pen body. The rubber grip from another pen was then slid over the metal to insulate it from accidental contact with circuit parts.

A molded mono earphone lead was used to get the signal out from the probe.

Step 5: Put It All Together

articulate
stories from where life meets art
KQED
KQED - Sundays at 6:30
KQED World - Sundays at 6:30 beginning November 12

I used teflon tape to insulate the turned pin socket and capacitor, which had to go inside the barrel of the jack. A dab of petroleum jelly kept its bore from filling up as superglue was applied to hold it in position.

A HAM friend of mine measured about 5pf of capacitance for this probe, which is pretty good.

In use, a sharp probe is inserted into the turned pin socket. The ground lead is wire wrapped around the barrel of the jack. This is necessary if accurate measurements are to be made in a noisy environment.

I hope this will be of use to the HAMs among us.

i never knew what those clear things with the colors on them are until now, why do i only see them on tvs and monitors?

S33PlusPlus (/member/S33PlusPlus/) ▸ Jimmy Proton (/member/Jimmy+Proton/)

2011-07-17 Reply

What kinds of things do you take apart? I find so many signal diodes (1N4148's typically) in trashed electronics I don't bother desoldering them anymore. (Besides, they're cheap enough that using a new one in a project is less troublesome than using a damaged scrap bin diode.)

2011-07-17 Reply

I take apart everything that i can get my hands on. =)

S33PlusPlus (/member/S33PlusPlus/) ▸ Jimmy Proton (/member/Jimmy+Proton/)

2011-07-19 Reply

Me too :3
I prefer early 90's or late 80's era devices, before everything went surface mount.
If you take recent products apart, you'll be quite disappointed at the component yield. You've probably seen few discrete signal diodes because manufacturers cram everything they can into ICs to reduce component counts.
On the other hand, an early 90's handheld four-in-a-row style game I recently took apart (lack of backwards current protection fried a LED) has 34 discrete transistors in it!
Try going through free piles after garage sales or the free section on your local craigslist boards.

Jimmy Proton (/member/Jimmy+Proton/) ▸ S33PlusPlus (/member/S33PlusPlus/)

2011-07-20 Reply

Old CRT TV's probably have the best stuff in them.
Whenever I take apart new things I put the boards in the toaster oven or i destroy them.

Punkguyta (/member/Punkguyta/) 2007-02-18 Reply

Oh wow, this does look good. Is it as fragile as it looks?

neelandan (/member/neelandan/) ▸ Punkguyta (/member/Punkguyta/) Reply

2007-02-19

It isn't, because the socket at the tip, the series capacitor and the ends of the resistor and diode are held securely inside the tip of the audio jack. You may use hot melt glue to hold them in position. I wrapped it in teflon tape (available at plumbing stores) and secured it in position using superglue. Epoxy would also work.

Punkguyta (/member/Punkguyta/) ▸ neelandan (/member/neelandan/) Reply

2007-02-19

I think that epoxy would be best, hot glue expands, and you tend to get a but too much, super glue is runny and I always get it on my fingers (my tongue too once, don't ask).

cylver (/member/cylver/) 2007-02-11 Reply

Okay, for those of you who want a more in-depth understanding of how it works... c1 is a dc-blocking capacitor. It's there to make sure you're only measuring the AC voltage in the circuit. d1 is there to convert the ac into dc pulses. c2 is a filtering capacitor, so that you're reading the peak voltage (or close to it) rather than the average, which will be quite a bit lower. It also allows any remaining ac a nice path to ground. R makes sure that you don't draw too much current through your meter, destroying it. One thing to keep in mind is that you'll probably want a shielded cable, to keep from picking up stray AC from the board you're testing. RG 174 coax would be nice if you've got some. Connect the shield to the - side of the circuit, and the center conductor to the + side. Slap a BNC connector on the end, rather than a phone plug, and you can use the probe with an oscilloscope, too.

DonTron (/member/DonTron/) 2007-02-10 Reply

This is a classic from the AARL. The neatest ones were built, IMHO, out of lipstick tubes. The non-linearity of the diode, not to mention the integrator, limits the accuracy of this technique, so nowadays, something built out of today's high-speed op-amps might be possible. A bolometer would be more complex, and slower, but far more accurate. This is a very useful instrument, where it is indicated. "Rectify and integrate" is also the principal behind simple AM detection, although with a shorter time-constant, typically.

admanrocks (/member/admanrocks/) 2007-02-09 Reply

this may be a stupid question. but i dont know what it does. so what does it do?

sysadmn (/member/sysadmn/) ▸ admanrocks (/member/admanrocks/) Reply

2007-02-09

Most voltmeters don't accurately measure AC (alternating current) at high frequencies (RF = Radio Frequency). At RF frequencies, the components in the probe convert the AC value to an equivalent DC

value that a voltmeter can accurately measure. There is a good writeup here (http://www.io.com/~n5fc/rfprobe1.htm (http://www.io.com/~n5fc/rfprobe1.htm))

admanrocks (/member/admanrocks/) ▸ sysadmn (/member/sysadmn/) Reply

2007-02-10

ok, cool

END FED 6–40 Meter Multiband HF Antenna

Introduction

This EARC project produces an inexpensive, multiband, end fed HF antenna matchbox that is quick and easy to setup and use. The end fed feature adds portable convenience, but does present another issue. The problem with an end fed half wave antenna is that the antenna presents high impedance, creating a significant miss match with the usual transceiver impedance of 50 ohms. This miss match is significantly greater than typical tuners can accommodate without a matching transformer.

This project creates a trifilar wound, 9:1 UNUN (unbalance to unbalance) toroid matching transformer that will match the high input impedance of an end fed antenna into the range where most antenna tuners can produce good performance. The matchbox handles 100 watts of power. ***This project requires an antenna tuner to achieve satisfactory SWR***. If you need an auto tuner, we recommend the LDG line of auto tuners, shown to work well with these matchbox antennas, and highly rated by users. They are reasonably priced and available at most ham stores.

The matchbox project uses readily available common hardware and materials listed below.

Matchbox Parts List

1	small plastic enclosure (shown right)
1	powdered iron toroid T130-2
3	20” pieces of 18 AWG solid insulated copper wire in red, green, and black
2	# 8-32 x 3/4” hex head machine screws
2	# 8 lock washers
2	# 8 ring wire lugs
2	# 8 flat washers
2	# 8 lock washer/nut combination
2	# 8 wing nut
1	SO-239 panel mount connector to fit keyed enclosure opening

30’ # 18 AWG insulated stranded wire antenna with ring lug attached Small amount of clear silicone caulk to secure toroid in place

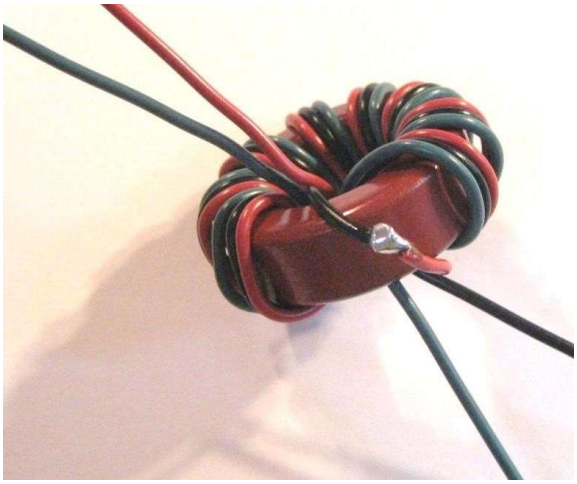
Preparing the MATCHBOX Plastic Enclosure

The enclosure needs one 5/8” hole for the SO-239 connector, and one 11/64” hole for the counterpoise wing nut on the lower side of the enclosure. An 11/64” hole on the upper right side of the box facilitates antenna connector mounting.

TOROID WINDING

First, wind the three 20” pieces of insulated solid wire onto the toroid. Place the wires as shown green-black-red, and wrap the toroid 9 turns so that it looks like the photo on the right. Notice there are three wires extending from the left winding and three wires extending from the right winding. As the connections are completed, the steps refer to the specific wires by left or right and color.

NOTE: Count turns by counting the number of times the wire goes thru the toroid center.



Crimp together and solder ***the left black wire*** with the ***right red wire*** When the step is completed, it will look like the right photo.

The next three steps should appear as shown in the first photo on page 3. Crimp and solder a # 8 lug to the ***left red*** wire about 2” from the toroid. The completed lug will later connect to the antenna connection bolt on the upper inside of the enclosure.

Twist the **left green** wire with the ***right black*** wire. Strip the ends of the two wires and twist together at about 2”. This twisted pair will solder to the center connection of the SO-239 connector in a later step.

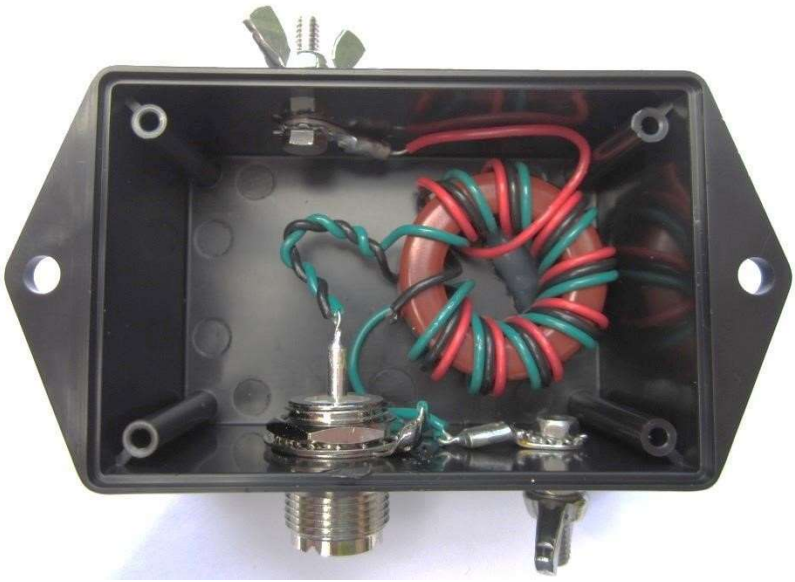
Trim and strip the remaining ***right green*** wire at about 2”. Cut an additional 2” piece of green wire, and crimp and solder both wires to a # 8 lug. The 2” green wire will connect to the ground

connector on the SO-239 already installed in the enclosure. Strip remaining green wire end 3/8” and bend into a hook for connection to the SO-239 ground connector.

The SO-239 connector and ground lug should be installed through the keyed hole in the lower right with the mounting nut securely tightened.

Solder the green and black twisted pair to the SO-239 center connector. Solder the green wire hook to the ground lug on the SO-239 connector.

From inside the box, place an 8-32 machine screw through a lock washer, the # 8 lug on the green wire, then through the lower 11/64’” mounting hole. Place a flat washer on the outside protruding machine screw followed by # 8 lock washer/nut and tighten securely. Place a # 8 wing nut on the machine screw to finish the **counterpoise connector**.



Position the toroid inside the box to allow connection of the red antenna wire lug to an 832 machine screw and lock- washer on the upper box side. Place a flat washer on the outside of the box followed with a # 8 lock washer/nut. Tighten the nut securely. Next, place the wing nut on the **antenna connector** and your project appears as shown above.

A small spot of clear silicone compound is used to secure the toroid from movement in the enclosure. The final assembly step is to secure the box cover in place with four screws.

Preparing the Antenna Wire

Matchbox performance will be determined by two factors: The length of the antenna wire, and the capability of the tuner. The length of the antenna wire should be between 24 and 60 feet for best performance. Additional counterpoise is not normally required, as the coax shield provides the counterpoise function. Wires longer than 60 feet may have excessive impedance for some tuners to properly match. Wires shorter than 24 feet may not radiate as effectively. A 30 foot insulated 18 gauge stranded wire antenna and connecting lug is included with the project and should meet most requirements without need for any counterpoise.

Experience has shown that most external tuners and some internal tuners will tune 80–6 meters with an antenna length of 24’ to 30’. If a longer antenna is desired, the provided antenna can be lengthened.

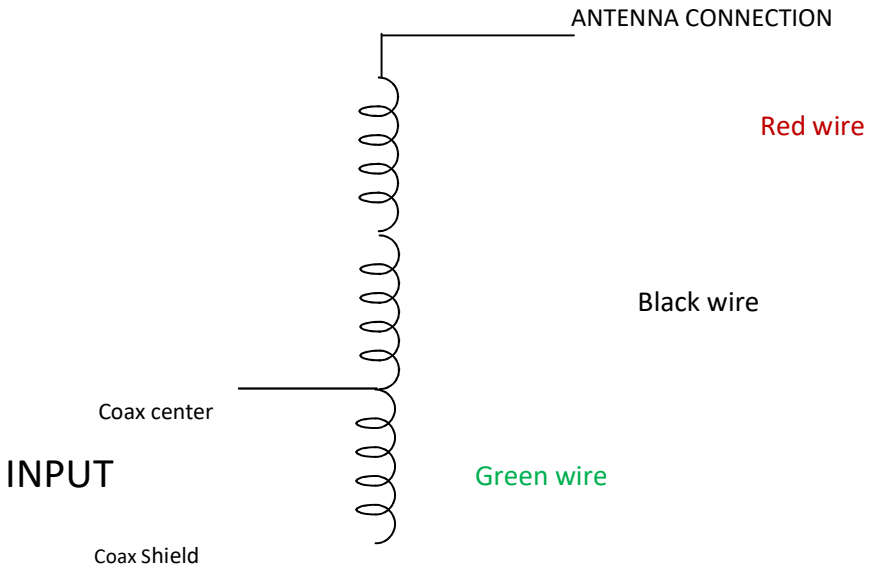
Some tuners, in particular internal tuners, may not tune the full 80-6 meter range. You may need to try different wire lengths to optimize your antenna configuration. If you are having difficulty getting your rig to tune, start with a 26’ wire. This should produce good results on at least 40-6 meters using the narrowest performance range of internal tuners.

Best performance is achieved with a coax of 16’ or longer, with the coax shield providing the counterpoise function. Additional counterpoise is usually not required in this design, although the lower wing nut provides a convenient counterpoise connector if needed. The end fed antenna system works well in horizontal, sloper, and vertical configurations.

Observe established safety practices when working with antennas, and avoid proximity to power or utility wires. Permanent installations should be equipped with appropriate static and lighting protection.

Keep amateur radio safe and fun!

Toroid Wiring Schematic



Feedback on 6-40 End Fed Matchbox Antennas

The antenna is amazing. I receive fantastic signal report from DX stations as well as hams around the country. I previously used a short version GR5V that was in an inverted V configuration on the roof of our house. This antenna was noisy but worked. Your antenna out performs the prior antenna and is much quieter. Thanks again for the fine product that your club offers. ***May 2012***

It took me 10 minutes to install and WOW - within 10 minutes I made my first HF contact (from CT to GA). And in the span of 4 hours made 3 more !! I was transmitting just 5 Watts from Yaesu 857ND using this antenna. This antenna rocks ! Thanks a ton ! 73 ***May 2012***

The 6 - 40 Matchbox antenna works great! Easily tunes with the Z100 tuner - very low SWR's on 20m thru 10m. Antenna was up about 45 feet on tree branch - wire length was about 52.5 feet, slight slope, 55 feet of coax, line isolator at radio. ***Work Hawaii for the very first time. Guess the antenna wanted to call home :-) 57 report, 100 watts, 15 Meter band, Icom 718.*** A great portable antenna that I will use often at Montrose Harbor along the lakefront in Chicago. Thank you for a fine, well made product. ***April 2012***

It arrived today in fine shape. I got is up in the air this afternoon using a 31 foot radiator. Top is at 45 feet. Loads on all bands 80-10M with my LDG auto-tuner absolutely no problem, My first QSO was KH7X in the ARRL SS contest with 100W. Amazing. This thing rocks! It's a great antenna! Nice job and a great buy. ***November 2011***

I set-up my jackite pole today and tried a 68' wire with the 9:1 unun matchbox. I set it up as an inverted L with about 26 feet vertical and 42 feet horizontal. With my IC-703 it tuned 80 through 6 all well below 1.5:1. I am going to leave the antenna up a few days and make a few contacts. I think the matchbox is terrific. ***October 2011***

My 6 – 40 meter end fed arrived through the UK holiday mail and I departed from my norm of a sloper and mounted it vertically on a 10m fishing pole. It is surprisingly effective and rewarded me with a surprise contact on 17m into the Falkland Islands at 20:30UT last night. ***January 2012***
When I attached it to a 10m fiberglass fishing pole and went vertical - wow! Easy 5/9 contacts out to 6,000+ miles when propagation was anything better than the worst. My simple ATU easily matches the antenna with SWR never greater than about 1.4 on any band it is built for. ***December 2012***

You can dither and procrastinate, but with this antenna, you'll be talking to the world in no time on any band that happens to be hot - and with your hard-earned cash hardly touched! ***January 2012***

Just wanted to report back that I have tossed the antenna into a tree about 20' up in an inverted vee shape and I am pleased to report that I can tune anywhere I need on 40-10M using the TS-590 internal tuner!! My first contact was on 40M within 10 minutes of erecting the antenna and was all the way to TX from my condo here in MI using just 10 watts. This is by far the best HAM related investment I have made in a long time. Living in a condo with strict association rules, I am able to conceal this wire in a tree out my bedroom window and talk all over. I'm very happy and would recommend this antenna to anyone in a similar situation. ***March 2013***

I have had your multiband end fed antenna installed here in Singapore for a few weeks now and am very pleased. I used the wire from my previous antenna which is 66 feet long. It works beautifully! I have it hanging vertically outside my 15th story apartment window on a 5 foot horizontal pole (to get it away from the reinforced concrete building). A couple of fish weights on the end keep it from blowing around too much. I would recommend this antenna to anyone who is facing a challenging QTH. ***April 2013*** I received my antenna yesterday, a quick 4 days since I ordered it. I attached it to a 31 foot pole and my IC-706MK2. Within minutes, I made my first contact with 9A4KW in Zagreb, Croatia on 20 meters. Being able to reach out over 4,000 miles gives me real confidence that I have found my portable antenna. Thanks for your rapid response and fine product. ***May 2013***

In only 2 weeks of casual on-air time. If you could see how I had to zig-zag it through a big tree above the roof of my RV, you'd be saying like I am, "how the heck can that work? I worked 90% of the stations I called, and just added Mexico City on 15m that gave me a 5x9. ***September 2013***

Just wanted to let you know how pleased I am with my ERAC matchbox antenna. I put the EARC antenna in the backyard with the feed point at 4 feet and the wire sloping up to 35 feet. I have 125 feet of coax feed line. My transceiver's built-in antenna tuner will adjust the SWR to below 1.2 to 1 on all bands 80-6 meters. Last weekend I worked 65 countries on 5 continents. I live in an antenna restricted community and this antenna has allowed me to enjoy ham radio again. ***February 2014***

I used the EARC Matchbox today. It works GREAT on 20m with a 30 ft radiator in vertical positioning, fed with 25ft of RG175/u coax. I've been talking up and down the east coast with 3W on SSB all afternoon! People ask me to repeat my power output again and again. I can't wait until I get the chance to use it at night, where I think it'll really shine! This has a permanent place in my portable kit. Thanks for the great product! ***April 2014***

I performed a simple install in Virginia making it vertical by using a 28 foot fiber glass kite pole. Within 30 minutes (NO KIDDING) I was receiving Lebanon on 17 meters! I also worked Russia and Eastern Europe that night on 20 meters. I love this antenna and I give it a 100% (5 STAR) rating. ***May 2014***

This little box is magic. NY, IA and NM from GA with ease on 100w ***June 2014***

Just wanted to let you guys know, this matchbox is wonderful. I built the matchbox, connected it to 55 feet of solid #14 about 20 feet in the air. My rig is a Yaesu FT-817ND connected to a MFJ-971 tuner with coax running between the tuner and the matchbox. So far I have worked Slovenia twice, Morocco, St. Helena Island, Cuba, Cost Rica, Vermont, Wyoming, Florida, North Dakota, Brazil, and Colombia. This setup works really well on the higher bands. Thank you for putting this design on the internet. I like it so much its become permanent here. ***September 2014***

This antenna continues to amaze me. It worked well U-shaped "indoors" with 50 watts, and now outdoors as a sloper. It easily loads 10-40m with my TS-570s internal tuner. I'm sold on it and own two of them now. I'm working at least 90% of the DX I chase. I have no RFI in the shack either. ***November 2014***

EARC Antennas are operating in virtually every state, these countries and more!

Hong Kong India Ireland Israel Italy Mexico Mozambique New Zealand Russia Singapore Sweden Tasmania United Kingdom

ORDERING A MATCHBOX ANTENNA FROM EARC

Volunteers of the Honolulu Emergency Amateur Radio Club (EARC) carefully assemble the 6-40 End Fed matchbox antennas for those who prefer not to build one. For a donation of **$56** (Including USPS priority mail shipping) club volunteers will build and deliver a 6-40 matchbox with a 30 foot antenna wire anywhere in the U.S., we do not ship internationally. Note that coax cable is not included.

Payment by PayPal

To pay via **PayPal**, make your payment to paypal@earchi.org using any major credit card. Include your name, mailing address, and email address with the order.

We will ship promptly and you will likely receive the order in the US in 7 days or less. If you have any questions about your order, please email webmaster@earchi.org

Thank you for your interest in the activities of Honolulu Emergency Amateur Radio Club and amateur radio.

Preface

If you are interested in amateur radio, short-wave listening, scanner monitoring, or any other radio hobby, then you will probably need to know a few things about radio antennas. This book is intended for the radio enthusiast – whether ham operator, listening hobbyist, or radio science observer – who wants to build and use antennas for their particular requirements and location. All of the antennas in this book can be made from wire, even though it is possible to use other materials if you desire.

These antennas have several advantages. One of the most attractive is that they can provide decent performance on the cheap. As one who has lived through the experience of being broke, I learned early to use bits of scrap wire to get on the air. My first novice antenna back in the late 1950s was a real patched-together job – but it worked really well (or so I thought at the time!).

Another advantage of wire antennas is that they are usually quite easy to install. A couple of elevated supports (tree, roof, mast), a few meters of wire, a few bits of radio hardware, and you are in the business of putting up an antenna. As long as you select a safe location, then you should have little difficulty erecting that antenna.

Finally, most high-frequency (HF) short-wave antennas are really easy to get working properly. One does not need to be a rocket scientist – or professional antenna rigger – to make most of these antennas perform as well as possible with only a little effort. There is quite a bit of detailed technical material to digest if you want to be a professional antenna engineer, but you can have good results if you follow a few simple guidelines.

SOFTWARE SUPPLEMENT TO THIS BOOK

At the time this book was conceived it was noted that the technology now exists to make Microsoft Windows-based antenna software available to readers along with the book. The software can be used to calculate the dimensions of the elements of most of the antennas in this book, as well as a few that are not. There are also some graphics in the software that show you a little bit about antenna hardware, antenna construction, and the like.

ANTENNA SAFETY

Every time I write about antenna construction I talk a little bit about safety. The issue never seems too old or too stale. The reason is that there seem to be plenty of people out there who never get the word. Antenna erection does not have to be dangerous, but if you do it wrong it can be very hazardous. Antennas are deceptive because they are usually quite lightweight, and can easily be lifted. I have no trouble lifting my trap vertical and holding it aloft – on a windless day. But if even a little wind is blowing (and it almost always is), then the 'sail area' of the antenna makes it a lot 'heavier' (or so it seems). Always use a buddy-system when erecting antennas. I have a bad back caused by not following my own advice.

Another issue is electrical safety. Do not ever, ever, ever toss an antenna wire over the power lines. Ever. Period. Also, whatever type of antenna you put up, make sure that it is in a location where it cannot possibly fall over and hit the power line.

The last issue is to be careful when digging to lay down radials. You really do not want to hit water lines, sewer lines, buried electrical service lines, or gas lines. I even know of one property where a long-distance oil pipeline runs beneath the surface. If you do not know where these lines are, try to guess by looking at the locations of the meters on the street, and the service entrance at the house. Hint: most surveyers' plans (those map-like papers you get at settlement) show the location of the buried services. They should also be on maps held by the local government (although you might have to go to two or three offices!. The utility companies can also help.

A NOTE ABOUT UNITS AND PRACTICES

This book was written for an international readership, even though I am American. As a result, some of the material is written in terms of US standard practice. Wherever possible, I have included UK standard wire sizes and metric units. Metric units are not in common usage in the USA, but rather we still use the old English system of feet, yards, and inches. Although many Americans (including myself) wish the USA would convert to SI units, it is not likely in the near future. UK readers with a sense of

history might recognize why this might be true – as you may recall from the George III unpleasantness, Americans do not like foreign rulers, so it is not likely that our measuring rulers will be marked in centimeters rather than inches.* For those who have not yet mastered the intricacies of converting between the two systems:

1 inch = 2.54 centimeters (cm) = 25.4 millimeters (mm)
1 foot = 30.48 cm = 0.3048 meter (m)
1 m = 39.37 inches = 3.28 feet

Joseph J. Carr

*I apologize for the bad play on words, but I could not help it.

CHAPTER 1

Radio signals on the move

Anyone who does any listening to radio receivers at all – whether as a ham operator, a short-wave listener, or scanner enthusiast – notices rather quickly that radio signal propagation varies with time and something mysterious usually called 'conditions.' The rules of radio signal propagation are well known (the general outlines were understood in the late 1920s), and some predictions can be made (at least in general terms). Listen to almost any band, and propagation changes can be seen. Today, one can find propagation predictions in radio magazines, or make them yourself using any of several computer programs offered in radio magazine advertisements. Two very popular programs are any of several versions of IONCAP, and a Microsoft Windows program written by the Voice of America engineering staff called VOACAP.

Some odd things occur on the air. For example, one of my favorite local AM broadcast stations broadcasts on 630 kHz. During the day, I get interference-free reception. But after the Sun goes down, the situation changes radically. Even though the station transmits the same power level, it fades into the background din as stations to the west and south of us start skipping into my area. The desired station still operates at the same power level, but is barely audible even though it is only 20 miles (30 km) away.

Another easily seen example is the 3–30 MHz short-wave bands. Indeed, even those bands behave very differently from one another. The lower-frequency bands are basically ground wave bands during the day, and become long-distance 'sky wave' bands at night (similar to the AM broadcast band (BCB)). Higher short-wave bands act just the opposite: during the

day they are long-distance 'skip' bands, but some time after sunset, become ground wave bands only.

The very high-frequency/ultra high-frequency (VHF/UHF) scanner bands are somewhat more consistent than the lower-frequency bands. But even in those bands sporadic-E skip, meteor scatter, and a number of other phenomena cause propagation anomalies. In the scanner bands there are summer and winter differences in heavily vegetated regions that are attributed to the absorptive properties of the foliage. I believe I experienced that phenomenon using my 2 m ham radio rig in the simplex mode (repeater operation can obscure the effect due to antenna and location height).

THE EARTH'S ATMOSPHERE

Electromagnetic waves do not need an atmosphere in order to propagate, as you will undoubtedly realize from the fact that space vehicles can transmit radio signals back to Earth in a near vacuum. But when a radio wave does propagate in the Earth's atmosphere, it interacts with the atmosphere, and its path of propagation is altered. A number of factors affect the interaction, but it is possible to break the atmosphere into several different regions according to their respective effects on radio signals.

The atmosphere, which consists largely of oxygen (O_2) and nitrogen (N_2) gases, is broken into three major zones: the **troposphere**, **stratosphere**, and **ionosphere** (Figure 1.1). The boundaries between these regions are not very well defined, and change both diurnally (i.e. over the course of a day) and seasonally.

The troposphere occupies the space between the Earth's surface and an altitude of 6–11 km. The temperature of the air in the troposphere varies with altitude, becoming considerably lower at high altitude compared with ground temperature. For example, a $+10^{\circ}$C surface temperature could reduce to -55°C at the upper edges of the troposphere.

The stratosphere begins at the upper boundary of the troposphere (6–11 km), and extends up to the ionosphere ($\approx$50 km). The stratosphere is called an **isothermal region** because the temperature in this region is relatively constant despite altitude changes.

The ionosphere begins at an altitude of about 50 km and extends up to 500 km or so. The ionosphere is a region of very thin atmosphere. Cosmic rays, electromagnetic radiation of various types (including ultraviolet light from the Sun), and atomic particle radiation from space (most of it from the Sun), has sufficient energy to strip electrons away from the gas molecules of the atmosphere. The O_2 and N_2 molecules that lost electrons are called **positive ions**. Because the density of the air is so low at those altitudes, the ions and electrons can travel long distances before neutralizing each other

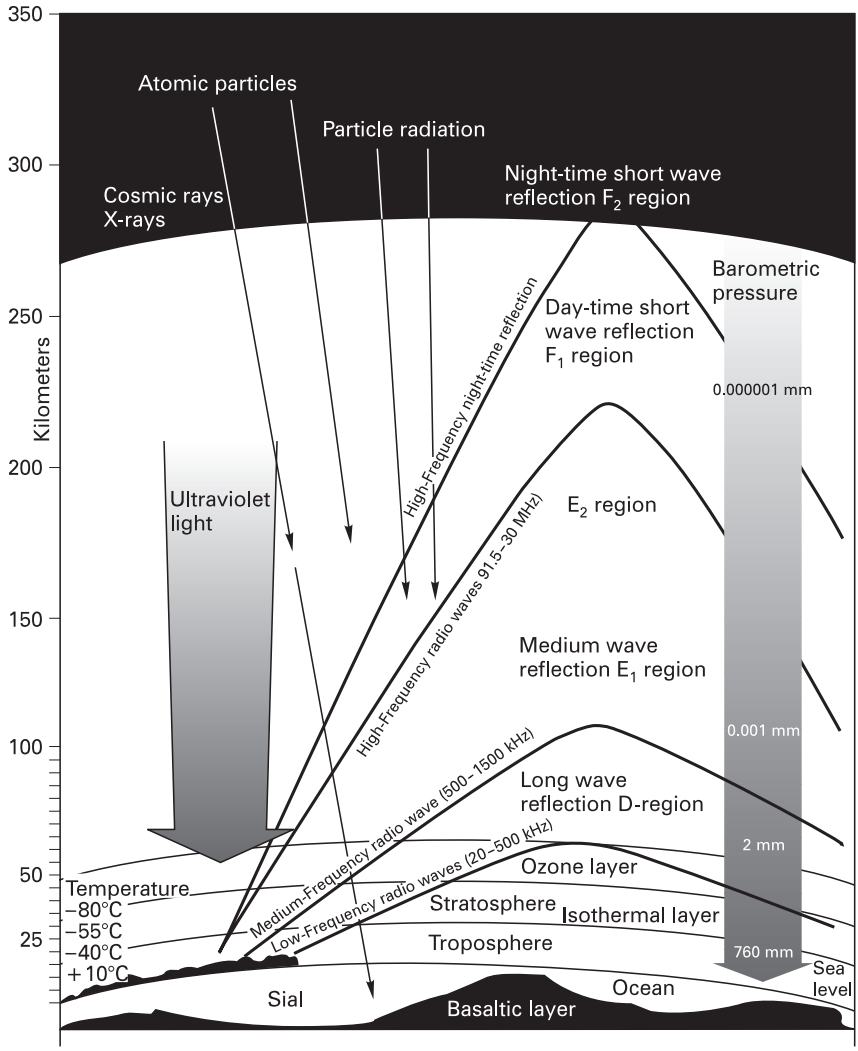

FIGURE 1.1

by recombining. Radio propagation on some bands varies markedly between daytime and night-time because the Sun keeps the level of ionization high during daylight hours, but the ionization begins to fall off rapidly after sunset, altering the radio propagation characteristics after dark. The ionization does not occur at lower altitudes because the air density is such that the positive ions and free electrons are numerous and close together, so recombination occurs rapidly.

PROPAGATION PATHS

There are four major propagation paths: **surface wave**, **space wave**, **tropospheric,** and **ionospheric**. The ionospheric path is important to medium-wave and HF propagation, but is not important to VHF, UHF, or microwave propagation. The space wave and surface wave are both **ground waves**, but behave differently. The surface wave travels in direct contact with the Earth's surface, and it suffers a severe frequency-dependent attenuation due to absorption into the ground.

The space wave is also a ground wave phenomenon, but is radiated from an antenna many wavelengths above the surface. No part of the space wave normally travels in contact with the surface; VHF, UHF, and microwave signals are usually space waves. There are, however, two components of the space wave in many cases: **direct** and **reflected** (Figure 1.2).

The ionosphere is the region of the Earth's atmosphere that is between the stratosphere and outer space. The peculiar feature of the ionosphere is that molecules of atmospheric gases (O_2 and N_2) can be ionized by stripping away electrons under the influence of solar radiation and certain other sources of energy (see Figure 1.1). In the ionosphere the air density is so low that positive ions can travel relatively long distances before recombining with electrons to form electrically neutral atoms. As a result, the ionosphere remains ionized for long periods of the day – even after sunset. At lower altitudes, however, air density is greater, and recombination thus occurs rapidly. At those altitudes, solar ionization diminishes to nearly zero imme-

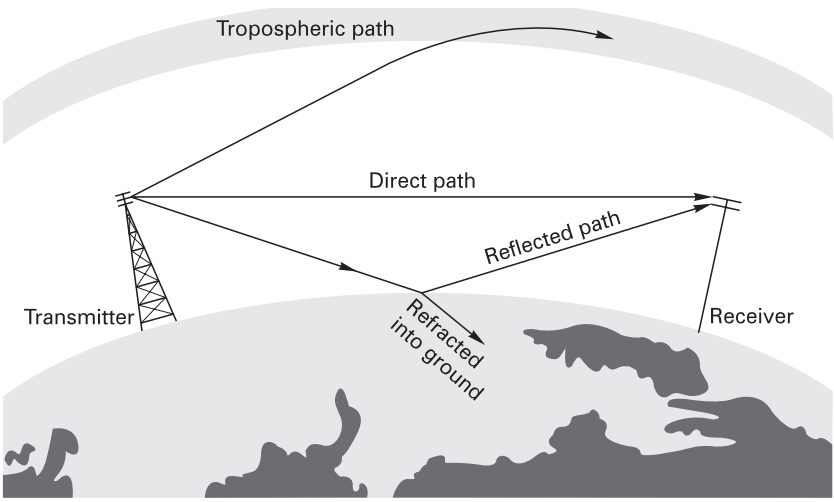

FIGURE 1.2

diately after sunset or never achieves any significant levels even at local noon.

Ionization and recombination phenomena in the ionosphere add to the noise level experienced at VHF, UHF, and microwave frequencies. The properties of the ionosphere are therefore important at these frequencies because of the noise contribution. In addition, in satellite communications there are some transionospheric effects.

GROUND WAVE PROPAGATION

The ground wave, naturally enough, travels along the ground, or at least in close proximity to it (Figure 1.3).

There are two basic forms of ground wave: **space wave** and **surface wave**. The space wave does not actually touch the ground. As a result, space wave attenuation with distance in clear weather is about the same as in free space (except above about 10 GHz, where absorption by H_2O and O_2 increases dramatically). Of course, above the VHF region, weather conditions add attenuation not found in outer space.

The surface wave is subject to the same attenuation factors as the space wave, but in addition it also suffers ground losses. These losses are due to ohmic resistive losses in the conductive earth. Surface wave attenuation is a function of frequency, and increases rapidly as frequency increases. For both of these forms of ground wave, communications is affected by the following factors: *wavelength*, *height of both receive and transmit antennas*, *distance between antennas*, and *terrain and weather along the transmission path*.

Ground wave communications also suffer another difficulty, especially at VHF, UHF, and microwave frequencies. The space wave is like a surface wave, but is radiated many wavelengths above the surface. It is made up of

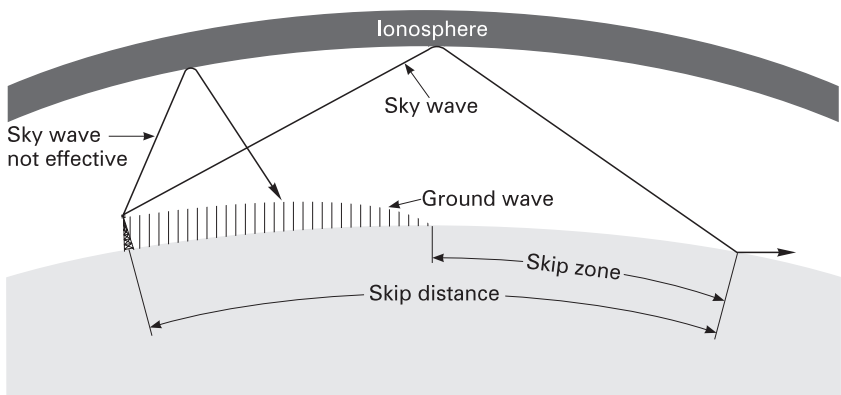

FIGURE 1.3

two components (see Figure 1.2): **direct** and **reflected** waves. If both of these components arrive at the receive antenna they will add algebraically to either increase or decrease signal strength. There is nearly always a phase shift between the two components because the two signal paths have different lengths. In addition, there may be a 180° (π radians) phase reversal at the point of reflection (especially if the incident signal is horizontally polarized).

Multipath phenomena exist because of interference between the direct and reflected components of the space wave. The form of multipath phenomenon that is, perhaps, most familiar to many readers (at least those old enough to be 'pre-cable') is ghosting in television reception. Some multipath events are transitory in nature (as when an aircraft flies through the transmission path), while others are permanent (as when a large building or hill reflects the signal). In mobile communications, multipath phenomena are responsible for reception dead zones and 'picket fencing.' A dead zone exists when destructive interference between direct and reflected (or multiple reflected) waves drastically reduces signal strengths. This problem is most often noticed at VHF and above when the vehicle is stopped; and the solution is to move the antenna a quarter wavelength. Picket fencing occurs as a mobile unit moves through successive dead zones and signal enhancement (or normal) zones, and sounds like a series of short noise bursts.

At VHF, UHF, and microwave frequencies the space wave is limited to so-called 'line of sight' distances. The horizon is theoretically the limit of communications distance, but the radio horizon is actually about 15% further than the optical horizon. This phenomenon is due to refractive bending in the atmosphere around the curvature of the Earth, and makes the geometry of the situation look as if the Earth's radius is four-thirds the actual radius.

The surface wave travels in direct contact with the Earth's surface, and it suffers a severe frequency-dependent attenuation due to absorption by the ground (Figure 1.3). The zone between the end of the ground wave and where the sky wave touches down is called the **skip zone**, and is a region of little or no signal. Because of this phenomenon, I have seen situations on the 15 m band (21.390 MHz) where two stations 65 km apart (Baltimore, Maryland, and Fairfax, Virginia) could not hear each other, and their communications have to be relayed via a ham station in Lima, Peru!

The surface wave extends to considerable heights above the ground level, although its intensity drops off rapidly at the upper end. The surface wave is subject to the same attenuation factors as the space wave, but in addition it also suffers ground losses. These losses are due to ohmic resistive losses in the conductive earth, and to the dielectric properties of the Earth. Horizontally polarized waves are not often used for surface wave communications because the Earth tends to short circuit the electrical (E) field

component. On vertically polarized waves, however, the Earth offers electrical resistance to the *E*-field and returns currents to following waves. The conductivity of the soil determines how much energy is returned.

IONOSPHERIC PROPAGATION

Now let us turn our attention to the phenomena of **skip communications** as seen in the short-wave bands, plus portions of the medium-wave and lower VHF regions. Ionospheric propagation is responsible for intercontinental broadcasting and communications.

Long-distance radio transmission is carried out on the HF bands (3–30 MHz), also called the 'short-wave' bands. These frequencies are used because of the phenomenon called **skip**. Under this type of propagation the Earth's ionosphere acts as if it is a 'radio mirror,' to reflect the signal back to Earth. This signal is called the **sky wave**. Although the actual phenomenon is based on refraction (not reflection, as is frequently believed) the appearance to the casual ground observer is that short-wave and low-VHF radio signals are reflected from the ionosphere as if it were a kind of radio mirror. The actual situation is a little different, but we will deal with that issue in a moment.

The key lies in the fact that a seeming radio mirror is produced by ionization of the upper atmosphere. The upper portion of the atmosphere is called the 'ionosphere' because it tends to be easily **ionized** by solar and cosmic radiation phenomena. The reason for the ease with which that region (50–500 km above the surface) ionizes is that the air density is very low. Energy from the Sun strips away electrons from the outer shells of oxygen and nitrogen molecules, forming free electrons and positive ions. Because the air is so rarified at those altitudes, these charged particles can travel great distances before recombining to form electrically neutral atoms again. As a result, the average ionization level remains high in that region.

Several sources of energy will cause ionization of the upper atomosphere. Cosmic radiation from outer space causes some degree of ionization, but the majority of ionization is caused by solar energy. The role of cosmic radiation was first noticed during World War II when military radar operators discovered that the distance at which their equipment could detect enemy aircraft was dependent upon whether or not the Milky Way was above the horizon (although it was theorized 10 years earlier). Intergalactic radiation raised the background microwave noise level, thereby adversely affecting the signal-to-noise ratio.

The ionosphere is divided for purposes of radio propagation studies into various layers that have different properties. These layers are only well defined in textbooks, however, and even there we find a variation in the height above the Earth's surface where these layers are found. In addition,

the real physical situation is such that layers do not have sharply defined boundaries, but rather fade one into another. The division into layers is therefore somewhat arbitrary. These layers (shown earlier in Figure 1.1) are designated D, E, and F (with F being further subdivided into the F_1 and F_2 sublayers).

D-layer

The D-layer is the lowest layer in the ionosphere, and exists from approximately 50 to 90 km above the Earth's surface. This layer is not ionized as much as higher layers because all forms of solar energy that cause ionization are severely attenuated by the higher layers above the D-layer. Another reason is that the D-layer is much denser than the E- and F-layers, and that density of air molecules allows ions and electrons to recombine to form electroneutral atoms very quickly.

The extent of D-layer ionization is roughly proportional to the height of the Sun above the horizon, so will achieve maximum intensity at midday. The D-layer exists mostly during the warmer months of the year because of both greater height of the sun above the horizon and the longer hours of daylight. The D-layer almost completely disappears after local sunset, although some observers have reported sporadic incidents of D-layer activity for a considerable time past sunset. The D-layer exhibits a large amount of absorption of medium-wave and short-wave signals, to such an extent that signals below 4–6 MHz are completely absorbed by the D-layer.

E-layer

The E-layer exists at altitudes between approximately 100 and 125 km. Instead of acting as an attenuator it acts primarily as a reflector although signals do undergo a degree of attenuation.

Like the D-layer, ionization in this region only exists during daylight hours, peaking around midday and falling rapidly after sunset. After nightfall the layer virtually disappears although there is some residual ionization there during the night-time hours.

The distance that is generally accepted to be maximum that can be achieved using E-layer propogation is 2500 km, although it is generally much less than this and can be as little as 200 km.

One interesting and exciting aspect of this region is a phenomenon called Es or sporadic E. When this occurs a layer or cloud of very intense ionization forms. This can reflect signals well into the VHH region of the radio spectrum. Although generally short lived, there can be openings on bands as high as 2 meters (144 MHz). These may last as little as a few minutes, whilst long openings may last up to a couple of hours. The phenomenon also affects lower frequencies like the 10 meter and 6 meter amateur bands as

well as the VHF FM band. Sporadic E is most common in the summer months, peaking in June (in the northern hemisphere). Distances of between 1000 and 2500 km can be reached using this mode of propagation.

F-layer

The F-layer of the ionosphere is the region that is the principal cause of long-distance short-wave communications. This layer is located from about 150–500 km above the Earth's surface. Unlike the lower layers, the air density in the F-layer is low enough that ionization levels remain high all day, and decay slowly after local sunset. Minimum levels are reached just prior to local sunrise. Propagation in the F-layer is capable of skip distances up to 4000 km in a single hop. During the day there are actually two identifiable, distinct sublayers in the F-layer region, and these are designated the 'F_1' and 'F_2' layers. The F_1 layer is found approximately 150–250 km above the Earth's surface, while the F_2 layer is above the F_1 to the 450–500 km limit. Beginning at local sundown, however, the lower regions of the F_1 layer begin to de-ionize due to recombination of positive ions and free electrons. At some time after local sunset the F_1 and F_2 layers have effectively merged to become a single reduced layer beginning at about 300 km.

The height and degree of ionization of the F_2 layer varies over the course of the day, with the season of the year, and with the 27 day cycle of the sun. The F_2 layer begins to form shortly after local sunrise, and reaches a maximum shortly before noon. During the afternoon the F_2 layer ionization begins to decay in an exponential manner until, for purposes of radio propagation, it disappears sometime after local sunset. There is some evidence that ionization in the F-layer does not completely disappear, but its importance to HF radio communication does disappear.

IONOSPHERIC VARIATION AND DISTURBANCES

The ionosphere is an extremely dynamic region of the atmosphere, especially from a radio operator's point of view, for it significantly alters radio propagation. The dynamics of the ionosphere are conveniently divided into two general classes: **regular variation** and **disturbances**. We will now look at both types of ionospheric change.

Ionospheric variation

There are several different forms of variation seen on a regular basis in the ionosphere: **diurnal**, **27 day** (monthly), **seasonal**, and **11 year cycle**.

Diurnal (daily) variation

The Sun rises and falls in a 24 hour cycle, and because it is a principal source of ionization of the upper atmosphere, one can expect diurnal variation. During daylight hours the E- and D-levels exist, but these disappear at night. The height of the F_2 layer increases until midday, and then decreases until evening, when it disappears or merges with other layers. As a result of higher absorption in the E- and D-layers, lower frequencies are not useful during daylight hours. On the other hand, the F-layers reflect higher frequencies during the day. In the 1–30 MHz region, higher frequencies (>11 MHz) are used during daylight hours and lower frequencies (<11 MHz) at night. Figure 1.4B shows the number of sunspots per year since 1700.

27 day cycle

Approximately monthly in duration, this variation is due to the rotational period of the Sun. Sunspots (Figure 1.4A) are localized on the surface of the Sun, so will face the Earth only during a portion of the month. As new sunspots are formed, they do not show up on the earthside face until their region of the Sun rotates earthside.

Seasonal cycle

The Earth's tilt varies the exposure of the planet to the Sun on a seasonal basis. In addition, the Earth's yearly orbit is not circular, but elliptical. As a result, the intensity of the Sun's energy that ionizes the upper atmosphere varies with the seasons of the year. In general, the E-, D-, and F-layers are affected, although the F_2 layer is only minimally affected. Ion density in the F_2 layer tends to be highest in winter, and less in summer. During the summer, the distinction between F_1 and F_2 layers is less obvious.

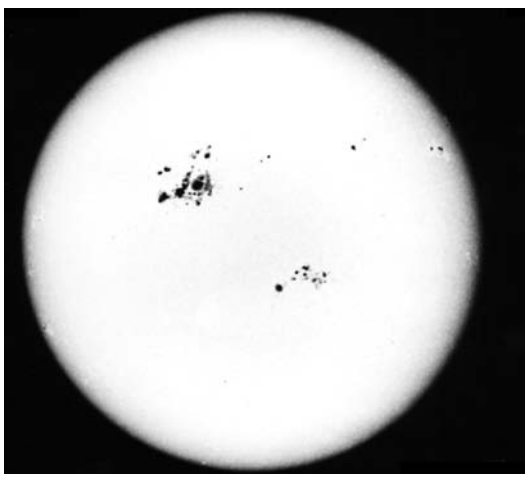

FIGURE 1.4A

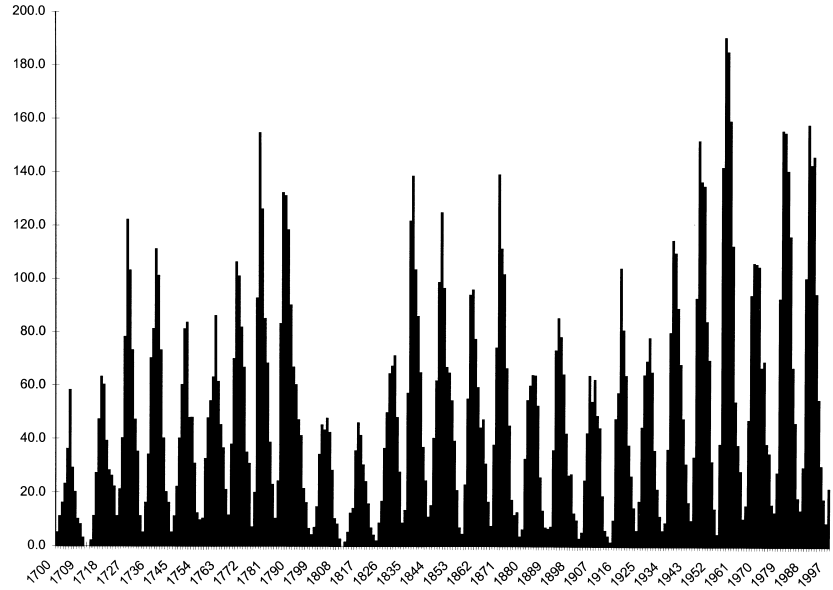

FIGURE 1.4B

11 year cycle

The number of sunspots, statistically averaged, varies on an approximately 11 year cycle (Fig. 1.4B). As a result, the ionospheric effects that affect radio propagation also vary on an 11 year cycle. Radio propagation in the short-wave bands is best when the average number of sunspots is highest. Peaks occurred in 1957, 1968, 1979, and 1990.

Events on the surface of the Sun sometimes cause the radio mirror to seem almost perfect, and make spectacular propagation possible. At other times, however, solar disturbances disrupt radio communications for days at a time.

There are two principal forms of solar energy that affect short-wave communications: **electromagnetic radiation** and **charged solar particles**. Most of the radiation is beyond the visible spectrum, in the ultraviolet and X-ray/γ-ray region of the spectrum. Because electromagnetic radiation travels at the speed of light, solar events that release radiation cause changes to the ionosphere about 8 minutes later. Charged particles, on the other hand, have a finite mass and so travel at a considerably slower velocity. They require 2 or 3 days to reach the Earth.

Various sources of both radiation and particles exist on the Sun. Solar flares may release huge amounts of both radiation and particles. These events are unpredictable and sporadic. Solar radiation also varies over an approximately 27 day period, which is the rotational period of the Sun. The same source of radiation will face the Earth once every 27 days, so events tend to be somewhat repetitive.

Solar and galactic noise affect the reception of weak signals, while solar noise will also either affect radio propagation or act as a harbinger of changes in propagation patterns. Solar noise can be demonstrated by using an ordinary radio receiver and a directional antenna, preferably operating in the VHF/UHF regions of the spectrum. If the antenna is aimed at the Sun on the horizon at either sunset or sunrise a dramatic change in background noise will be noted as the Sun slides across the horizon.

Sunspots

A principal source of solar radiation, especially the periodic forms, is sunspots (Figure 1.4A). Sunspots can be as large as 100 000–150 000 km in diameter, and generally occur in clusters. The number of sunspots varies over a period of approximately 11 years, although the actual periods since 1750 (when records were first kept) have varied from 9 to 14 years (Fig. 1.4B). The sunspot number is reported daily as the statistically massaged **Zurich smoothed sunspot number**, or **Wolf number**. The number of sunspots greatly affects radio propagation via the ionosphere. The low was in the range of 60 (in 1907), while the high was about 200 (1958).

Another indicator of ionospheric propagation potential is the **solar flux index** (SFI). This measure is taken in the microwave region (wavelength of 10.2 cm, or 2.8 GHz), at 1700 U.T. Greenwich Mean Time in Ottawa, Canada. The SFI is reported by the National Institutes of Standards and Technology (NIST) radio stations WWV (Fort Collins, Colorado) and WWVH (Maui, Hawaii).

The ionosphere offers different properties that affect radio propagation at different times. Variations occur not only over the 11 year sunspot cycle but also diurnally and seasonally. Obviously, if the Sun affects propagation in a significant way, then differences between night-time and daytime, and between summer and winter, must cause variations in the propagation phenomena observed.

Ionospheric disturbances

Disturbances in the ionosphere can have a profound effect on radio communications – and most of them (but not all) are bad. In this section we will briefly examine some of the more common forms.

Sporadic E-layer

A reflective cloud of ionization sometimes appears in the E-layer of the ionosphere; this layer is sometimes called the E_s layer. It is believed that the E_s layer forms from the effects of wind shear between masses of air moving in opposite directions. This action appears to redistribute ions into a thin a layer that is radio-reflective.

Sporadic-E propagation is normally thought of as a VHF phenomenon, with most activity between 30 and 100 MHz, and decreasing activity up to about 100 MHz. However, about 25–50% of the time, sporadic-E propagation is possible on frequencies down to 10–15 MHz. Reception over paths of 2300–4200 km is possible in the 50 MHz region when sporadic-E propagation is present. In the northern hemisphere, the months of June and July are the most prevalent sporadic-E months. On most days when the sporadic-E phenomenon is present it lasts only a few hours.

Sudden ionospheric disturbances (SIDs)

The SID, or 'Dellinger fade,' mechanism occurs suddenly, and rarely gives any warning. Solar flares (Figure 1.5) are implicated in SIDs. The SID may last from a few minutes to many hours. It is believed that SIDs occur in correlation with solar flares or 'bright solar eruptions' that produce immense amounts of ultraviolet radiation that impinge the upper atmosphere. The SID causes a tremendous increase in D-layer ionization, which accounts for the radio propagation effects. The ionization is so intense that all receiver operators on the sunny side of the Earth experience profound loss of signal strength above about 3 MHz. It is not uncommon for receiver owners to think that their receivers are malfunctioning when this

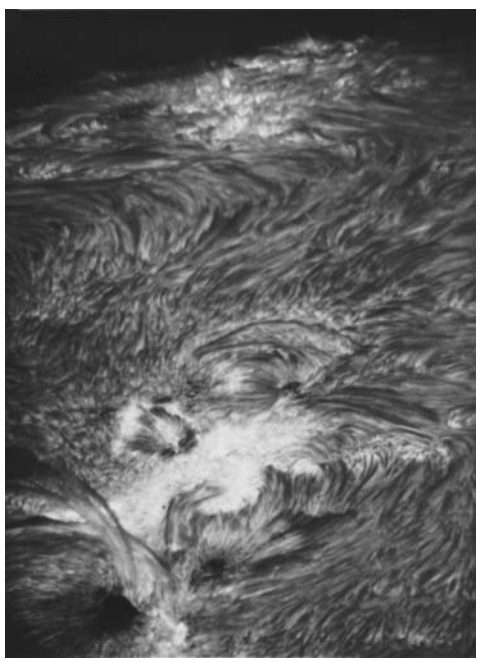

FIGURE 1.5

occurs. The sudden loss of signal by sunny-side receivers is called **Dellinger fade**. The SID is often accompanied by variations in terrestial electrical currents and magnetism levels.

An interesting anomaly is seen when SIDs occur. Although short-wave reception is disrupted, and may stay that way for awhile, distant very low-frequency (VLF) signals, especially in the 15–40 kHz region, experience a sudden increase in intensity. This is due to the fact that the SID event results in deep ionization way into the D-layer. This ionization increases absorption of HF signals. But the wavelength of VLF signals is close to the distance from the Earth's surface to the bottom of the D-layer, so that space acts like a gigantic 'waveguide' (as used in the transmission of microwaves) when the SID is present – thus propagating the VLF signal very efficiently.

Ionospheric storms

The ionospheric storm appears to be produced by an abnormally large rain of atomic particles in the upper atmosphere, and is often preceded by a SID 18–24 hours earlier. These storms tend to last from several hours to a week or more, and are often preceded by 2 days or so by an abnormally large collection of sunspots crossing the solar disk. They occur most frequently, and with greatest severity, in the higher latitudes, decreasing toward the Equator. When the ionospheric storm commences, short-wave radio signals may begin to flutter rapidly and then drop out altogether. The upper ionosphere becomes chaotic, turbulence increases, and the normal stratification into 'layers' or zones diminishes.

Radio propagation may come and go over the course of the storm, but it is mostly absent. The ionospheric storm, unlike the SID which affects the sunny side of the Earth, is worldwide. It is noted that the maximum usable frequency (MUF) and critical frequency tend to reduce rapidly as the storm commences.

An ionospheric disturbance observed over November 12–14, 1960 was preceded by about 30 minutes of extremely good, but abnormal propagation. At 15.00 hours EST, European stations were noted in North America with S9+ signal strengths in the 7000–7300 kHz region of the spectrum, which is an extremely rare occurrence. After about 30 minutes, the bottom dropped out, and even AM broadcast band skip (later that evening) was non-existent. At the time, WWV was broadcasting a 'W2' propagation prediction at 19 and 49 minutes after each hour. It was difficult to hear even the 5 MHz WWV frequency in the early hours of the disturbance, and it disappeared altogether for the next 48 hours. Of course, as luck would have it, that event occurred during the first weekend of the ARRL Sweepstakes ham radio operating contest that year.

GREAT CIRCLE PATHS

A great circle is a line between two points on the surface of a sphere that lies on a plane through the sphere's center. When translated to 'radio speak,' a great circle is the shortest path on the surface of the Earth between two points. Navigators and radio operators use the great circle for similar, but different reasons: the navigator in order to get from here to there, and the radio operator to get a transmission path from here to there.

The heading of a directional antenna is normally aimed at the receiving station along its great circle path. Unfortunately, many people do not understand the concept well enough, for they typically aim the antenna in the wrong direction. Radio waves do not travel along what appears to be the best route on a flat map. Instead they travel along the shortest distance on a real globe.

Long path versus short path

The Earth is a sphere (or more precisely, an 'oblique spheroid'), so from any given point to any other point there are two great circle paths: the **long path** (major arc) and **short path** (minor arc). In general, the best reception occurs along the short path. In addition, short-path propagation is more nearly 'textbook' compared with long-path reception. However, there are times when the long path is better, or is the only path that will deliver a signal to a specific location from the geographic location in question.

USING THE IONOSPHERE

The refraction of HF and some medium-wave radio signals back to Earth via the ionosphere gives rise to intercontinental HF radio communications. This phenomenon becomes possible during daylight hours, and for a while after sunset when the ionosphere is ionized. Figure 1.6 reiterates the mechanism of long-distance skip communications. The transmitter is located at point T, while receiving stations are located at sites R1 and R2. Signals 1 and 2 are not refracted sufficiently to be returned to Earth, so they are lost in space. Signal 3, however, is refracted enough to return to Earth, so it is heard at station Rl. The skip distance for signal 3 is the distance from T to Rl. At points between T and R1, signal 3 is inaudible, except within ground wave distance of the transmitter site (T). This is the reason why two stations 50 km apart hear each other only weakly, or not at all, while both stations can communicate with a third station 3000 km away. In American amateur radio circles it is common for South American stations to relay between two US stations only a few kilometers apart.

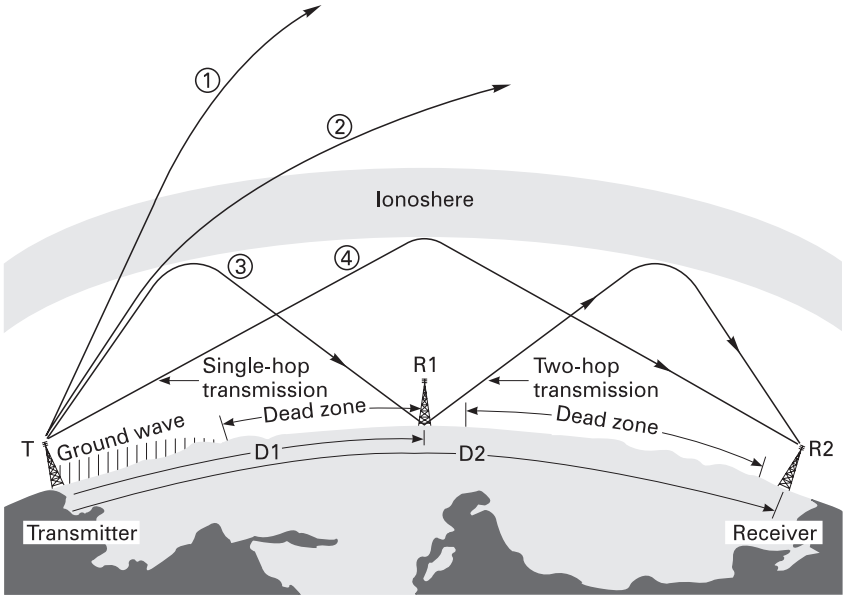

FIGURE 1.6

Multi-hop skip is responsible for the reception of signal 3 at site R2. The signal *reflects* (not refracts) from the surface at R1, and is retransmitted into the ionosphere, where it is again refracted back to Earth.

The location where skip signals are received (at different distances) depends partially upon the **angle of radiation** of the transmitting antenna. A high angle of radiation causes a shorter skip zone, while a lower angle of radiation results in a longer skip zone. Communication between any particular locations on any given frequency requires adjustment of the antenna radiation angle. Some international short-wave stations have multiple antennas with different radiation angles to ensure that the correct skip distances are available.

SUPER-REFRACTION AND SUBREFRACTION

At VHF frequencies and well up into the microwave bands there are special propagation modes called *super-refraction* and *subrefraction*. Depending upon the temperature gradient and humidity, the propagation may not be straight line. At issue is something called the *K-factor* of the wave. Figure 1.7 shows these modalities. The straight line case has a K-factor of one, and is the reference. If super-refraction occurs, then the value of K is greater than one, and if subrefraction occurs it is less than one.

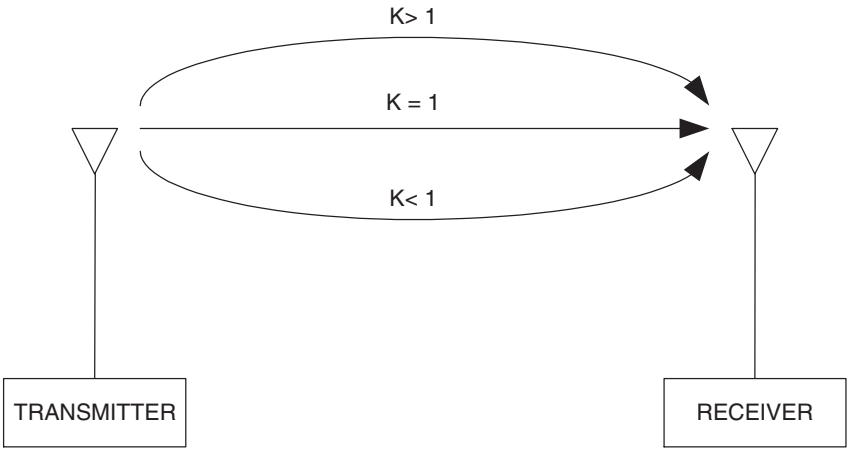

FIGURE 1.7

Figure 1.8 shows a case where super-refraction occurs. The value of K can be substantially above one in cases where a hot body of land occurs next to a relatively cool body of water. This occurs off Baja, California, the Persian Gulf and Indian Ocean, parts of Australia and the North African coast. In those areas, there may be substantial amounts of super-refraction occurring, making directional antennas point in the wrong direction.

Figure 1.9 shows a case of subrefraction. In this case, there is a relatively cold land mass next to relatively warm seas. In the Arctic and Antarctic this situation exists. The K factor will be substantially less than one in these cases. In fact, the signal may be lost to terrestrial communications after only a relatively short distance.

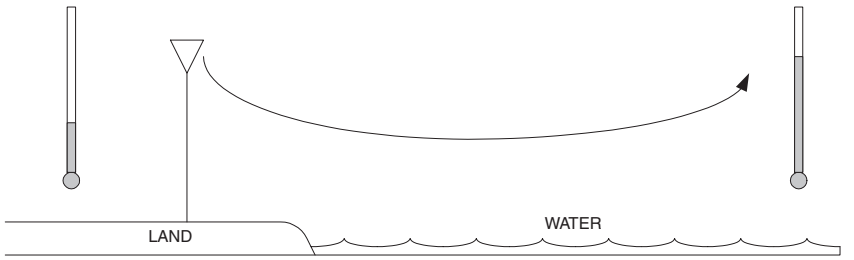

FIGURE 1.9

CHAPTER 2

Antenna basics

Before looking at the various antennas we need to look at some of the basics of antenna systems. In this chapter you will learn some of these basics. And while they will not make you a red-hot professional antenna engineer they will set you up well enough to understand this book and others on amateur and hobbyist antennas. We will look at the matter of antenna radiation, antenna patterns, the symbols used to represent antennas, voltage standing wave ratio (VSWR), impedance, and various methods suitable for constructing wire antennas in the high-frequency (HF) and very high-frequency (VHF) regions of the spectrum.

ANTENNA SYSTEM SYMBOLS

Figures 2.1 and 2.2 show the various symbols used to represent antennas and grounds. The reason why there are so many variants is that there are differences from country to country, as well as different practices within any one country (especially between technical publishers). As for antenna symbols, I see the symbol in Figure 2.1C more often in the USA, but Figure 2.1B comes in for a close second. The supposedly correct symbol (endorsed by a professional society drawing standards committee) is that of Figure 2.1A – but it is only occasionally seen in the USA.

The situation for grounds is a little different because some differences reflect different forms of ground (although some of the differences also represent national or publisher differences). The ground in Figure 2.2A is usually found representing a true earth ground, i.e. the wire is connected to a

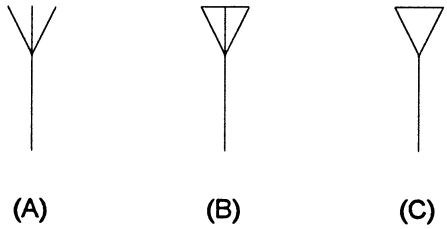

FIGURE 2.1

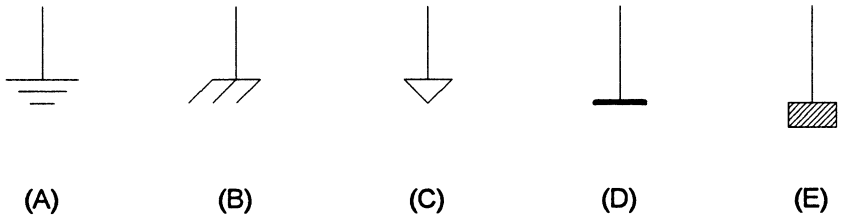

FIGURE 2.2

rod driven into the earth. The variant of Figure 2.2B usually represents a chassis ground inside a piece of equipment. The symbol in Figure 2.2C has two uses. One is to represent a common grounding point for different signals or different pieces of equipment. The other use is exactly the opposite: the triangle ground symbol often represents an **isolated ground** that has no direct electrical connection to the rest of the circuit, or with the earth. You will see this usage in medical devices. The grounds of Figures 2.2D and 2.2E are found mostly outside the USA.

From the time of Hertz and Marconi to the present, one thing has remained constant in wireless communications: radio waves travel, as if by magic, from a transmitting antenna to a receiving antenna (Figure 2.3). Whether the two antennas are across the garden from each other, across continents and oceans, or on the Earth and the Moon, if there is not a transmitting antenna and at least one receiving antenna in the system then no communications can take place.

At one time, physicists believed that there must be some invisible medium for carrying the radio signal. But we now know that no such medium exists, yet radio waves travel even in outer space. Being electromagnetic waves, radio signals need no medium in order to propagate. If radio signals traveled only in the Earth's atmosphere, then we could make some guesses about a medium for carrying the wave, but space communications demonstrates that the atmosphere is not necessary (although it does affect radio signal propagation).

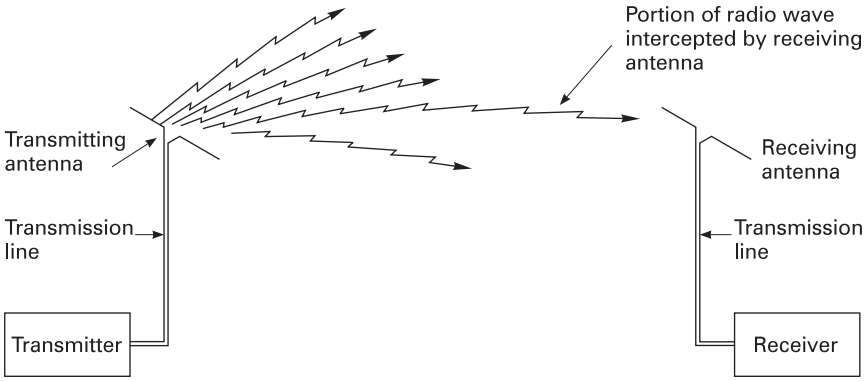

FIGURE 2.3

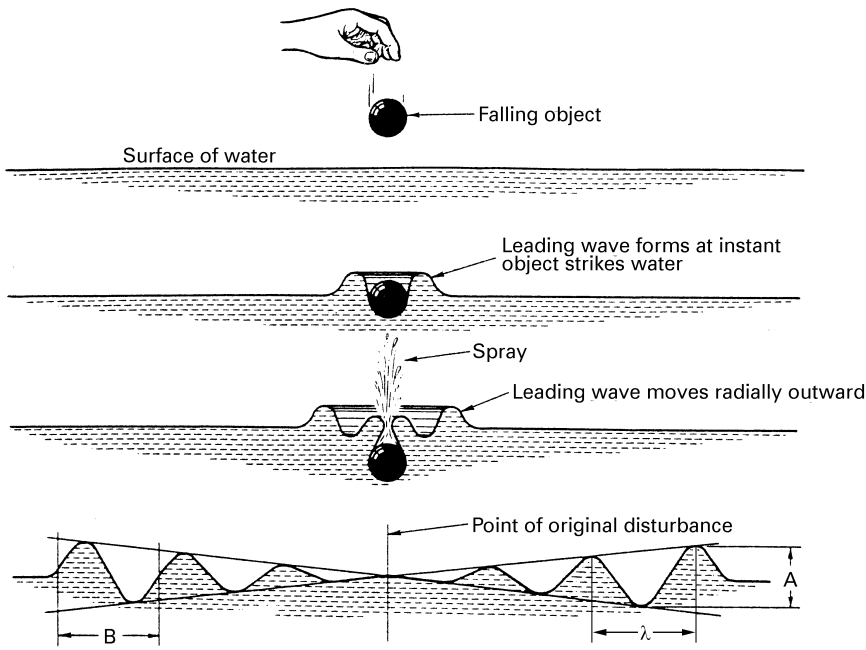
Although there is no medium in which radio waves travel, it is useful to look at water waves for an analogy (even though imperfect). In Figure 2.4 we see what happens when an object is dropped into a pool of water. A displacement takes place, which forms a leading wave that pushes out in concentric circles from the impact point. The situation in Figure 2.4 repre-



Notes: A, amplitude of leading wave.
B, corresponds to 1 cycle of oscillation.

FIGURE 2.4

sents a single pulse of energy, as if a transmitter fired a single burst of energy. Real transmitters send out wave trains that are analogous to cyclically bobbing the object up and down so that it goes in and out of the water (Figure 2.5). The result is a continuous stream of identical waves propagating out from the 'transmitter' impact point. If another object is floating on the surface, say a cork or toy boat, then it will be perturbed as the wave passes. This is analogous to the receiver antenna.

The waves have an **amplitude** ('A'), which corresponds to the signal strength. They also have a **wavelength** (λ), which corresponds to the distance traveled by the wave in one complete up-and-down cycle. In radio work, the wavelength is measured in **meters** (m), except in the microwave region where **centimeters** (cm) and **millimeters** (mm) make more sense. Wavelength can be measured at any pair of points on the wave that are identical: two peaks, two troughs, two zero crossings, as convenient in any specific case.

The number of cycles that pass a given point every second is the **frequency** of the wave. The classic measure of frequency was cycles per second (cps or c/s), but that was changed in 1960 by international consensus to the hertz (Hz), in honor of Heinrich Hertz. But since 1 Hz = 1 cps, there is no

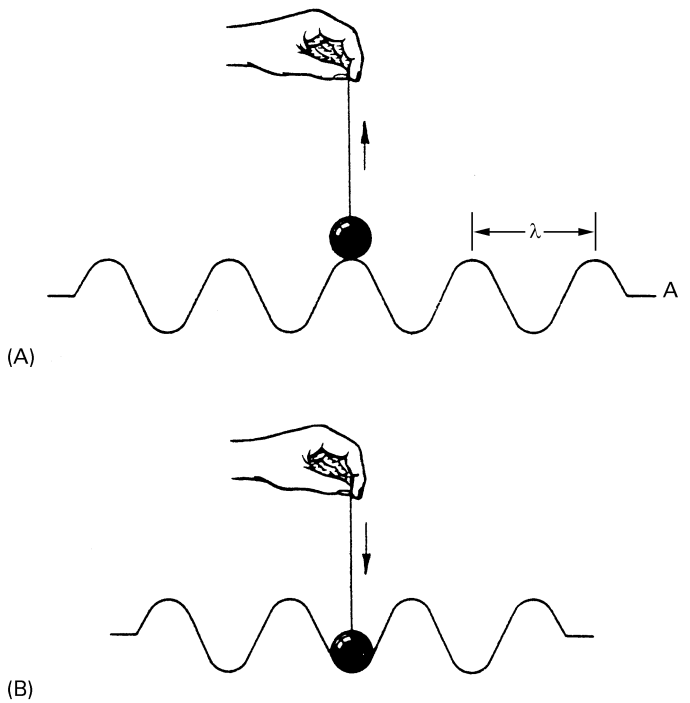


FIGURE 2.5

practical difference. The hertz is too small a unit for most radio work (although many of our equations are written in terms of hertz). For radio work the **kilohertz** (kHz) and **megahertz** (MHz) are used: 1 kHz = 1000 Hz, and 1 MHz = 1 000 000 Hz. Thus, a short-wave frequency of 9.75 MHz is 9750 kHz and 9 750 000 Hz.

Wavelength and frequency are related to each other. The wavelength is the reciprocal of frequency, and vice versa, through the velocity constant. In free space, the velocity constant is the speed of light (c), or about 300 000 000 m/s. This is the reason why you often see '300' or its submultiples (150 and 75) in equations. When the frequency is specified in megahertz, then 300 000 000 becomes 300 for one wavelength. The half-wavelength constant is 150, and the quarter-wavelength constant is 75. The relationship is

$$\lambda_{\text{meters}} = \frac{300}{F_{\text{MHz}}}$$

INVERSE SQUARE LAW

When radio waves travel they become weaker by a relationship called the **inverse square law**. This means that the strength is inversely proportional to the square of the distance traveled ($1/D^2$). Figure 2.6 shows how this works using the analogy of a candle. If the candle projects a distance r, all of the light energy falls onto square 'A'. At twice the distance ($2r$) the light spreads out and covers four times the area (square 'B'). The total amount of light energy is the same, but the energy per unit of area is reduced to one-fourth of the energy that was measured at 'A.' This means that a radio signal gets weaker very rapidly as the distance from the transmitter increases, requiring ever more sensitive receivers and better antennas.

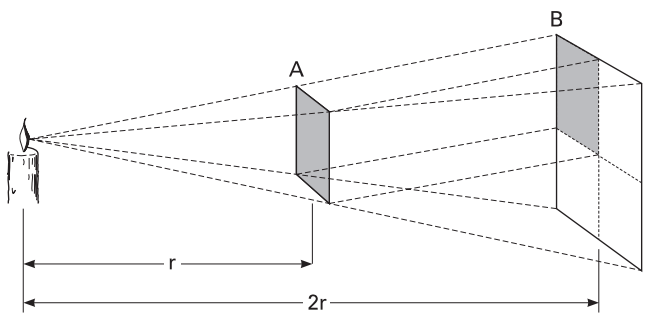

FIGURE 2.6

THE ELECTROMAGNETIC WAVE

The electromagnetic (EM) wave propagating in space is what we know as a 'radio signal.' The EM wave is launched when an electrical current oscillates in the transmitting antenna (Figure 2.7). Because moving electrical currents possess both electrical (*E*) and magnetic (*H*) fields, the electromagnetic wave launched into space has alternating *E*-field and *H*-field components. These fields are **transverse** (meaning they travel in the same direction) and **orthogonal** (meaning the *E*- and *H*-fields are at right angles to each other). When the EM wave intercepts the receiver antenna, it sets up a copy of the original oscillating currents in the antenna, and these currents are what the receiver circuitry senses.

The orthogonal *E*- and *H*-fields are important to the antenna designer. If you could look directly at an oncoming EM wave, you would see a plane front advancing from the transmitting antenna. If you had some magical dye that would render the *E*-field and *H*-field line of force vectors visible to the naked eye, then you would see the *E*-field pointing in one direction, and the *H*-field in a direction 90° away (Figure 2.8).

The **polarization** of the signal is the *direction of the* E-*field vector*. In Figure 2.8 the polarization is vertical because the electric field vector is up and down. If the *E*-field vector were side-to-side, then the polarization would be horizontal. One way to tell which polarization an antenna produces when it transmits, or is most sensitive to when it receives, is to note the direction of the radiator element. If the radiator element is vertical, i.e. perpendicular to the Earth's surface, then it is vertically polarized. But if

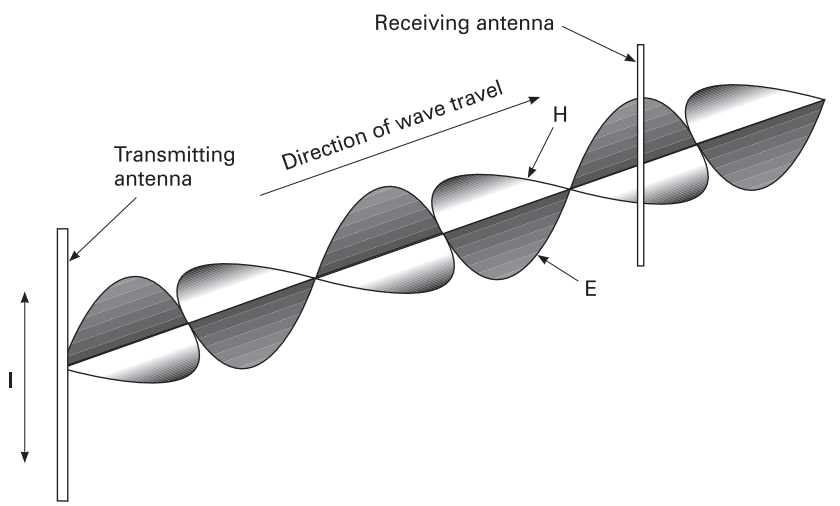

FIGURE 2.7

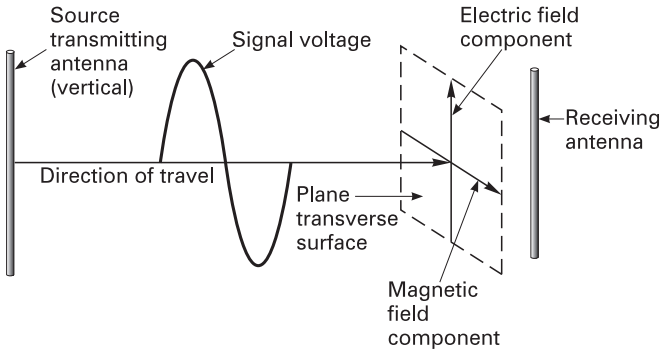

FIGURE 2.8

the radiator element is horizontal with respect to the Earth's surface, then it is horizontally polarized. Figure 2.9 shows these relationships. In Figure 2.9, two dipole receiver antennas are shown, one is vertically polarized (VD) and the other is horizontally polarized (HD). In Figure 2.9A, the arriving signal is vertically polarized. Because the *E*-field vectors lines are vertical, they cut across more of the VD antenna than the HD, producing a considerably larger signal level. The opposite is seen in Figure 2.9B. Here the *E*-field is horizontally polarized, so it is the HD antenna that receives the most signal. The signal level difference can be as much as 20 dB, which represents a 10-fold decrease in signal strength if the wrong antenna is used.

DECIBELS (dB)

In the section above the term **decibel** (symbol 'dB') was introduced. The decibel is a unit of measure of the ratio of two signals: two voltages, two currents, or two powers. The equations for decibels take the logarithm of the ratio, and multiply it by a constant (10 for powers and 20 for voltages or currents). The use of decibel notation makes it possible to use **ratios**, such as found in gains and losses in electronic circuits, but use only addition and subtraction arithmetic. It is not necessary to be able to calculate decibels, but you should know that +dB represents a gain, and −dB represents a loss. The term '0 dB' means that the ratio of the two signals is 1:1 (neither gain nor loss). Some common ratios encountered in radio work include those listed in Table 2.1.

You can see that doubling a signal strength results in a +3 dB gain, while halving it produces a −3 dB loss. To put these figures into perspective, most S-meters on receivers use a scaling factor of 6 dB per S-unit (some use 3 dB per S-unit). Receiver designers tell us that a signal-to-noise ratio of 10 dB is necessary for 'comfortable listening,' while a signal-to-noise ratio of 3 dB is

TABLE 2.1

Ratio	Power (dB)	Voltage (dB)
1:1	0	0
2:1	+3	+6
1:2	−3	−6
10:1	+10	+20
1:10	−10	−20

needed for barely perceptible but reliable communication for a listener who tries hard to hear what is being said.

LAW OF RECIPROCITY

Radio antennas obey a kind of **law of reciprocity**, i.e. they work the same on transmit as they do on receive. If an antenna has a certain gain and directivity on transmit, then that exact same pattern is seen in the receive mode. Similarly, the feedpoint impedance, element lengths, spacings, and other issues are the same for both modes. An implication of this law is that receiver owners are able to translate the theory from discussions of transmitting antennas to their own needs (and vice versa).

Reciprocity does not necessarily mean that the same antennas are the best selection for both transmit and receive. For example, the use of gain on a transmit antenna is to increase the apparent signal power level at a distant point in a particular direction. Alternatively, some licensing authorities use antenna directivity to protect the coverage areas of relatively nearby stations that share the same or adjacent frequencies. To the receiver operator, there may be a reason to want the gain of the antenna to boost the received signal power to a useful level. There is, however, often a powerful argument for aiming an antenna such that the main sensitivity is not in the direction of the desired station. Instead, the receiver antenna owner may wish to position a null, i.e. the least sensitive aspect of the antenna, in the direction of an offending station in order to reduce its effect. The issue is, after all is said and done, the signal-to-noise ratio.

Another restriction is that there are several antennas that are fit for receive use, especially those for difficult installation situations, but are either technically unsuited or unsafe for transmitters except at the lowest of power levels. The issue might be impedance, VSWR, voltage arcing, or some other undesirable factor that occurs in transmit situations (even at moderate power levels such as 50–100 W).

ANTENNA TYPES

Most antennas fall into either of two broad categories: **Marconi** or **Hertzian**. The Marconi antennas (Figure 2.10) are considered unbalanced with respect to ground because one side of the signal source (or receiver input load) is grounded. The Marconi antenna can be either vertical (Figure 2.10A) or at some angle (Figure 2.10B), including horizontal. The name derives from the types of antenna used by Guglielmo Marconi in his early radio experiments. In his famous 1903 transatlantic communication, ol' 'Gug' used a single wire tethered to a kite aloft above the Newfoundland coast.

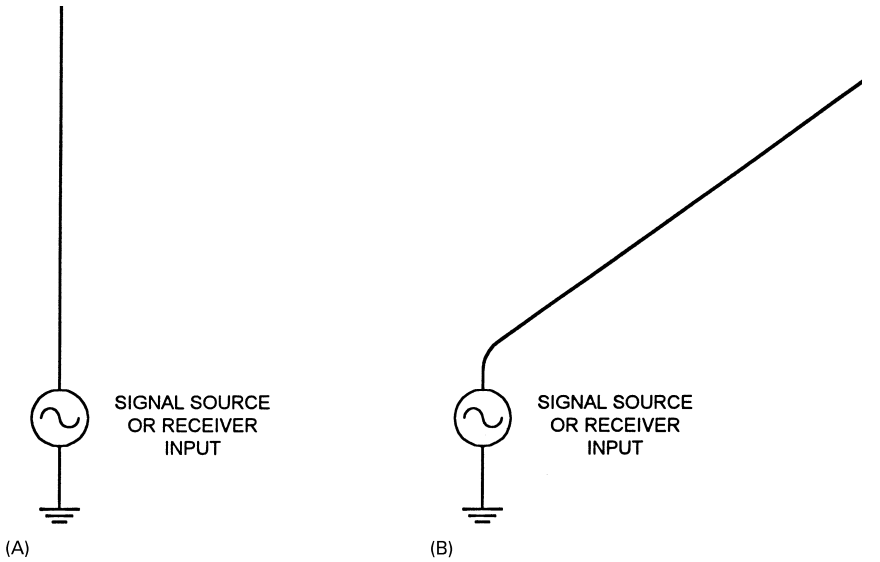

FIGURE 2.10

The Hertzian antennas (Figure 2.11) are balanced with respect to the ground, i.e. neither side of the oscillator or receiver load is grounded. Dipoles fall into this category. Both Marconi and Hertzian antennas can be either vertically or horizontally polarized. However, most Marconi antennas are designed for vertical polarization and most Hertzian antennas for horizontal polarization. The long wire and vertical dipoles are obvious exceptions to that rule, however.

RECEIVER–ANTENNA INTERACTIONS

The antenna and the receiver (or the antenna and transmitter on the other end) form a system that must be used together. Either alone is not too useful. Figure 2.12 shows an antenna connected to a receiver through a transmission line. For our practical purpose here, the receiver looks to the

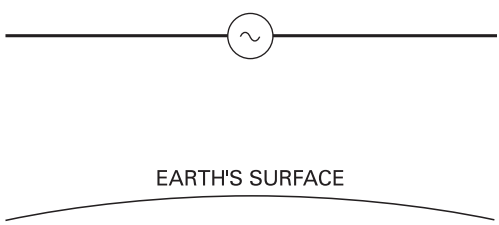

FIGURE 2.11

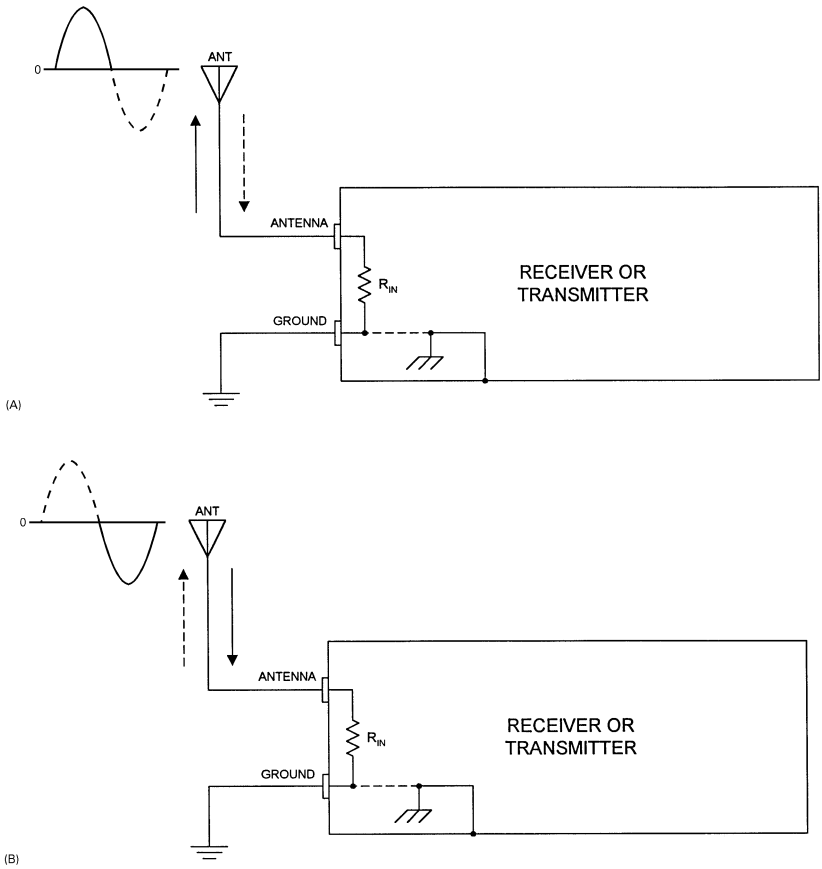

FIGURE 2.12

antenna and transmission line like a load resistor, R_{IN}. On the positive half-cycle (Figure 2.12A), the passing wave creates a current in the antenna–receiver system that flows in one direction (shown here as 'up'). When the oscillation reverses and becomes negative, the direction of current flow in the antenna–receiver reverses (Figure 2.12B). This is the mechanism by which the oscillating electromagnetic wave reproduces a signal in the input of the receiver – the signal that is then amplified and demodulated to recover whatever passes for 'intelligence' riding on the signal.

STANDING WAVE RATIO

The issue of the **standing wave ratio** (SWR) is of constant interest to radio enthusiasts. Some of the heat and smoke on this matter is well justified. In other cases, the perceived problems are not real.

Figure 2.13 shows how the SWR comes into play in an antenna system. In Figure 2.13A, a single cycle of a signal is launched down a transmission line (it is called the '**incident**' or '**forward**' wave). When it reaches the end of the line, if it is not totally absorbed by a load resistor or antenna, then it (or part of it) will be reflected back toward the source. This **reflected** wave is shown in Figure 2.13B. The incident and reflected waves are both examples of **travelling waves**. The reflected wave represents power that is lost, and can cause other problems as well.

The situation in Figures 2.13A and 2.13B represent a single-cycle pulse launched down a transmission line. In a real radio system, the oscillations of the incident wave are constant (Figure 2.13C). When this situation occurs, then the reflected waves will interfere with following incident waves. At any given point, the amplitude of the wave is the algebraic sum of the interfering incident and reflected signals. The resultant caused by the interference of the incident and reflected waves is called a **standing wave**.

Figure 2.14 shows what happens when continuous incident and reflected waves coexist on the same transmission line. In the case of Figure 2.14A, the two waves coincide, with the resultant as shown. The waves begin to move

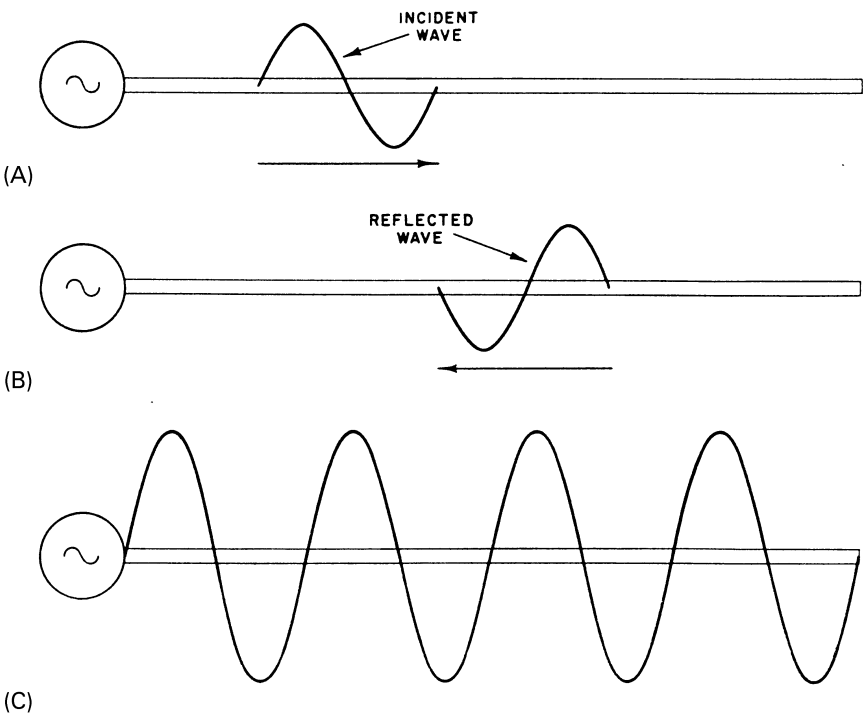

FIGURE 2.13

(G)

FIGURE 2.14 *(continued)*

apart in opposite directions in Figure 2.14B, which causes the overall amplitude of the standing wave to decrease, but the location of the maximum and minimum points remain stable. The condition of 180° out of phase between the two traveling waves results in a zero-amplitude standing wave, as shown in Figure 2.14C. No current flows in this case. As the waves continue to move apart, the standing wave reappears, as shown in Figure 2.14D. The final case, Figure 2.14E, is the case with the traveling waves in-phase with each other (0° difference). Notice that the standing wave in Figure 2.14E is the same amplitude as that of Figure 2.14A, but is 180° out of phase with it.

Figure 2.14F shows the voltage along a transmission line when a VSWR higher than 1:1 is present. The antenna or load end is on the left, and the lengths along the transmission line are plotted in terms of wavelength. In the

situation shown, the voltage is a minimum at the antenna end (marked '0'). It rises to a peak or 'antinode' at a quarter wavelength, and then drops back to a minimum ('node') at the half-wavelength ($\lambda/2$) point. The voltage then rises again to a peak at $3\lambda/4$, falling back to minimum at 1λ. The current rises and falls in a similar manner, but the nodes and antinodes are offset from the voltage by 90° (quarter wavelength).

Note that the voltage is at a minimum and the current at a maximum at the same points that are integer multiples of a half wavelength. This situation has the effect of making it advisable to measure the VSWR at the transmitter end only when integer multiples of an electrical half wavelength of transmission line (note: the most valid measurement is made at the interface of the transmission line and antenna feedpoint).

The plot shown in Figure 2.14G is the same line system under the situation where the antenna impedance and transmission line impedance are matched. For obvious reasons, this line is said to be 'flat.'

Measures of SWR

There are several different methods for measuring the SWR of an antenna transmission line system. For example, one could measure the incident and reflected signal voltages along the line, producing a result of $\text{VSWR} = (V_\text{i} + V_\text{r})/(V_\text{i} - V_\text{r})$. The method of Figures 2.14F and 2.14G can be used by comparing the maximum and minimum voltages: $\text{VSWR} = V_\text{MAX}/V_\text{MIN}$. We can also measure the forward and reverse power levels to find the VSWR. A simple way to predict the VSWR is to compare the antenna feedpoint resistive impedance (Z_L) to the transmission line characteristic impedance (Z_0). The value of the VSWR is found from either

$$\text{VSWR} = \frac{Z_0}{Z_\text{L}} \qquad (Z_0 > Z_\text{L})$$

or

$$\text{VSWR} = \frac{Z_\text{L}}{Z_0} \qquad (Z_\text{L} > Z_0)$$

If, for example, we measure the antenna feedpoint impedance as being 25 ohms, and the antenna transmission line is 52 ohm coaxial cable, then the $\text{VSWR} = 52/25 = 2.08{:}1$.

We can find the resonant frequency of an antenna by finding the frequency at which the VSWR is a minimum. But that point may not be a VSWR of 1:1 unless the resistive component of the antenna feedpoint impedance is the same as the transmission line impedance, and the complex portion of the impedance is zero. To create this situation one might need an impedance matching device (see Chapter 12).

AN OLD MYTH REVIVED?

There are a number of myths that are widely held among radio communications hobbyists – and amateur radio is no less infested with some of these myths than others (CB, for example). Twenty-five years ago I worked in a CB shop in Virginia, and we kept hearing one old saw over and over again: you can 'cut your coax to reduce the VSWR to 1' (actually, they meant '1:1' but routinely called it '1'). Hoards of CBers have 'cut the coax' and watched the VSWR reduce to 1:1, so they cannot be talked out of the error. I even know of one shop that kept 30 cm lengths of coaxial cable, with connectors on both ends, so they could insert them into the line at the transmitter in order to find the correct length that would reduce the VSWR to 1:1. What actually happens in that case is a measurement artifact that makes it appear to be true.

Of course, hams are superior to CBers and so do not believe that error, right? I would like to think so; but having been in both the CB and the amateur worlds, and 'Elmered' (mentored) more than a few CBers studying for amateur licenses, I have to admit that at least as many amateurs believe the 'cut the coax' error as CBers (sorry, fellows, but that's my observation).

The only really proper way to reduce the VSWR to 1:1 is to tune the antenna to resonance and then match the impedance. For a center-fed half-wavelength dipole, or a bottom-fed quarter-wavelength vertical, the proper way to resonate the antenna is to adjust its length to the correct point. The formulas in the books and magazines only give approximate lengths – the real length is found from experimentation on the particular antenna after it is installed. Even commercial antennas are adjusted this way. On certain CB mobile antennas, for example, this trick is done by raising (or lowering) the radiator while watching the VSWR meter. On amateur antennas similar tuning procedures are used.

Even when the resonant point is found, the feedpoint impedance may not be a good match to the transmission line. A VSWR will result in that case. The impedance matching should be done between the far end of the transmission line (i.e. away from the receiver or rig) at the feedpoint of the antenna. Antenna tuners intended for strictly coaxial cable are little more than line flatteners. They do not really 'tune' the antenna, but rather they reduce the VSWR looking into the transmission line so that the transmitter will work properly. If the antenna tuner is not a high-pass filter (as some are), then it will also provide some harmonic attenuation.

An approach used by many amateurs (including myself) is to connect an antenna-matching unit (tuner) at the output of the transmitter. For my Kenwood TS-430, I use either a Heath SA-2060A or an MFJ Differential Tuner to 'tune-out' the VSWR presented by my Hustler 4BTV and 23 m of coaxial cable. But I do not even pretend to be tuning the antenna. The

TS-430 is a solid-state rig, and the finals are, therefore, not terribly tolerant of VSWR, and will shut down with a high VSWR. The purpose of the antenna tuner is to reduce the VSWR seen by the transmitter – ignoring the actual antenna mismatch on the roof. The tuner also serves to reduce harmonics further, thereby helping to prevent television interference.

The best form of antenna tuner is one that both reduces the VSWR (for the benefit of the transmitter), and also resonates to the antenna frequency, preventing harmonics from getting out (a little secret is that many 'line flattener' antenna tuning units are actually variable high-pass filters, and must be used with a low-pass filter ahead of them if spurious signals are to be kept in abeyance).

Should you even worry about VSWR on a system? Or, more correctly stated, given that a 1:1 VSWR often requires a herculean effort to achieve, at what point do you declare the battle won and send the troops home? Some of the issues are:

- Transmitter heating of the transmission line due to power losses.
- Reduction of power from solid-state transmitters due to SWR shutdown circuitry.
- At kilowatt levels there may be excessive radio frequency voltage at nodes, which could lead to transmission line shorting.
- Loss of receiver sensitivity. The feedline loss is added directly to the receiver noise figure, so may degrade the matched noise figure of the receiver. This problem is especially severe in the VHF/UHF scanner bands.

Where these problems result in unacceptable performance, work hard to match the antenna to the feedline, and the feedline to the transmitter or receiver. As one of my correspondents said: 'The question then is to what extent does the problem impair the actually ability to use the receiver or transmitter successfully?' The same reader provided the guidelines below:

(1) The actual SWR on a feedline is 1:1 only if the load (e.g. an antenna) connected to the line is equal to the characteristic impedance of the line. Adjusting an antenna to resonance will improve the SWR only if the impedance of the antenna at resonance is closer to the impedance of the feedline than before it was adjusted. If the impedance of the antenna at resonance is not equal to the impedance of the feedline, you will never get the SWR down to 1:1.

(2) The only possible places to measure the SWR with consistent accuracy are:

(a) at the load

(b) at a distance of 0.5 electrical wavelength (accounting for the velocity factor of the line), or integer multiples thereof, from the load.

The latter is true because a half-wavelength long piece of feedline 'repeats' the impedance of whatever is connected to its far end; it is almost as if you are measuring right up at the feedpoint. As a consequence, many professional antenna installers go to pains to make the transmission line $\lambda/2$ or an integer multiple of $\lambda/2$. The VSWR and impedance looking into the line will reflect the situation at the feedpoint. Be aware that the velocity factor of the transmission line reduces the physical length required to make an electrical half wavelength.

(3) An easy way to check if your SWR measurements are being accurately made is as follows: Add a piece ($\lambda/8$ to $\lambda/4$ wavelength) of *identical* line to your feedline. Repeat the SWR measurement. If it is not the same, your SWR measurement is not accurate, i.e. you are not measuring the actual SWR.

(4) Know that a few things can upset SWR measurements, e.g. currents flowing on the outside of a coaxial feedline (a common situation). This can be caused by not using a BALUN when feeding a balanced antenna (e.g. a symmetric dipole) with an unbalanced (coaxial) feedline. It can also be induced by antenna currents onto a nearby coaxial feedline.

ANTENNA GAIN, DIRECTIVITY, AND RADIATION PATTERNS

Antennas do not radiate or receive uniformingly in all directions (and, indeed, you usually do not want them to!). The interrelated concepts of **antenna gain** and **directivity** are of much concern to antenna builders. Gain refers to the fact that certain antennas cause a signal to seem to have more power than it actually can claim. The gain of the antenna can be expressed as either a multiple (e.g. a twofold increase in apparent power) or in decibel notation (e.g. a 3 dB increase). Both methods of expressing gain reflect the fact that a gain antenna seems to produce a signal that is stronger than the signal produced by some comparison antenna (e.g. a dipole). The apparent power produced by the antenna and transmitter combination is called the **effective radiated power** (ERP), and is the product of the transmitter power and the antenna gain. For example, if the antenna gain is 7 dB, the power is increased by a factor of five times. The ERP of a 100 W transmitter is therefore $5 \times 100\,\text{W} = 500\,\text{W}$.

On a receive-only antenna, the signal picked up by a gain antenna is louder than the same signal picked up on a non-gain antenna or the comparison antenna. Because of reciprocity, the gain is the same for both receive and transmit.

Directivity refers to the fact that the radiation or reception direction is not constant. Certain directions are favored and others rejected. Indeed, this is how the antenna gets gain. After all, if there is an apparent increase in the

signal power, there must be some phenomenon to account for it – after all, antennas do not produce power. Figure 2.15A shows how the gain and directivity are formed. Consider an **isotropic radiator** source located at point 'A' in Figure 2.15A. An isotropic radiator is a perfectly spherical

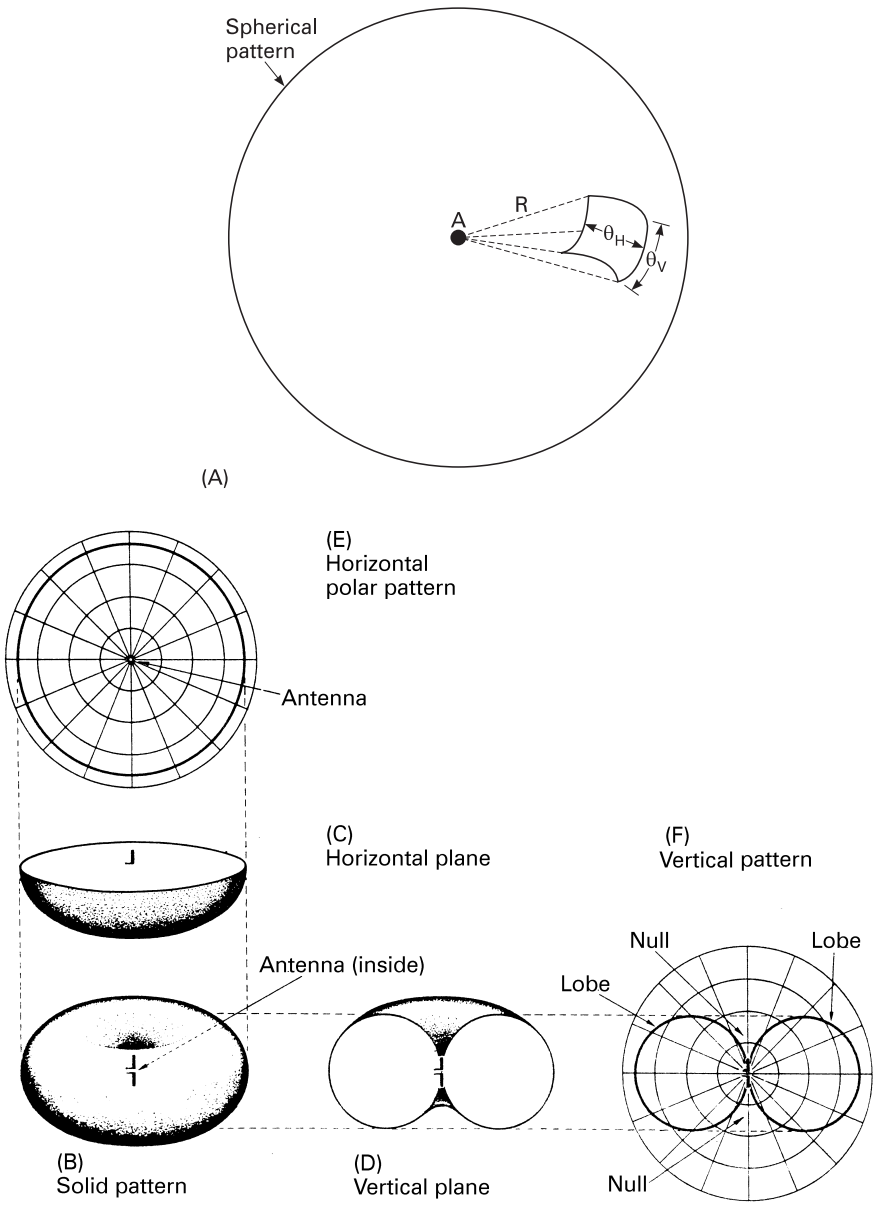

FIGURE 2.15

point source. The signal radiates outward from it in a spherical pattern. At some distance R we can examine the surface of the sphere. The entire output power of the transmitter is uniformly distributed over the entire surface of the sphere. But if the antenna is directive, then all of the power is focussed onto a small area of the sphere with a vertical angle of θ_V and a horizontal area of θ_H. The same amount of energy exists, but now it is focussed onto a smaller area, which makes it appear as if the actual power level was a lot higher in that direction.

The **antenna pattern** is a graphical way of showing the relative radiation in different directions (i.e. directivity). The most commonly seen pattern is the **azimuthal** or **polar** plot. That pattern is measured in the horizontal plane at all angles around the antenna, and is plotted graphically as if seen from above. It is a 'bird's eye view' of the antenna radiation characteristic. But antenna radiation patterns are actually three-dimensional, and the azimuthal plot is merely a slice of that three-dimensional pattern, as seen from but one perspective.

Figures 2.15B through 2.15F show how antenna patterns are developed. The antenna in this case is a vertically polarized Hertzian radiator such as a half-wavelength dipole. It radiates poorly off the ends, and very well at angles perpendicular to the wire. The solid-pattern of Figure 2.15B shows the three-dimensional view of what the radiation looks like. To find the azimuthal and elevation patterns for this antenna, we take slices out of the solid (Figures 2.15C and 2.15D), and plot the results (Figures 2.15E and 2.15F). Because the radiator is vertical (and perfect, I might add), it radiates equally well in all horizontal directions (see Figure 2.15E), so the azimuthal or horizontal plot is termed **omnidirectional**. The elevation or vertical plane view (Figure 2.15F) has to take into account the minima found off the ends of the radiator, so plots as a figure '8.'

If the vertical radiator of Figures 2.15B–2.15F is rotated 90° to form a horizontal dipole, then the radiation patterns remain the same, but are reversed. The omnidirectional pattern of Figure 2.15E becomes the elevation or vertical extent, while the figure '8' pattern of Figure 2.15F is the horizontal or azimuthal extent.

The patterns of Figures 2.15B–2.15F make a rather bold and unwarranted assumption: the antenna is perfect and is installed somewhere in free space. Since most antennas are not in the zone midway between the Earth and Mars, one has to account for the effects of being close to the Earth's surface. Figure 2.16 shows the approximate patterns for horizontally polarized half-wavelength dipoles close to the ground. In Figure 2.16 we see the azimuthal pattern. It is the figure '8,' but is pinched a bit. Notice that the maxima are perpendicular to the wire, and the minima (or 'nulls') are off the ends. One use for this type of pattern is to position the antenna so that it

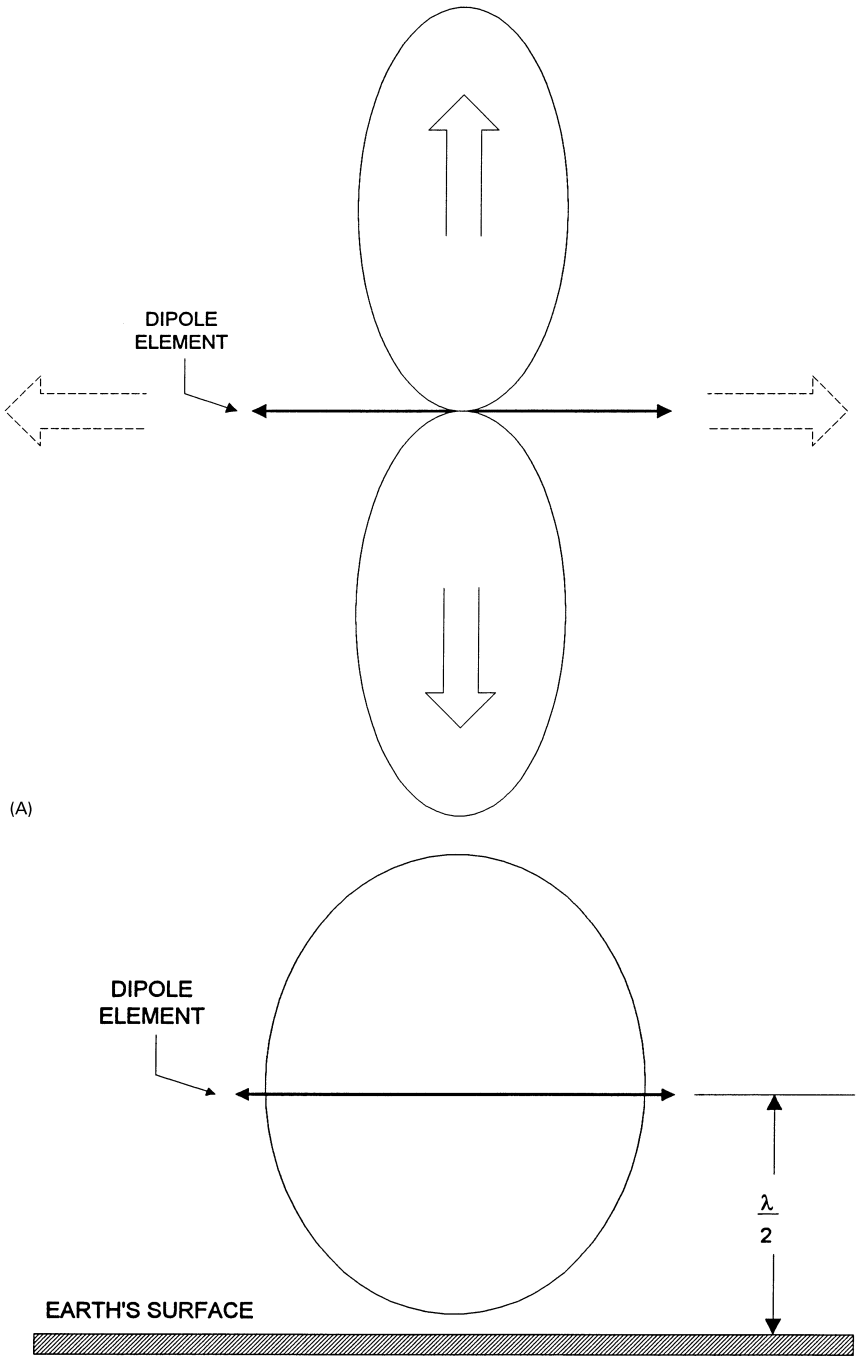

FIGURE 2.16

nulls out interfering signal or noise sources, making the overall signal-to-noise ratio higher – and increasing listenability.

Figure 2.16B shows the elevation extent. This view is taken from a site perpendicular to the wire, and is essentially looking into one end of the three-dimensional figure '8' pattern. In other words, the directivity, or maxima, is in and out of the page. In free space, one would expect this pattern to be omnidirectional. But close to the Earth's surface, reflections from the surface add to the pattern, causing the pinching effect apparent in Figure 2.16B. The shape shown is approximately that for a half wavelength above the ground. Other heights produce variants of this pattern.

The patterns shown in Figure 2.17 are for a vertically polarized Marconi radiator, such as a quarter-wavelength, bottom-fed vertical. The azimuthal pattern, as seen from above, is shown in Figure 2.17A. It is the omnidirectional pattern that one would expect. The elevation pattern in Figure 2.17B

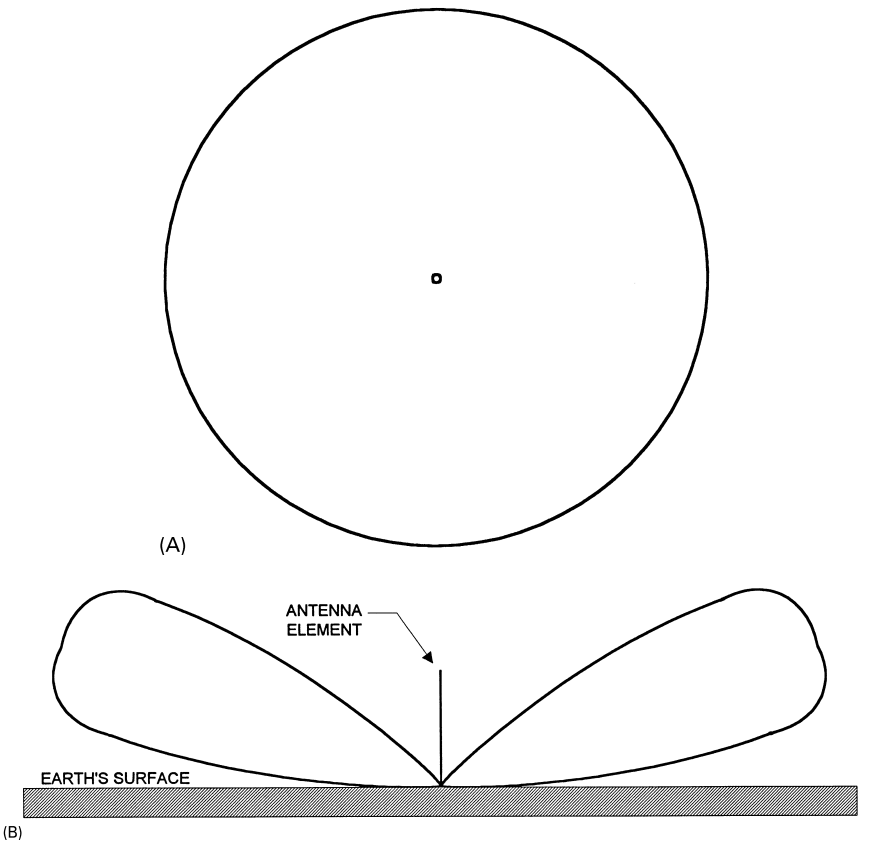

FIGURE 2.17

represents a vertical slice taken from the 'doughnut' seen earlier. Note that the lobes are elevated, rather than being exactly on the horizon. The angle of these lobes is the **angle of radiation**, and affects the distance that an antenna will transmit to or receive from. A low angle of radiation is usually prescribed for long-distance 'DX,' while a high angle of radiation produces skip to nearer regions.

Figure 2.18 shows the conventions for specifying antenna patterns. The antenna is a dipole, with both relative electric field strength and relative powers plotted (both types of plot are done). The 0–270° line is along the length of the dipole, while the 90–180° line is perpendicular to the dipole. The **beamwidth** of the antenna, which is specified in degrees, is measured as the angle between the **half-power points**, i.e. the points where the voltage field drops off to 70.7% of the maximum (along the 90° line), or to the 0.5 power point. These points are also called the '−3 dB' points. Recall that −3 dB represents a power ratio of 1:2.

SOME ANTENNA CONSTRUCTION HINTS

This section will help you think up some good ideas on how to erect the antenna. First, though, let us talk a little bit about antenna safety. It is difficult to say too much about this topic. Indeed, I mention it elsewhere in this book as well as here. Wherever it seems prudent, I warn readers that

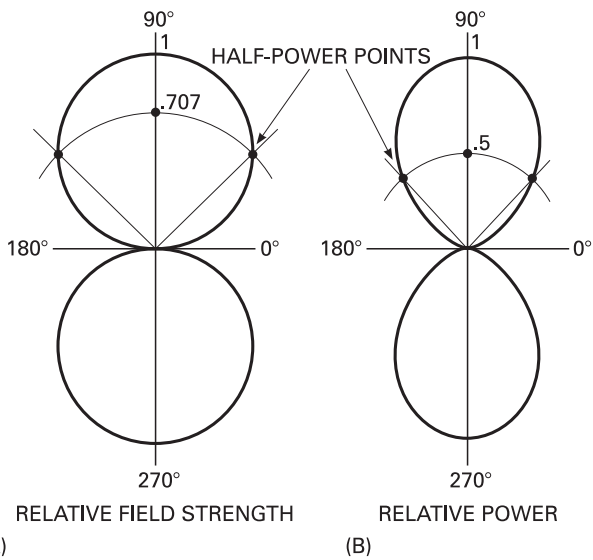

FIGURE 2.18

antenna erection can be dangerous if you do not follow certain precautions. Do it right, and the risk is mitigated and the job can be quite safe.

Safety first!

Before dealing with the radio and performance issues, let us first deal with safety matters – you do not want to be hurt either during installation, or during the next wind storm. Two problems present themselves: reliable mechanical installation and electrical safety.

Electrical safety note. Every year we read sad news in the magazines of a colleague being electrocuted while installing, or working on, an antenna. In all of these tragic cases, the antenna somehow came into contact with the electrical power lines. Keep in mind one dictum and make it an absolute:

There is never a time or situation when it is safe to let an antenna contact the electrical power lines! None. Ever. BELIEVE THIS NO MATTER WHAT ANYONE SAYS TO THE CONTRARY.

This advice includes dipoles and long wires 'thrown over' supposedly insulated power mains lines, as well as antennas built from aluminum tubing. The excuse that the lines are insulated is nonsense. Old insulation crumbles on contact with even a thin wire antenna. Do not do it! The operant word is **never**!

Consider a typical scenario involving a four-band trap vertical antenna made of tubing. It will be 5–8 m tall (judging from adverts in magazines), and will be mounted on a roof, or mast, 4–10 m off the ground. At my home in Virginia, a 7.6 m tall trap vertical is installed atop a 4.6 m telescoping television antenna mast. The total height above ground is the sum of the two heights: 7.6 m + 4.6 m = 12.2 m. The tip of the vertical is 12.2 m above the ground. I had to select a location, on the side of my house, at which a 12.2 m aluminum pole could fall safely. Although that requirement limited the selection of locations for the antenna, neither my father-in-law (who helped install the thing) nor myself was injured during the work session. Neither will a wind storm cause a shorted or downed power line if that antenna falls over.

In some jurisdictions, there might be legal limitations on antenna location. For example, some local governments in the USA have a requirement that the antenna be able to fall over and land entirely on your own property. Before installing the antenna, check local building codes.

When installing a vertical, especially one that is not ground mounted, make sure that you have help. It takes at least two people to safely install the standard HF vertical antenna, and more may be needed for especially large models. If you are alone, then go and find some friends to lend an arm or two. Wrenched backs, smashed antenna (and house parts), and other

calamities simply do not happen as often to a well-organized work party that has a sufficient number to do the job safely.

Mechanical integrity

The second issue in installing antennas is old-fashioned mechanical integrity. Two problems are seen. First, you must comply with local building regulations and inspections. Even though the courts in the USA seem to forbid local governments from prohibiting amateur radio activity (on grounds that it is Federal prerogative), local governments in the USA and eslewhere have a justifiable interest, and absolute right, to impose reasonable engineering standards on the mechanical installation of radio antennas. The second issue is that it is in your own best interest to make the installation as good as possible. View local regulations as the *minimum acceptable standard*, not the maximum; go one better. In other words, build the antenna installation like a brick outhouse.

Both of these mechanical integrity issues become extremely important if a problem develops. For example, suppose a wind or snow storm wrecks the antenna, plus a part of your house. The insurance company will not pay out (in most cases) if your local government requires inspections and you failed to get them done. Make sure the mechanical and/or electrical inspector (as required by US law) leaves a certificate or receipt proving that the final inspection was done. It could come in handy when disputing with the insurance company over damage.

A quality installation starts with the selection of good hardware for the installation. Any radio/television parts distributor who sells television antenna hardware will have what you need. I used Radio Shack stand-off brackets, ground pin, and a 5.8 m telescoping mast. Wherever you buy, select the best-quality, strongest material that you can find. Opt for steel masts and brackets over aluminum, no matter what the salesperson behind the counter tells you. Keep in mind that, although salespeople can be knowledgeable and helpful, you, not they, are responsible for the integrity of the installation. In my own case, I found that the 5.8 m mast was considerably sturdier at 4.6 m than when fully up, so I opted to use less than the full length because the installation is unguyed. Because I have never trusted the little cotter pin method of securing the mast at the slip-up height, I drilled a single hole through both bottom and slip-up segments (which telescope together), and secured the antenna mast with a 8 mm stainless steel bolt. The bolt was 'double nutted' in order to ensure that it did not come loose over time.

The television mast is set on a ground mounting pin/plate that is set into a 76 cm deep (local frost line regulations required only 71 cm) fencepost hole filled with concrete. The top end of the mast was secured to the roof over-

hang of the house (see Figure 2.23). That overhang was beefed up with 5×20 cm kiln-dried lumber that was bolted between two, 60 cm center, roof rafters. I felt it necessary to do that because the roof is only plywood, and the gutter guard is only 2.5×20 cm lumber (and is old), and the soffits are aluminum. There was not enough strength to support a 12 m lever arm, whipping around in a 35 knot wind.

Wind can be a terrible force, especially when acting on the 'sail area' of the antenna through a 7.5–12 m lever arm. A shabby installation will tear apart in wind, causing the antenna to be damaged, damage to the house, and destruction of the installation. That is why I recommend 'brick outhouse' construction methods. Over the 33 years I have been in amateur radio, I have seen a lot of verticals toppled over. Except for a few shabby models that were so poorly built that they should not have been on the market in the first place, all of these failed installations were caused by either poor installation design or poor-quality materials.

Antenna erection methods

In this section we will look at some methods for erecting wire antennas. It is recommended that you also consult Chapter 3 to find out how to make connections to wire antennas and the usual fittings (end insulators, center insulators, BALUN transformers, etc.). Chapter 3 also deals with the type of wire used for antenna construction. The ideas in this chapter are not the be-all-end-all discussion, but rather points of departure of representative methods. Your own innate intelligence can figure out other methods suitable for your own situation (keeping safety foremost in your plans).

Figure 2.19 shows one of the most basic methods for installing a wire antenna. A mast is installed on the roof of the house, or on the side of the building close to the roof. Alternatively, the mast could be replaced by some

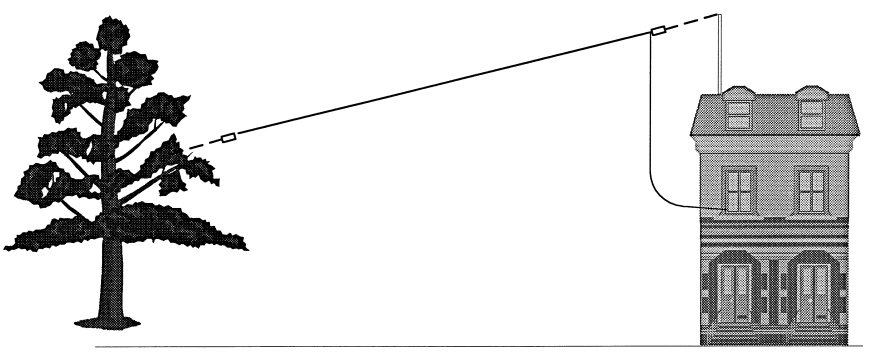

FIGURE 2.19

other support on the house. The other support is a convenient nearby tree. It could also be another building or a mast erected on the ground. The antenna is supported between two end insulators, that are in turn supported by ropes connected to the mast and the tree. For a simple random length Marconi antenna, as shown here, the direction of the wire can be up, down, or horizontal, depending on the convenience of the situation (horizontal is preferred but not always easily attained). The down-lead to the receiver or antenna tuner is run through a convenient window. There are special straps and fittings for making the connection under the window (see your radio dealer).

The installation shown in Figure 2.20 is a half-wavelength dipole, although it could represent a variety of doublet antennas. As with the previous case, the supports can be masts, a building, or a convenient tree. The installation is very much like that in Figure 2.19. The goal in making this installation is to make the antenna horizontal, with the feed-line coming away from the antenna center at a right angle for as far as is practical.

The installation in Figure 2.21 is for a dipole, but it must be a small dipole (either inductively loaded or for a high frequency), or built over a very wide roof. Both end supports are on the roof, or on the walls at either end of the roof. The coaxial cable comes away at a right angle, and then passes through a window. A vertically polarized dipole is shown in Figure 2.22.

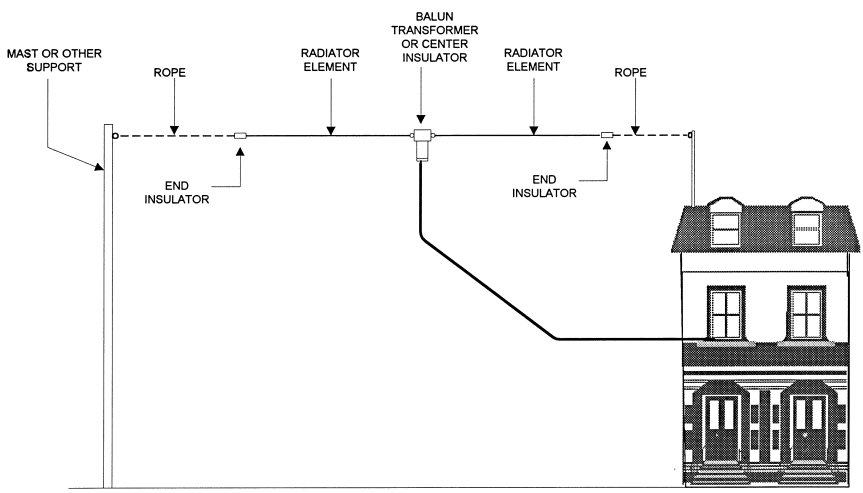

FIGURE 2.20

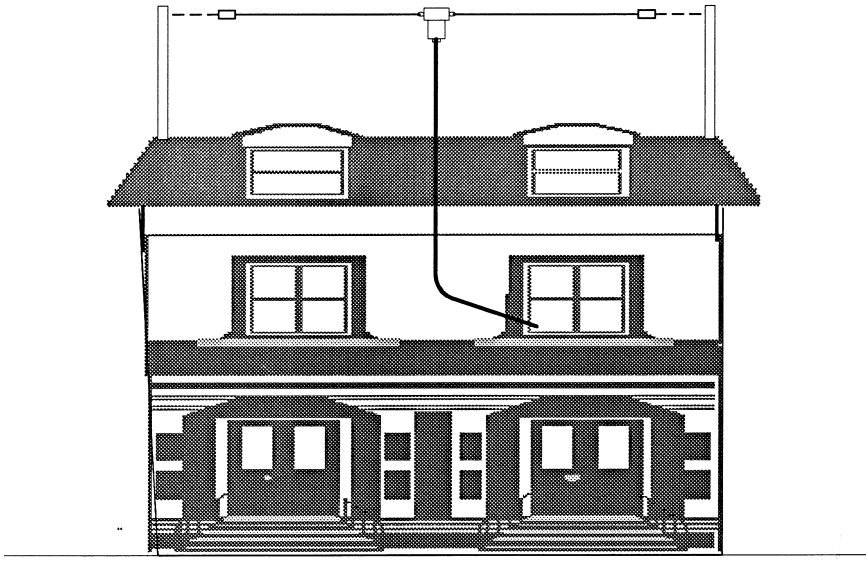

FIGURE 2.21

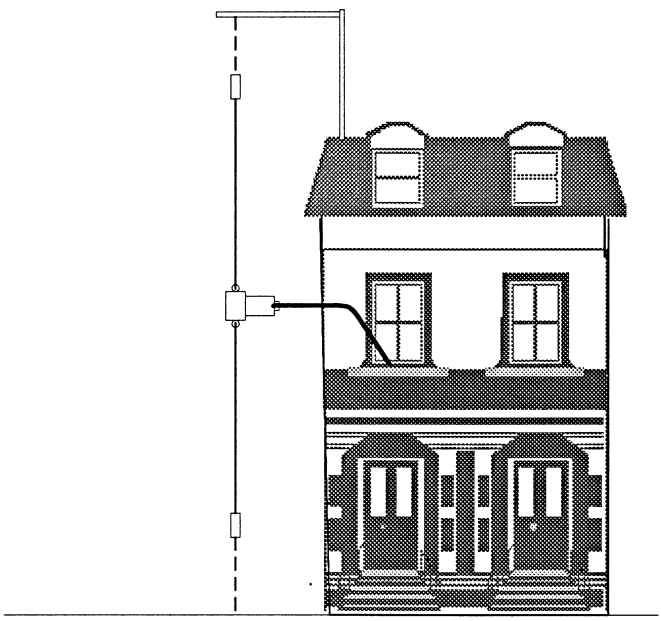

FIGURE 2.22

Figures 2.23A and 2.23B show methods for installing quad loops and delta loops, respectively. As above, the end supports can be a tree, a mast, or a building. It is necessary to support both the top and bottom of loops. The weight of the BALUN transformer and coaxial cable is not sufficient to keep the antenna from whipping around in the wind, and possibly doing some damage to either itself or other structures (not to mention the odd passerby). The bottom support can be either separate ropes to the end supports (Figure

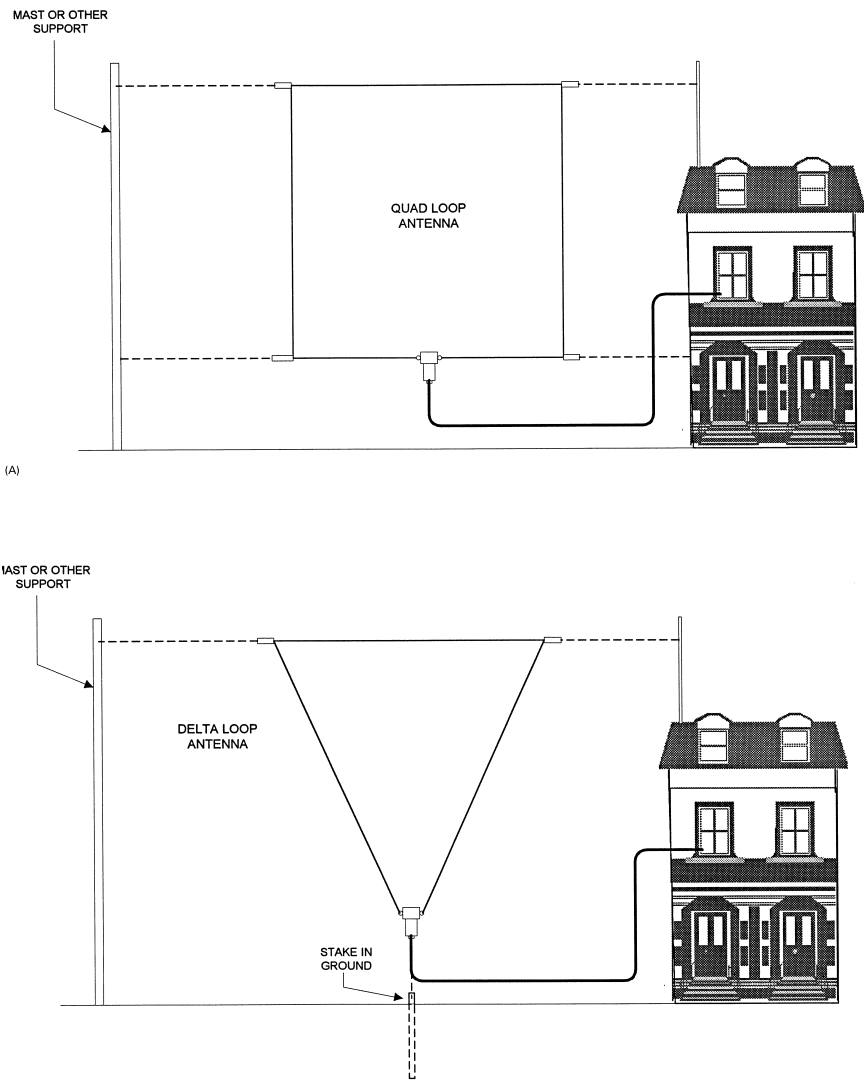

FIGURE 2.23

2.23A), or to a stake in the ground (Figure 2.23B). Make sure that the stake is secure against pulling out under the stress of wind blowing against the sail area of the antenna.

Now, let us go to Chapter 3 to talk about wire and connections.

CHAPTER 3

Wire, connection, grounds, and all that

In this chapter we will take a look at the types of wire useful for antenna elements, the different types of transmission lines, and grounding. The wire used in an antenna project can make or break the results, especially the reliability of the project over time. Antennas, especially outdoor antennas, are exposed to a lot of stress and environmental factors that tend to deteriorate both the performance and life expectancy.

TYPES OF WIRE

There are basically two types of wire used for the radiating element and other parts of antennas: **solid** (Figure 3.1A) and **stranded** (Figure 3.1B). The solid type of wire is made of a single thick strand of copper or copper alloy. Pure copper is rarely used because of both cost and strength problems, while aluminum is almost never used because it does not take solder without special, high-cost, industrial equipment. Solid wire is extruded from a single piece of copper. This is the type of wire used most often in household electrical wiring. In its smaller sizes, it is also the type of wire most commonly used as hook-up wire in electronic construction projects.

The stranded form of wire is made of two or more (sometimes many more) lengths of solid wire twisted together (Figure 3.1B). The number of strands used to make the wire sets the flexibility of the wire. Coarse stranded wire has fewer strands, and is less flexible than wire of the same overall diameter that is made up of many more strands of finer wire.

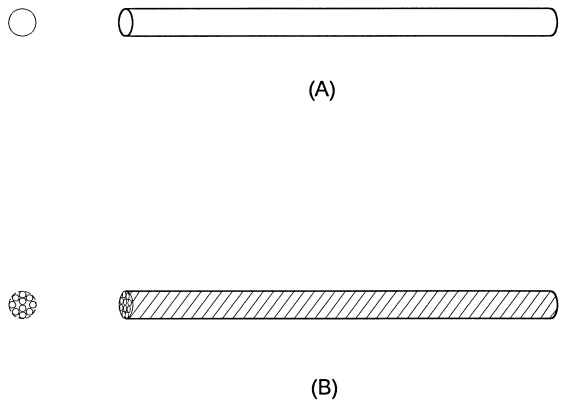

FIGURE 3.1

Antennas should normally be built with stranded wire. The reason is that the stranded wire stands up better to the constant flexing an antenna experiences, especially in windy areas. All wire will begin to stretch because of both gravity and wind. Solid wire will stretch rather rapidly, and eventually come to a point where it is too thin at the strain point to hold its own weight – and will come tumbling down. Stranded wire, on the other hand, withstands the normal stresses and strains of antenna installations much better, and will stay up a lot longer. Stranded wire antennas may come tumbling down as well, but in general it takes a lot more time and effort for the stranded wire antenna to break, compared to the solid wire type.

WIRE SIZES

Both stranded and solid wire comes in certain standard sizes. The specifications for each size wire were set basically for their ability to carry certain standard loads of direct current or the 50/60 Hz alternating current (AC) used in power systems. Table 3.1 gives some of the standard wire sizes in the range normally used by antenna constructors. In most cases, it is a good idea to stick to sizes around AWG 14 (SWG 16) for antenna work. The larger sizes are expensive, and difficult to work (most antenna hardware assumes AWG 14 or SWG 16, unless otherwise marked). The smaller sizes, on the other hand, are nice to use but often provide poor reliability – they break easily. The trade off is to use wires, of whatever standard size, that are in the 1–2.2 mm diameter region.

TABLE 3.1

AWG (USA)	Diameter		Nearest SWG (UK)
	mil[a]	mm	
8	128.5	3.264	10
10	101.9	2.588	12
12	80.8	2.053	14
14	64.1	1.628	16
16	50.8	1.291	18
18	40.3	1.024	19
20	32.0	0.812	21
22	25.3	0.644	24

[a]1 mil $= \frac{1}{1000}$ inch.

COPPER-CLAD WIRE

Pure copper wire is not terribly good for radio antenna work because it is too soft to withstand the rigors of being outdoors, or supporting its own weight plus the weight of the fixtures and transmission lines used. As a result, one needs to find a better wire. Some people will use copper wires of harder alloys, but even that type of wire is not all that good. Others buy 'hard drawn' copper wire, and while it is better than straight electrical wiring copper wire it is not the best suited to antenna construction. The best wire for radio antennas is **copper-clad steel wire**, perhaps the most famous brand of which is Copperweld. This type of wire is made of a solid steel core coated with a copper layer. It looks like ordinary copper wire on the outside. The steel provides strength and thereby increases the reliability of the antenna installation. But steel is not a terribly good electrical conductor, so the manufacturer places a layer of copper over the outside of the wire.

The standard wire sold with the better antenna kits and by the better sources is copper-clad steel, stranded wire of AWG 14 (SWG 16) size. Each strand is copper-clad steel, and the strands are wound together to form the antenna wire.

The copper-clad wire is better for the purposes of strength, but there is a workability problem with it: copper-clad steel-core wire knots easily. If you get a knot or kink (even a minor bend) in it, that feature is always present from then on. Even if you attempt to straighten it out, it will not come anywhere near the original state. Although ordinary copper wire also possesses this attribute, it is not nearly as severe as with copper-clad steel-core wire, and can often be worked into a negligible size when it does occur. The trick is to make sure that the wire does not knot or kink during the installation process (and that can be a monumental task!).

One fair question regarding copper-clad steel-core wire concerns its resistivity. After all, any basic electrical text tells us that the cross-sectional area of the wire sets the current-carrying capacity. That is true for direct current (DC), and power line frequency AC, but only partially true for higher-frequency AC. Radio signals cause AC currents to be set up in the antenna wire, and because their frequency is so much higher than power line AC the currents flow only near the surface. The operating principle here is called the **skin effect**.

SKIN EFFECT

The skin effect refers to the fact that AC tends to flow on the surface of a conductor. While DC flows in the entire cross-section of the conductor, AC flows in a narrow band near the surface (Figure 3.2). Current density falls off exponentially from the surface of the conductor toward the center (inset to Figure 3.2). At the **critical depth** (δ), also called the **depth of penetration**, the current density is $1/\varepsilon$, or $1/2.718 = 0.368$, of the surface current density. The value of δ is a function of operating frequency, the permeability (μ) of the conductor, and the conductivity (s).

WIRE SIZE AND ANTENNA LENGTH

The size of the wire used to make an antenna affects its performance. For amateur radio operators, one concern is the current-carrying capacity. For normal amateur radio RF power levels, the AWG 14 wire size works well,

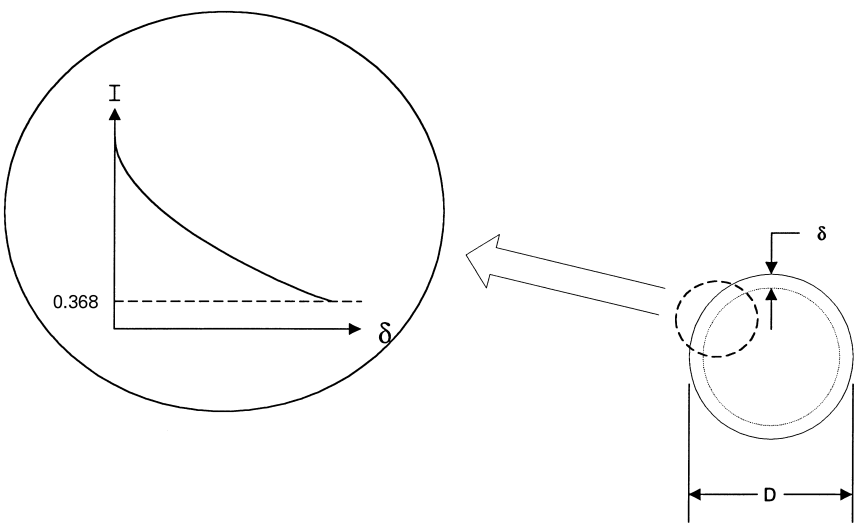

FIGURE 3.2

although those tempted to use smaller diameters with the higher legally permitted powers are forewarned: *it is not such a good idea.*

Both short-wave listeners and amateur radio operators need to be aware of another problem with the wire: the **length to diameter ratio**, or as it is sometimes specified, the **signal-wavelength-to-wire-diameter ratio**, determines the **velocity factor** (VF) of the conductor. The VF is defined as the velocity of the wave in the medium (i.e. wire) compared with the velocity in free space (which is c, the speed of light).

Figure 3.3 shows the velocity factor as a function of the L/D ratio. Wire antennas tend to have very high L/D ratios, especially at high frequencies. For example, a half wavelength at 10 MHz is 15 m (or 15 000 mm), while AWG 14 wire is about 1.63 mm diameter, resulting in $L/D = 15\,000/1.63 = 9200$. The VF of this L/D ratio is around 0.97–0.98. At very high/ultrahigh frequencies (VHF/UHF), on the other hand, the L/D ratio declines. At 150 MHz, the AWG 14 wire half-wavelength antenna has a physical length of 1500 m, making $L/D = 1500/1.63 = 920$. The VF drops to about 0.95–0.96. At 450 MHz, the L/D ratio drops to 200, and the VF runs to 0.94 or so.

So what? Why is the VF important in antenna design? Most of the antennas in this book are designed to be resonant, which means that the element lengths are related to wavelength: quarter wavelength ($\lambda/4$), half

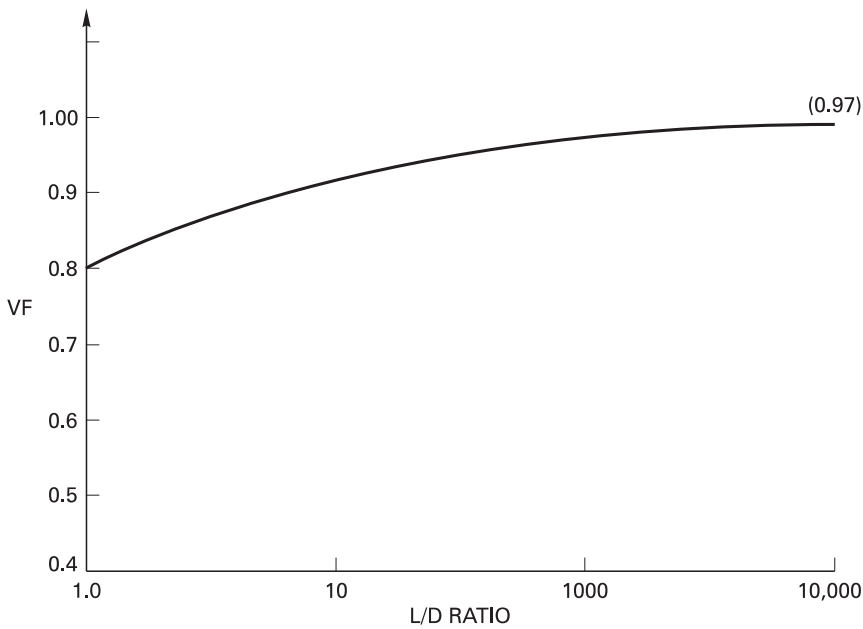

FIGURE 3.3

wavelength ($\lambda/2$), full wavelength (λ), and so forth. These lengths are required electrical lengths, and are only found in free space with perfect connectors. In antennas and transmission lines, the VF shortens the physical length required to achieve a specified electrical length. To find the physical length, multiply the required electrical length by the velocity factor. For example, a half wavelength in free space is defined as $150/F_{\mathrm{MHz}}$, while in a wire it is $(150 \times \mathrm{VF})/F_{\mathrm{MHz}}$. The result is that antenna elements must be shortened a small amount compared to the free space length. If you cut some antennas to a physical length that is comparable to the wavelength of the desired resonant frequency, then you will find that the actual resonant frequency is a tad low – meaning that the antenna is a little bit too long. This effect is almost negligible on the 80 m band, but becomes more substantial at 10 m and downright annoying at 2 m.

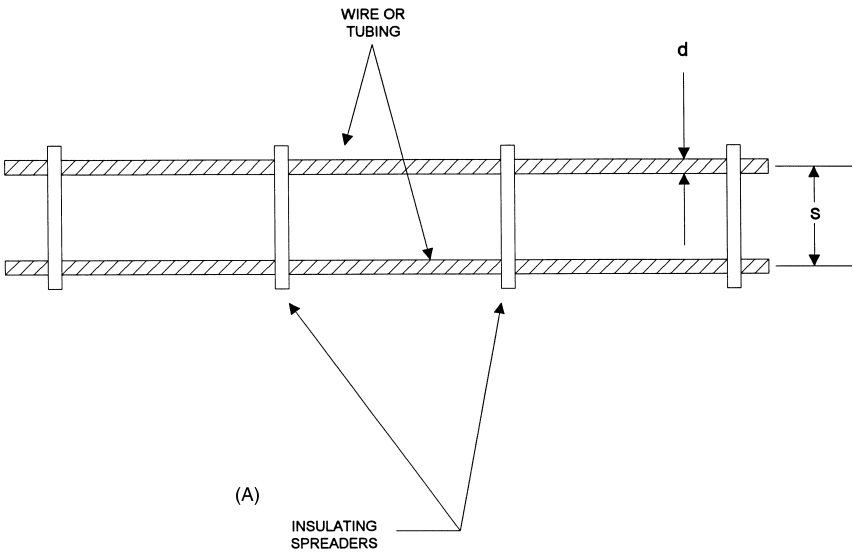
TRANSMISSION LINES

The wire between the antenna and either a transmitter or receiver is called the **transmission line**. Although it is tempting to think of the transmission line as a mere wire, it is actually equivalent to a complex inductor–capacitor network. The details of the transmission line network are a bit beyond the scope of this book, but can be found in antenna engineering textbooks for those who are interested. The main aspect of the transmission line network that you need to understand is that the line possesses a property called the **characteristic impedance** or **surge impedance**, which is symbolized by Z_0. The rigorous definition of Z_0 can get a bit involved, but it breaks down to one thing for most practical situations: Z_0 is the value of load impedance that will result in the maximum power transfer between the antenna and the transmission line, or between the receiver/rig and transmission line. The act of making these impedances equal to each other (a very desirable thing, as you will find out) is called **impedance matching**, and is covered in Chapter 11.

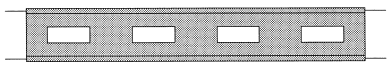
Transmission lines come in a bewildering variety of species, but there are only a few basic types: **parallel open lead**, **twin-lead**, and **coaxial cable** are the main types that we need to consider. Figure 3.4 shows all of these varieties.

Parallel open-wire line

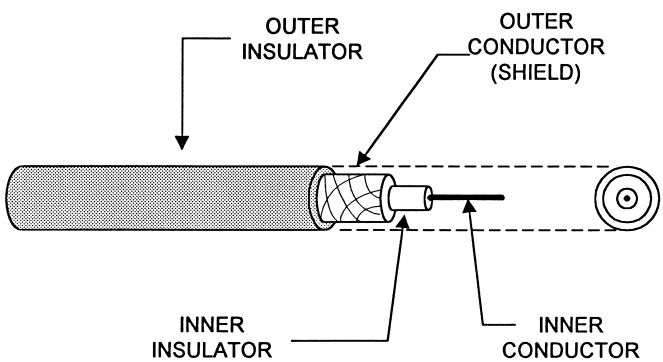
Parallel line is shown in Figure 3.4A. It consists of a pair of wires, run parallel to each other, and separated by a constant space. Insulating spacers (made of ceramic, nylon, or some other material) are used in practical parallel open line to keep the distance between the conductors constant. The characteristic impedance of open line is determined by the diameter (d) of the conductors and the spacing (s) between them. Typical values run from 300 to 1000 ohms. Although you can calculate the spacings needed



(B)



(C)



(D)

FIGURE 3.4

(and the wire diameters are given in some of my other books), there are some general guidelines in Table 3.2. The conductor type is along the vertical axis on the left, and the characteristic impedances are along the horizontal axis at the top. The entries in each cell are the spacings (s) in centimeters. As you can see from the table, only some of the calculated values are useful (who wants to make a 129 cm wide parallel line?).

Parallel open-wire transmission line can be either built or bought. For some applications, such as tuned feeders, it might be the best selection. But for many balanced antennas that use parallel line one might want to consider using twin lead instead.

Twin-lead line

The twin-lead form of transmission line is shown in Figures 3.4B and 3.4C. This type of line is like parallel line, except that the conductors are buried in an insulating material that also spans the space between the conductors. Spacings are shortened a little bit compared to the open-wire variety because the dielectric constant of the insulating material reduces the VF.

The most common form is 300 ohm television antenna twin-lead, of the sort shown in Figure 3.4B. This line is about 1 cm wide, and has a characteristic impedance of 300 ohms. Television twin-lead is easily available from a wide variety of sources, including shops catering for television and video customers. It can be used for transmitting at powers up to about 150 W, but even that level is questionable if the line is of a cheaper variety. Receive-only installations have no such limitation.

Television 300 ohm twin-lead may be solid as shown, or may have oblong or rectangular holes cut into the insulation separating the conductors. This tactic is used to reduce the losses inherent in the transmission line. In other cases, the center insulating material will be rounded and hollow. This

TABLE 3.2

	Characteristic impedance, Z_0 (ohms)				
Conductor	300	400	500	600	800
8 AWG	2.0	4.6	10.6	24.4	129
10 AWG	1.6	3.6	8.4	19.3	102
12 AWG	1.25	2.9	6.7	15.3	81
14 AWG	1.0	2.3	5.3	12.2	64
16 AWG	0.80	1.8	4.2	9.6	51
18 AWG	0.63	1.4	3.3	7.6	40
20 AWG	0.50	1.1	2.6	6.1	32
22 AWG	0.40	0.90	2.1	4.8	25

approach to design also reduces the losses, and is especially effective at UHF.

The type of twin-lead shown in Figure 3.4C is 450 ohm line. This type of line is specialist, and must be sought at shops catering for amateur and commercial radio operators. It is about twice as wide as the 300 ohm variety, and almost always comes with rectangular or oblong loss-reducing holes cut into the insulation. The 450 ohm twin-lead is considerably heavier than 300 ohm line, and uses larger conductors. As a result, it can handle higher power levels.

Twin-lead is wonderful stuff, but can cause problems in some installations. The problems are especially severe at VHF/UHF, but nonetheless exist at HF as well. For example, care must be given to where the line is run: it should not be in close proximity to metal structures such as aluminum house siding, rain gutter downspouts, and so forth. It is also susceptible to picking up local electrical fields, which means a possibility of interference problems. One solution is to use coaxial cable transmission line.

Coaxial cable

This type of cable is shown in Figure 3.4D. The name 'coaxial' comes from the fact that the two conductors are cylindrical (the inner one being a wire) and share the same axis. The inner conductor and outer conductor are separated by the inner insulator. The outer conductor is usually a braided wire or foil shield, and is covered with an outer insulating material.

The characteristic impedances of commercial coaxial cables are of the order of 36–120 ohms, with 52 and 75 ohms being the most common. The specific impedance value is a function of the conductor sizes and the spacing between them. There are several standard types of coaxial cable, and these are available in many subtypes (Table 3.3) that use similar numbering.

The terms 'thick' and 'thin' would have been replaced with actual dimensions if this book were being written only a few years ago, but because of the wide array of different types now available it was decided to use these designations instead. One reason is that there are some RG-8/U specialist cables used by amateur radio and commercial antenna installers that are smaller than regular RG-8/U but larger than RG-58/U or RG-59/U.

TABLE 3.3

Type	Characteristic impedance, Z_0 (ohms)	Size
RG-8/U	52	Thick
RG-11/U	75	Thick
RG-58/U	52	Thin
RG-59/U	75	Thin

One of the differences between the different forms of coaxial cable is the insulating material used for the center insulator. Several types are used: **polyethylene**, **polyfoam** and **Teflon**. A principal effect of these materials is to change the VF of the line.

Velocity factor

The VF (denoted by V in some textbooks) of transmission line is calculated in exactly the same way as the VF of other conductors: it is the ratio of the velocity of the signal in the transmission line over the velocity of the signal in free space. The free space velocity is the speed of light (c), or about 300 000 000 m/s. The VFs of several popular transmission lines are shown in Table 3.4.

The effect of the VF is to reduce the physical length of the coaxial cable that is cut for a particular frequency. And this foreshortening can be quite drastic. For example, if polyethylene cable is cut for an electrical half wavelength at, say, 5 MHz, the actual length $L = (150 \times 0.66)/5 = 19.8$ m, while the wavelength of the signal in free space is 1.52 times longer, or 30 m.

CONNECTING THE TRANSMISSION LINE TO THE RIG OR RECEIVER

The method used to connect the transmission line to a receiver or transmitter depends on the type of output/input connector that is provided for the antenna, and the type of transmission line. In the discussion to follow, the illustrations show a receiver, but apply equally well to transmitters. The only difference is that parallel output on transmitters tends to be large ceramic feedthrough insulators, while on receivers, parallel line inputs tend to be small screw terminals on a plastic, Bakelite or other insulating carrier.

Figure 3.5 shows the basic coaxial connector on a receiver. Although an SO-239 'UHF' connector is shown, and may well be the standard, you may also find BNC, Type-N, or RCA 'phono' plug connectors used on some rigs (I've even seen phono plug connectors used on 100 W transmitters, but that

TABLE 3.4

Type of line	VF
Parallel open-wire	0.95–0.99
300 ohm twin lead	0.82
300 ohm twin lead (with holes in insulation)	0.87
450 ohm twin lead	0.87
Coaxial cable	0.66–0.80
Polyethylene	0.66
Polyfoam	0.80
Teflon	0.72

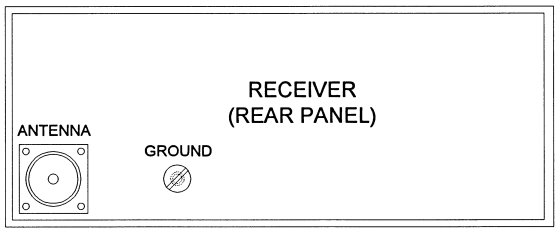


FIGURE 3.5

is not the recommended practice!). In this type of installation, the coaxial cable from the antenna (or any antenna tuning unit that might be present) is fitted with a connector that matches the chassis connector on the receiver. The threads of the male PL-259 connector are tightened onto the female SO-239 connector. Or, in the case of BNC connectors, they are pressed on and then rotated a quarter of a turn (it is a bayonet fitting), and phono plugs are just pushed into the socket.

If the receiver or transmitter is fitted with a ground connection, then it should be used. In short order we will discuss what a 'good ground' means in this context, but for the time being rest assured that you will need a heavy wire to the 'good ground' (whatever it is). If your receiver or transmitter lacks a ground terminal, then wonder why and consider that next time you select a new model.

Although most modern receivers are fitted with coaxial connectors for the antennas, there are a few models (including many that are old but still useful) which are fitted with a **balanced input** scheme such as that shown in Figure 3.6. In the case of Figure 3.6A, there are three screw terminals: A1, A2, and G (or the variants 'ANT1', 'ANT2', and 'GND'). The A1 and A2 terminals form a balanced input for a parallel transmission line, while G is the chassis ground. When an unbalanced antenna transmission line, such as a single-wire downlead (Figure 3.6B) is used, then the line goes to either A1 or A2, while the other is connected to G (in the case shown, A1 receives the antenna downlead, while A2 and G are connected together and then connected to the earth ground). Some models are equipped with only two terminals (Figure 3.6C), and in that case the selection is easy: connect the downlead to A1 (or just 'A' or 'ANT'), and the ground lead to 'G' or 'GND.' When parallel line, twin lead, or any other form of balanced line is used (Figure 3.6D), then connect 'G' or 'GND' to ground, and the two conductors of the transmission line to A1 (or ANT1) and A2 (or ANT2).

FIGURE 3.6

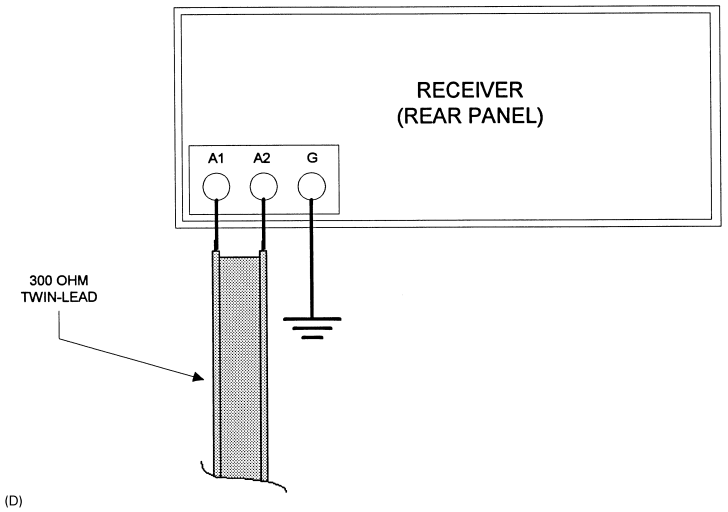

FIGURE 3.6 (*continued*)

CONNECTING WIRES TOGETHER

Wire antennas often require that two or more wires be spliced together (for example, two antenna elements or an antenna element and a downlead). There are right ways and wrong ways to accomplish this task. Let us look at some of the right ways.

All of the correct methods (only a few of which are shown here) have two things in common: they are (a) electrically sound, and (b) mechanically sound. Electrical soundness is created by making a good electrical connection, with the wires bound tightly together, and protected from the elements. The electrical soundness of the joint is made better and longer lasting by soldering the connection.

Figure 3.7 shows how to make the connection mechanically sound. Overlap the two wires being spliced by a few centimeters (Figure 3.7A), and then wrap each one onto the other (Figure 3.7B), forming seven or more tight turns (Figure 3.7C). Once the splice is made, then solder both knots to form a better electrical connection.

One mistake made by novice antenna builders is to assume that the purpose of soldering is to provide mechanical strength. This is false. Solder only improves and keeps good the electrical connection. Solder for radio work is a 50/50 or 60/40 lead/tin mixture with a resin core (NEVER acid core!). It is soft and has no inherent mechanical strength. Always depend on the splice to provide mechanical strength, and NEVER use solder for strength.

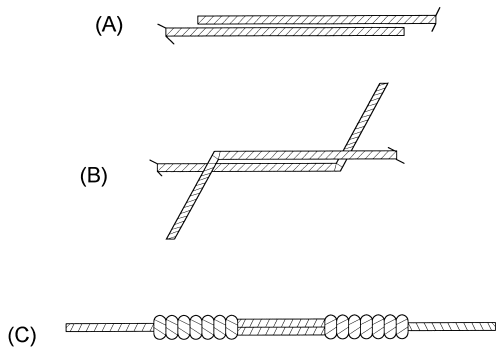

FIGURE 3.7

CONNECTING WIRES TO ANTENNAS AND SUPPORTS

The methods for connecting wires and antenna elements are basically the same as above, but with differences to account for the types of hardware being used in the antenna construction. Figure 3.8 shows how the ends of the wire antenna are supported. **An end insulator** is used. These insulators may be of glass, ceramic, or a synthetic material (nylon is common), but all will have a body and two holes. The wire from the antenna element is passed through one hole, and then looped back onto itself to form seven or more turns. As in the previous case, the splice may be plated with solder to prevent corrosion from interfering with the electrical integrity of the connection. The other end of the insulator is fitted to a rope that is run to a tree, edge of the building, or a mast of some sort. The rope should be treated similarly to the wire in that it should be wrapped over on itself several times before being knotted.

If you use an antenna that has a single-wire downlead, then you should connect it to the antenna in the manner of Figure 3.9. The downlead is almost always insulated wire, even when the antenna is not insulated. The insulation of the downlead prevents it being shorted out somewhere along its run. The scheme in Figure 3.9A shows how most people connect the downlead (and, indeed, how I have connected them quite often). This is not the best practice, although it will work most of the time. The problem is that the connection is stressed by the downlead, and may break. More

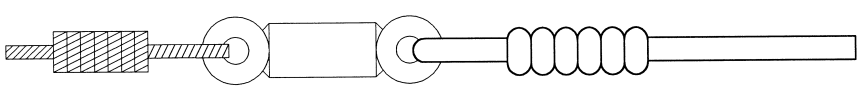

FIGURE 3.8

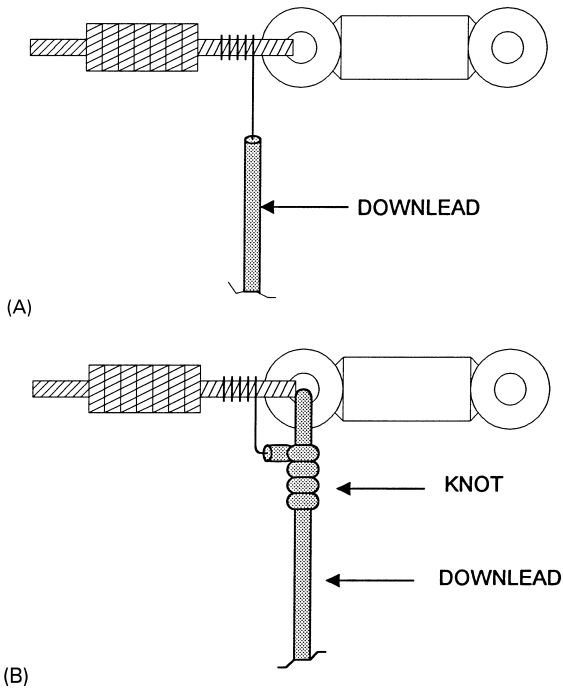

FIGURE 3.9

than once I have been off-the-air due to a spliced downlead breaking right at the junction with the antenna wire. A better solution is shown in Figure 3.9B. In this installation, the downlead wire is passed through the hole in the insulator, and then wrapped back on itself three or four times before being spliced to the antenna wire in the usual manner. This arrangement provides some strain relief to the downlead, and that (usually) translates into a longer life expectancy.

Some antennas, such as the center-fed half-wavelength dipole (a very popular wire antenna), use a center insulator to separate the two halves of the antenna. Coaxial cable is connected such that the inner conductor is spliced to one antenna element, and the shield (outer conductor) is connected to the other antenna element. Good practice is to splice the shield to the element closest to the house, if this is a factor. The method shown in Figure 3.10A will work, but it is also a bit foolish (I know, I know, I have used it and even recommended it in the past). The problem is that the center conductor is quite weak, and may be even smaller than single-wire downleads. As a result, it has no strength. To make matters worse, coaxial cable weighs more length-for-length than single-conductor downleads (or even some twin lead). The connection of Figure 3.10A will work, but only for

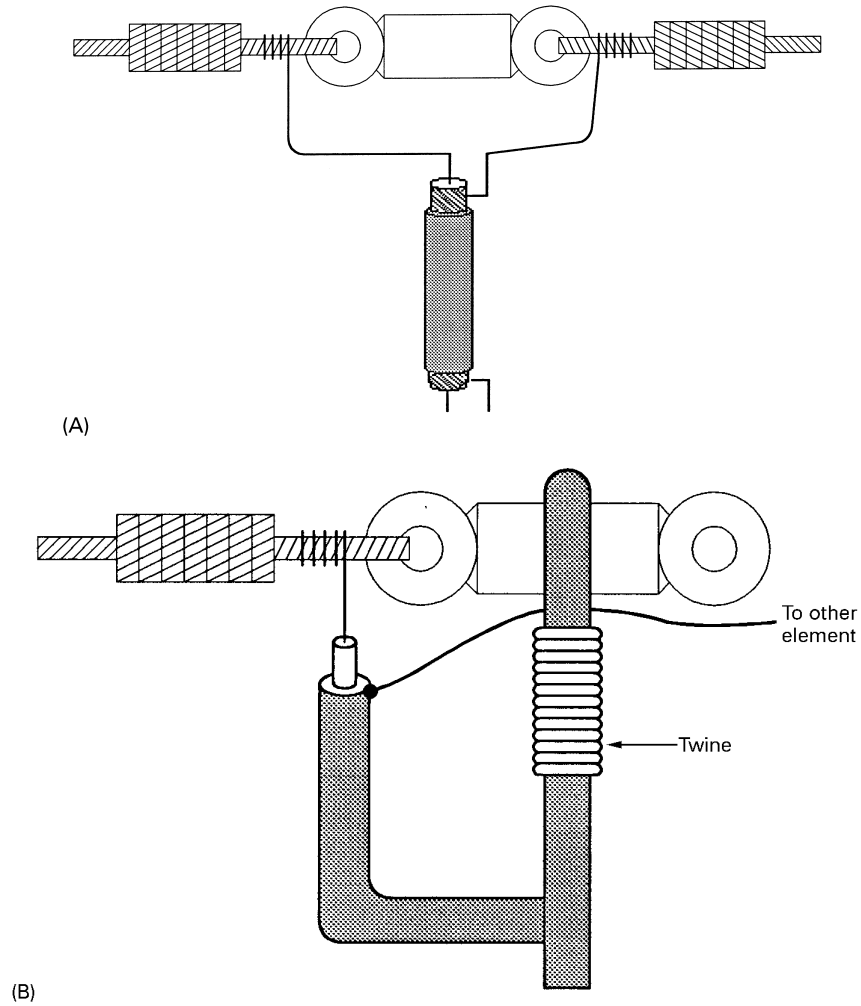

FIGURE 3.10

a while – it will surely come down prematurely. A better scheme is shown in Figure 3.10B. In this case, the coaxial cable is wrapped once around the center insulator, and secured with a length of twine or string. The electrical connections are made in exactly the same manner as shown in Figure 3.10A.

Perhaps the best solution is to use a manufactured center insulator (Figure 3.11). These devices come in a wide variety of sizes and shapes, so this illustration represents a lot of different devices. What they all share in common, however, are means for strain relieving the antenna element wires and coaxial cable. Some devices may be straight insulators, while others may

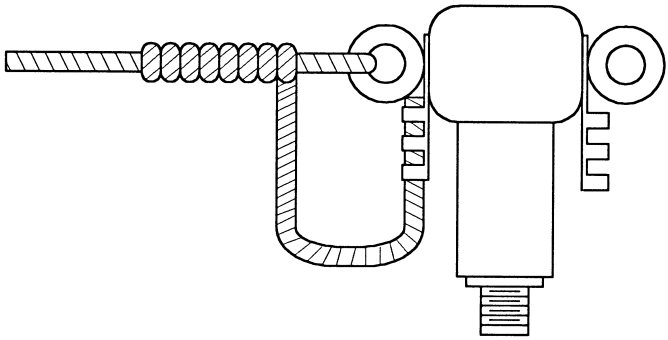

FIGURE 3.11

contain BALUN transformers inside (of which, more shortly). Some models include special strain relief features for the coaxial cable, or they may have a screw-eye on top to secure the antenna center to a mast or other support.

The electrical connections between the center insulator and the wire antenna elements are done in the usual manner (see above), but the ends of the wires are usually attached to eyelet connectors, which are crimped and then soldered. It has been my experience that these connectors are often corroded (as seen by the dull appearance) when they arrive, so brighten them with sandpaper or steel-wool before attempting to make the connections permanent.

LIGHTNING ARRESTORS

Lightning is messy stuff, and can create havoc with your radio – and might set your house on fire. But there are some things you can do to protect yourself. But first, let us take on one myth right away: contrary to popular belief, *antennas do NOT inherently attract lightning*. Lightning will usually strike the highest object around, and if that happens to be an antenna, then the antenna will take a hit. And that hit could set the house on fire, and the radio will be damaged or even destroyed. The lightning would have come anyway, and if it takes out the antenna rather than your house, then it acted like a lightning rod and protected your property.

If lightning actually strikes your antenna, then it will probably wipe out your transmitter or receiver no matter what you do. But a direct hit is not needed for fatal damage to occur: even lightning overhead or striking nearby will induce a large enough voltage into your antenna to wreak havoc inside the equipment. And it may be silent damage because it is not so spectacular as the problems seen with direct hits.

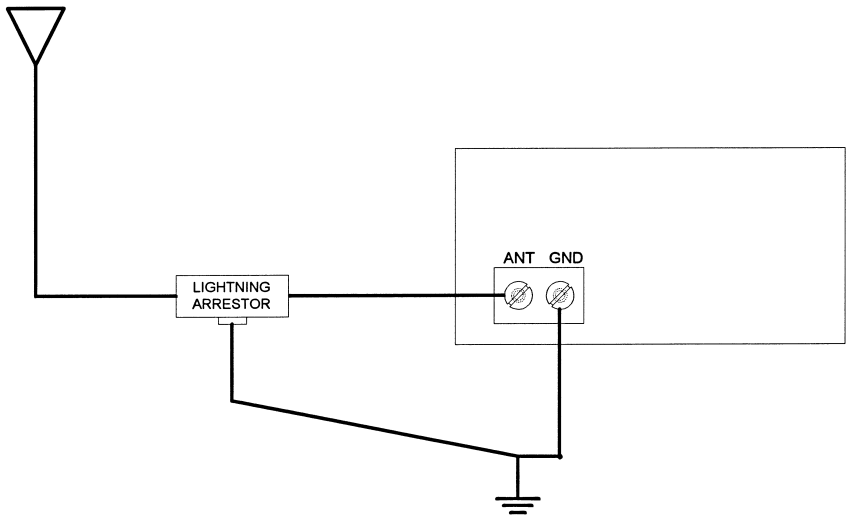

FIGURE 3.12

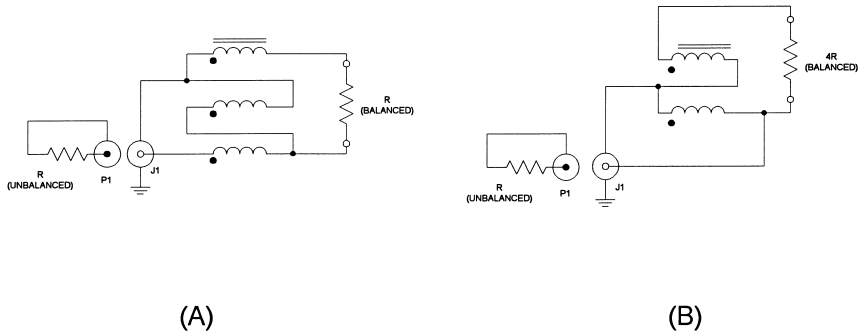
The key to protecting your equipment is to use a **lightning arrestor** (Figure 3.12). These devices come in several types, each suitable for coaxial line, parallel line, or single-wire downleads. Each will have at least one connection for the antenna wire, and a ground connection. It is placed in the line between the antenna lead and the receiver or transmitter, and should be mounted outside the house. There is very little that can be done for a direct hit, but I have heard tales of near hits only causing a small amount of rig or receiver damage because an effective lightning arrestor was in place. Also, keep in mind that some local laws or insurance regulations make the lightning arrestor mandatory. If you fail to use one, you may be liable for a fine from the local government, or find your homeowner's insurance not valid after a lightning episode. Lightning arrestors are cheap, and so make very reasonably priced insurance.

BALUN TRANSFORMERS

Both impedance transformation and conversion between unbalanced and balanced lines can be accomplished with a BALUN transformer (the name comes from **BALanced–UNbalanced**). Two sorts of transformers are used (Figure 3.13). The 1:1 BALUN transformer converts the balanced load to an unbalanced form (so it can be fed with coaxial cable). The impedance of the load must be the same as the source. The version shown in Figure 3.13B is a 4:1 BALUN. This transformer is used to provide not only a balanced-to-



(A) (B)

FIGURE 3.13

unbalanced conversion, but also a 4:1 impedance transformation. For example, a half-wavelength folded dipole antenna is balanced with respect to ground, and has a feedpoint impedance near 300 ohms. A 4:1 BALUN transformer converts the 300 ohm load to 75 ohms, and makes it appear an unbalanced rather than balanced load.

BALUN transformers can be easily built using toroidal coil forms or ferrite rods. The 1:1 BALUN is wound in the trifilar style, i.e. the three wires are wound side by side so that all three coils interleave with one another. The 4:1 BALUN is wound in the bifilar manner. If you do not wish to make your own BALUN transformers, then you will find that there are many commercially available BALUN transformers on the market.

VHF/UHF scanner users will find few BALUNs specially for their needs, but there are plenty of devices available. The television antenna transformers are not usually called 'BALUNs,' but when you find a transformer that converts 75 ohm coaxial cable to 300 ohm twin-lead, then it is (rest assured) a BALUN, and will work over the entire VHF/UHF range unless marked otherwise. BALUN transformers are bidirectional devices, so can be used either way around.

SAFETY

Antenna safety is an absolute must. First, let me make one thing absolutely, positively, clear in your mind:

DO NOT EVER TOSS AN ANTENNA WIRE OVER THE AC POWER LINES!

If you plan to do this trick, then have your family prepare for some solemn praying, sad music, and slow marching, for your funeral is imminent. This action kills radio hobbyists every year. There is no safe way to do it, so do not. Even if both the antenna wire and the power line are insulated, the forces of erecting the antenna will slice through both insulations! When that happens, the wires will come into contact with each other and with you – with disastrous consequences: human bodies make lousy fuses.

The next matter is like unto the first: do not erect your antenna where it can fall onto the power lines, or other people's property, either during erection or as a result of a structural failure. Falling onto the electrical lines can make the antenna deadly, and falling onto your neighbor's property is just plain rude (and might get you sued).

Finally, do not install an antenna without assistance. I know they are lightweight, and all that, but they have a remarkable 'sail area,' and even very weak winds will increase their apparent weight. I've suffered injury myself (wrenched back) by working alone, and a friend of mine broke a pelvis and a leg falling off a roof while trying to install a television antenna.

CHAPTER 4

Marconi and other unbalanced antennas

Marconi antennas are those that are *fed unbalanced with respect to ground* (Figure 4.1). In the case of a transmitter, one side of the output network is grounded, while the other side is connected to the radiator element of the antenna. The length of the radiator element varies with type, and determines many of the operating properties of the antenna. The direction of the radia-

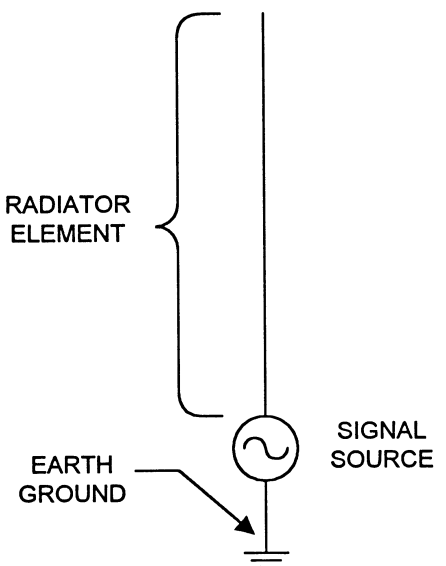


FIGURE 4.1

tor element also varies. It may be vertical as shown (indeed, vertical antennas are a species of Marconi antenna), or at a slant. In some cases, the Marconi antenna is connected directly to the rig or receiver, but in other cases an antenna tuning network is needed.

BASIC RECEIVING 'TEE' ANTENNA

Although most of the antennas in this chapter can be used on either receive or transmit, this one (Figure 4.2) is recommended for receive use only unless an antenna tuner is provided. This antenna is not particularly well thought-of, but is the antenna of choice for many first-time receiver owners, or those who live in a difficult antenna erection venue.

The radiator element is a 10–40 m long (more or less) piece of wire, preferably in the 12 AWG (≈14 SWG), 14 AWG (≈16 SWG), or 16 AWG (≈19 SWG) size. Smaller sizes can be used, but they are not recommended for structural reasons (they break and fall down too easily).

THE HALF-LAMBDA-'TEE' ANTENNA

The antenna in Figure 4.3 is called the half-lambda-'tee' because it is one-half wavelength long (i.e. $\lambda/2$) and is a 'tee' antenna. The 'tee' is seen by the fact that a downlead section is provided, and it comes away from the radiator element at a 90° angle. The length of this downlead section is quarter wavelength. This length differs from the top-hat tee antenna used by many

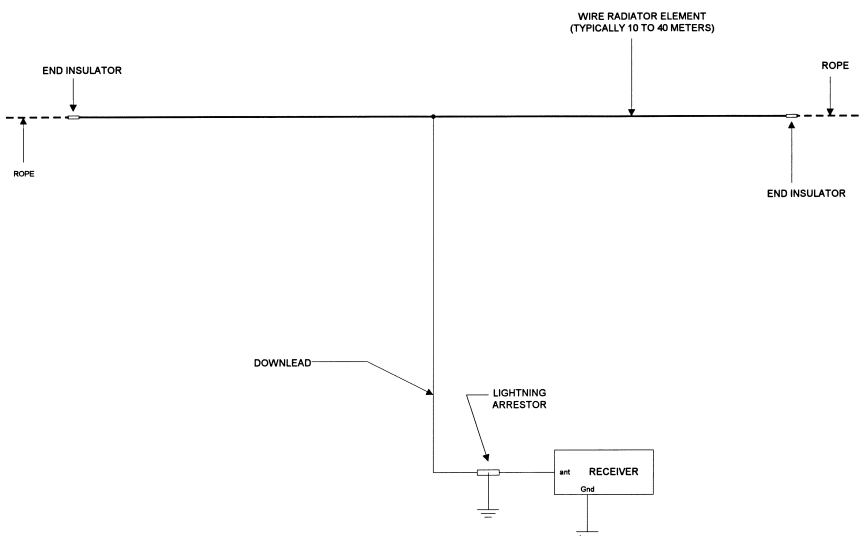

FIGURE 4.2

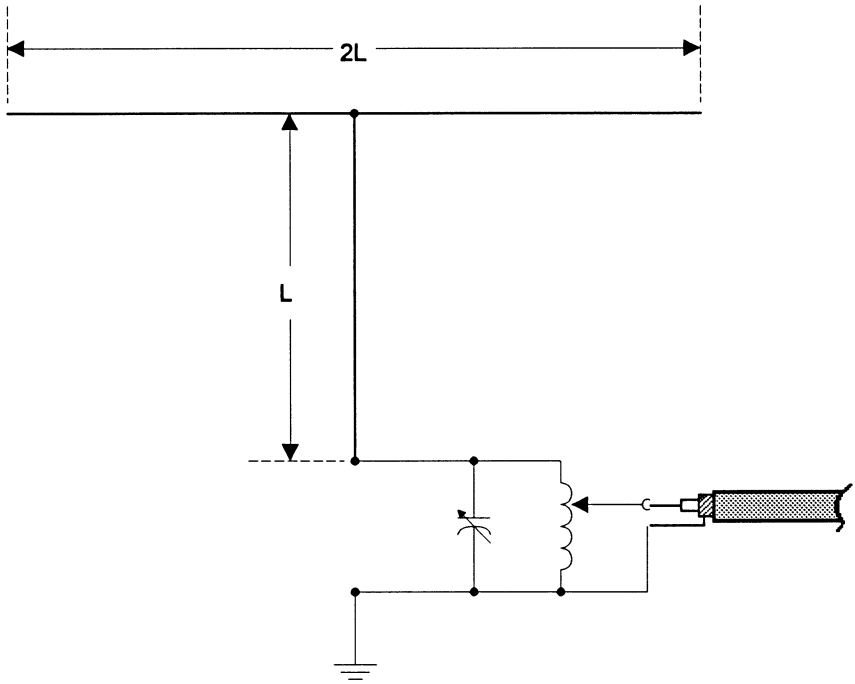

FIGURE 4.3

short-wave listeners where the radiator is half wavelength or longer and the downlead is a random length of wire. The lengths of these elements are

$$2L = \frac{143}{F_{\text{MHz}}} \text{ meters}$$

and

$$L = \frac{71.5}{F_{\text{MHz}}} \text{ meters}$$

These lengths make the antenna resonant. Examples of the proper lengths for various bands are:

Band	L	$2L$
60 m (5 MHz)	14.30 m	28.60 m
31 m (9.75 MHz)	7.33 m	14.66 m
20 m (14.2 MHz)	5.03 m	10.06 m

An antenna tuner is required for the half-lambda-'tee' antenna. Both the inductor and the capacitor should have reactances of 450 ohm, i.e.

$X_L = 450$ ohms and $X_C = 450$ ohms. Typical values for these components are:

Band	*C*	*L*
60 m (5 MHz)	65 pF	16.0 μH
31 m (9.75 MHz)	33 pF	8.2 μH
20 m (14.2 MHz)	23 pF	5.6 μH

For operation over a wider band, try using variable capacitor and/or inductor elements.

THE 'QUICK 'N' DIRTY' TWIN-LEAD MARCONI ANTENNA

The antenna shown in Figure 4.4 is one of the first that I ever used (when a mentor, MacIvor Parker, W4II, gave me a roll of twin-lead wire). I ran this antenna out of a basement window, and attached the top end to an old pine tree, and the middle supported by a 5×10 cm piece of construction lumber nailed rather unceremoniously to a tool shed on the back of the house.

Basically a quarter-wavelength 'round robin' Marconi, it consists of a 300 or 450 ohm twin-lead transmission line with a length (in meters) of $71.5/F_{MHz}$. Thus, for the 60 m (5 MHz) band the length would be about 14.3 m long overall. The length of the coaxial cable feedline is not critical. The 52 ohm coaxial cable feedline is connected such that the center conductor goes to one conductor of the twin-lead, and the shield goes to the other.

This antenna is basically a species of Marconi antenna, so requires a good ground in order to work properly. At the minimum, one of the longer copper or copper-clad steel ground rods should be driven into the earth at

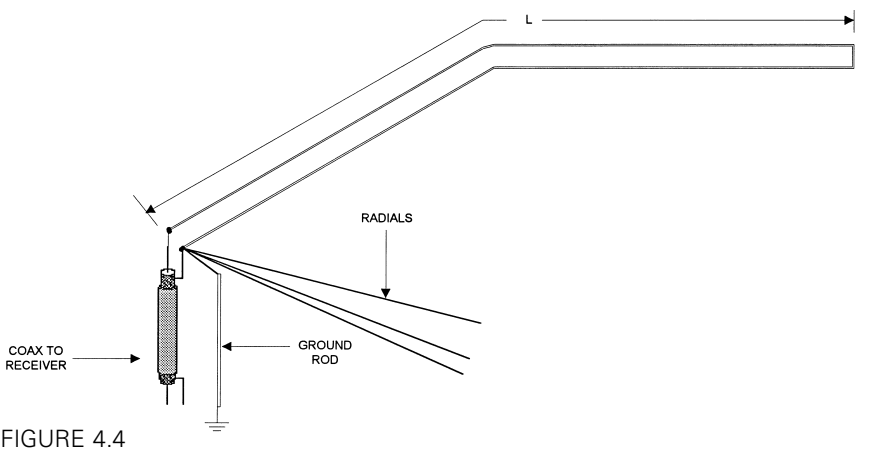

FIGURE 4.4

or very near the feedpoint. The best method is to use both a ground rod and a system of two to eight quarter-wavelength radials as a counterpoise ground.

The 'quick 'n' dirty' (or 'round robin' as my mentor called it) can be installed at an angle (as shown), although I suspect best performance occurs when the wire is straight. In the version that I had, there was only a small voltage standing wave ratio (VSWR) with one bend that put the vertical and horizontal segments at about a 120° angle.

Note the far end of the twin-lead wire (i.e. the end away from the coaxial cable). The two conductors of the twin lead are *shorted together*. I have encountered some confusion over this matter, after all a short is a short, isn't it? No, because this antenna is a quarter wavelength long, so the impedance reflected to the feedpoint by a short at the end is very high.

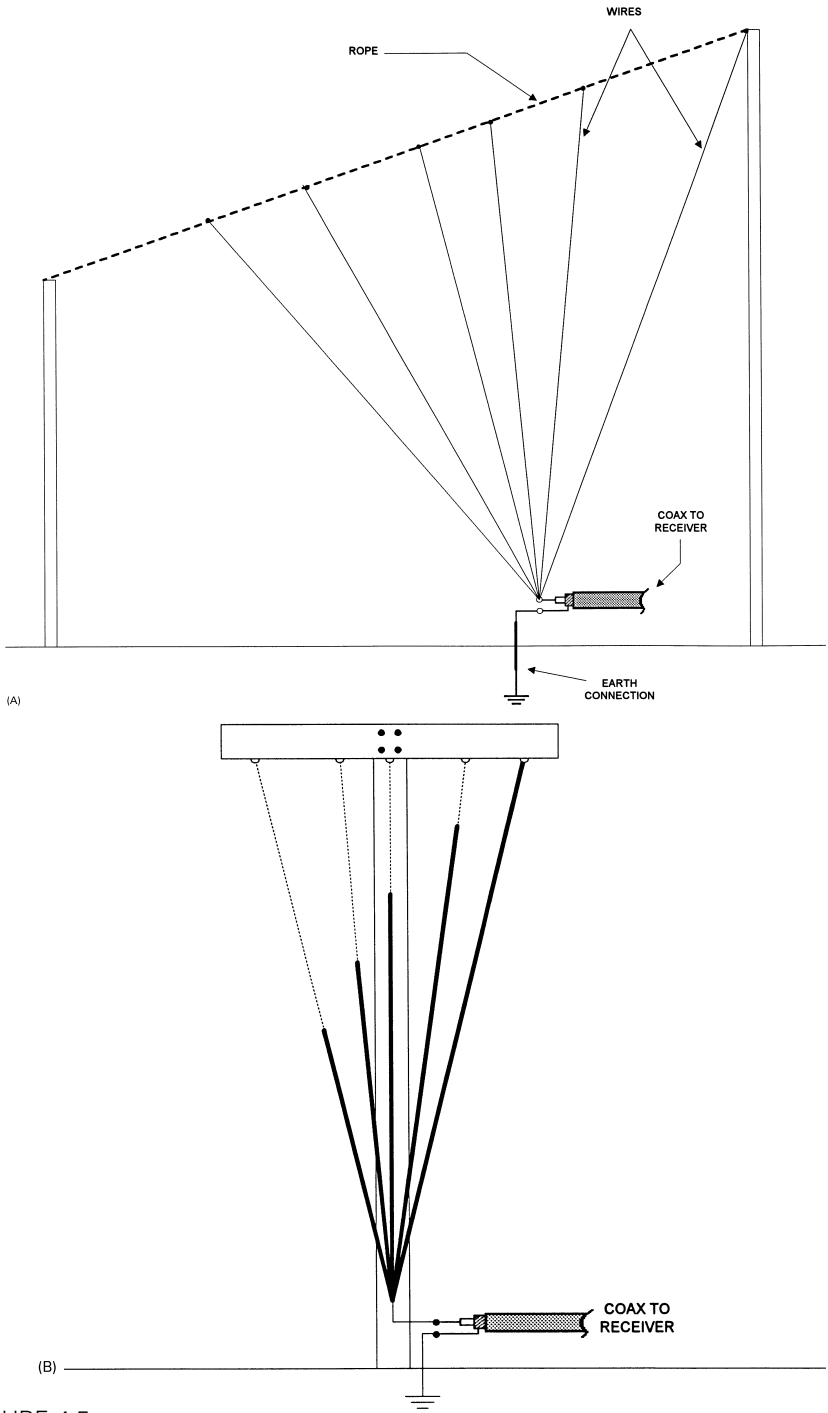
This antenna works better than single-conductor Marconi antennas because regular Marconi antennas suffer from ground losses. By supplying a return line, the radiation resistance is raised from 10 or 15 ohms to something of the order of 40–50 ohms – which makes it a good match to 52 ohm coaxial cable.

THE SWALLOW TAIL ANTENNA

Figure 4.5 shows two variants of the swallow tail multiband antenna. The radiator elements in both Figures 4.5A and 4.5B are cut to specific frequency bands, and are quarter wavelength ($L_{\text{meters}} = 75/F_{\text{MHz}}$). As many as needed to cover the bands of interest may be used, provided that they do not bear a 3:1 frequency ratio. The reason for the constraint is that for all antennas but the resonant one the impedances are so high that connecting them in parallel with each other does not affect the overall feedpoint impedance. However, at the third harmonic, the impedance again drops low and will load down the impedance seen by the transmission line. This is another situation where the results are more profound for amateur radio transmitters than for shortwave receivers, but it is a good idea to avoid it if possible. Besides, the antenna is actually resonant on its third harmonic, so you lose nothing.

The version in Figure 4.5A uses a pair of insulating masts, or support structures (roof of a house, tree, etc.) with a rope stretched between them. The quarter-wavelength resonant wires are spread out along the length of the rope, spaced approximately evenly.

The version shown in Figure 4.5B uses a large wooden cross-like structure. The antenna wires are connected to the cross-piece at the top end, and to the coaxial cable at the bottom end. This antenna apparently worked well for a fellow who wrote to me recently. He lives in a townhouse community that has a 'homeowners' association' of nit-picking little dictators who like



WIRES
ROPE

FIGURE 4.5

to tell people what they may do with their houses. One of the rules is 'no outdoor antennas' of any sort. He erected a mast in his rear garden shaped like a ship's mast and yardarm, and then convinced the busy-bodies snooping for 'the committee' (dread!) that it was somehow nautical, not radio.

RANDOM LENGTH MARCONI

There are several antennas that qualify as 'all-time favorites' with both ham operators and short-wave listeners. In the top three or four is the random-length wire antenna. This form of antenna consists of whatever length of wire that you happen to have (although there are reasonable limits!) run from the rig or receiver to a convenient elevated support (e.g. a tree, mast, or roof of a building). Figure 4.6 shows this most basic form of Marconi antenna.

Although a receiver owner can connect the random-length radiator wire to the antenna input of the receiver, the transmitter operator most certainly requires an antenna tuning unit (ATU). Even receiver operators will find this antenna a better performer when an ATU is used between the coaxial cable to the receiver and the radiator wire.

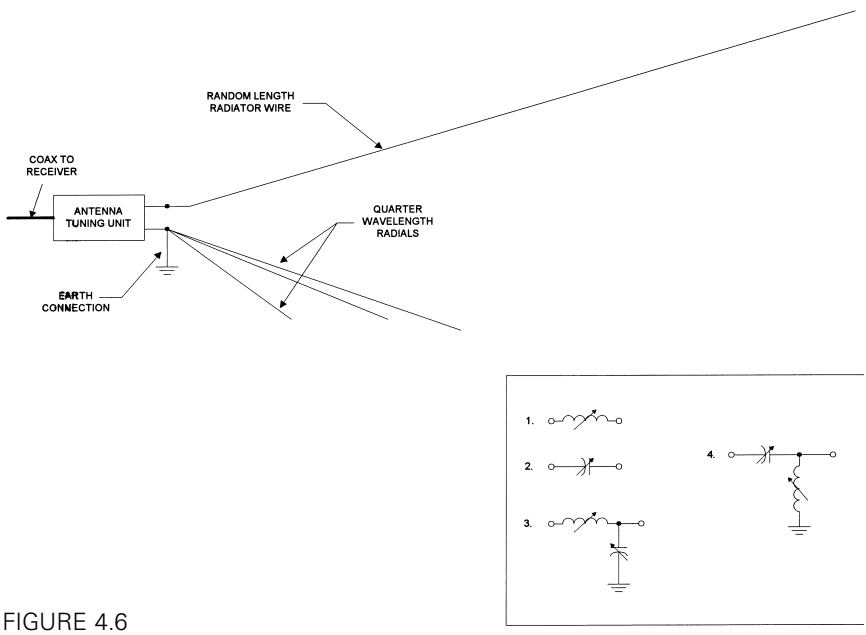

FIGURE 4.6

One requirement of this antenna is that it requires a good ground. It is essential that either an earth ground or a counterpoise ground (i.e. a system of radials) be provided. Methods of providing a good grounding system are described in Chapter 13.

There are several conditions for this form of antenna: an antenna that is shorter than a quarter wavelength, an antenna that is a quarter wavelength, and longer than a quarter wavelength. The inset in Figure 4.6 shows several options for the antenna tuning unit. At position 1 is a variable inductor. This is used when the antenna is quite short compared to a quarter wavelength. At position 2 is a variable capacitor. It is used when the antenna is longer than a quarter wavelength. When the antenna is exactly a quarter wavelength, then it may be possible to eliminate the antenna tuner. It is also possible to use the L-section couplers at positions 3 and 4. These ATUs combine the inductor and capacitor. These are used to match the feedpoint impedance to the 52 ohm coaxial cable.

Many commercial L-section couplers are designed with either switching or shorting straps that allow any of the combinations in the inset to Figure 4.6 to be realized by making some simple changes.

Receiver operators who use this antenna are well advised to use an ATU, just like transmitter operators. But there is at least one difference: you should be able to switch the ATU out of the system when you are receiving a frequency outside the limits of the tuner.

THE WINDOM ANTENNA

One of the first ham radio transmitting antennas that I ever used was not my own, but rather the antenna at my high school station in Arlington, Virginia (K4BGA, Washington-Lee High School). Although I had owned receive antennas, the K4BGA club station was one of the first I had operated. It used an HF Windom antenna running across the roof of the industrial arts building. The Windom antenna (Figure 4.7) has been around since the 1920s. Although Mr Loren Windom is credited with the design, there were actually a number of contributors. Co-workers with Windom at the University of Illinois were John Byrne, E. F. Brooke, and W. L. Everett, and they are properly co-credited. The designation of Windom as the inventor was probably due to the publication of the idea (credited to Windom) in the July 1926 issue of *QST* magazine. Additional (later) contributions were rendered by G2BI and GM3IAA (Jim MacIntosh). We will continue the tradition of crediting Loren Windom, with the understanding that others also contributed to this antenna design.

The Windom is a roughly half-wavelength antenna that will also work on even harmonics of the fundamental frequency. The basic premise is that the antenna radiation resistance varies from about 50 ohms to about 5000

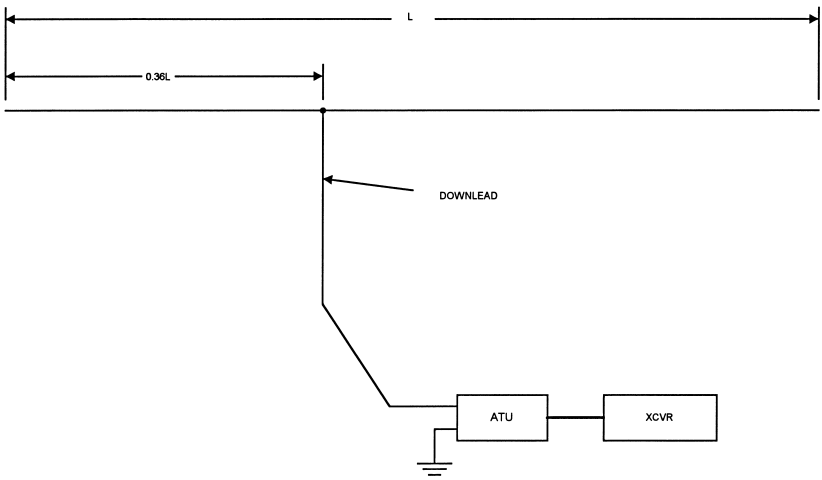

FIGURE 4.7

ohms, depending upon the selected feedpoint. When fed in the exact center, a current node, the feedpoint impedance will be 50 ohms; similarly, end-feeding the antenna finds a feedpoint impedance of about 5000 ohms. In Figure 4.7 the feedpoint is tapped away from the center at a point that is about one-third ($0.36L$) the way from one end, at a point where the impedance is about 600 ohms.

The feedline for the basic Windom of Figure 4.7 is an insulated length of wire. Of course, the size of the wire depends on the power level, but I suspect that No. 14 insulated stranded wire will do for most people who run less than 200 W of power (indeed, I would not like to use a Windom at high-power levels because of the 'radio frequency (RF) in the shack' problem).

The Windom antenna works well – but with some serious caveats. For example, the antenna has a tendency to put 'RF in the shack' because of the fact that it is voltage fed. This is why Windom antenna users (along with those using the random-length Marconi) get little 'nips' of RF shock when touching the transmitter chassis, or putting a lip on the microphone. Second, there is some significant radiation loss from the feedline. Finally, the antenna works poorly on odd harmonics of the fundamental frequency.

The antenna tuning unit can be either a parallel resonant, link-coupled, LC tank circuit or a π-network (i.e. high-impedance end toward the antenna).

Note that a good ground should be used with this antenna (note the ground connection at the output of the antenna tuning unit). This basically means (for most people) a 2–2.5 m ground rod, or a system of radials (see earlier discussion for random-length wire antennas).

A reasonable compromise Windom, which reduces feedline radiation losses, is shown in Figure 4.8. In this antenna a 4:1 BALUN transformer is placed at the feedpoint, and this in turn is connected to 75 ohm coaxial cable. It is necessary to ensure that the feedpoint is at a current node, so it is placed a quarter wavelength from one end. Also, the antenna on the other side of the BALUN transformer should have a length that is an odd multiple of a quarter wavelength. In the case shown it is three-quarter wavelength long.

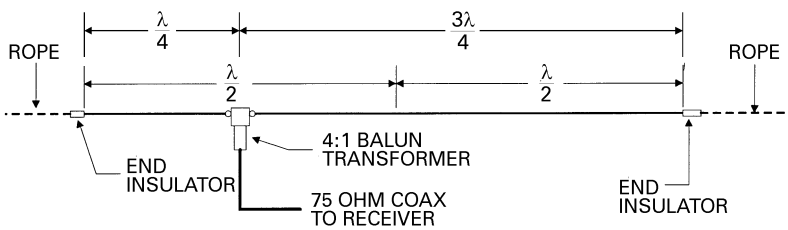

FIGURE 4.8

QUARTER WAVELENGTH VERTICAL

Perhaps the most classic form of Marconi antenna is the quarter wavelength vertical (Figure 4.9). It consists of a vertical radiator element that is quarter wavelength long, and a system of quarter wavelength radials for the ground system. The length of the radiator element is found from:

$$L_{\text{meters}} = \frac{75}{F_{\text{MHz}}}$$

where L_{meters} is the length in meters and F_{MHz} is the frequency in megahertz.

The radiator element can be made of pipe or wire. The former case, the pipe can be copper or aluminum, although I suspect that aluminum will be the choice of most readers. In the case of a wire radiator, it will be necessary to support the wire up top, so some form of mast or support is necessary. Make the mast or support out of an insulating material such as wood.

The radials are somewhat optional if you use it with a 'good ground'. But in the absence of a 'good ground', I would use at least four radials and as many as sixteen. Above sixteen the benefit of adding further radials drops off substantially.

Radials should be buried if the vertical is ground mounted (that is to prevent lawsuits over pedestrians tripping over them). In the case where the

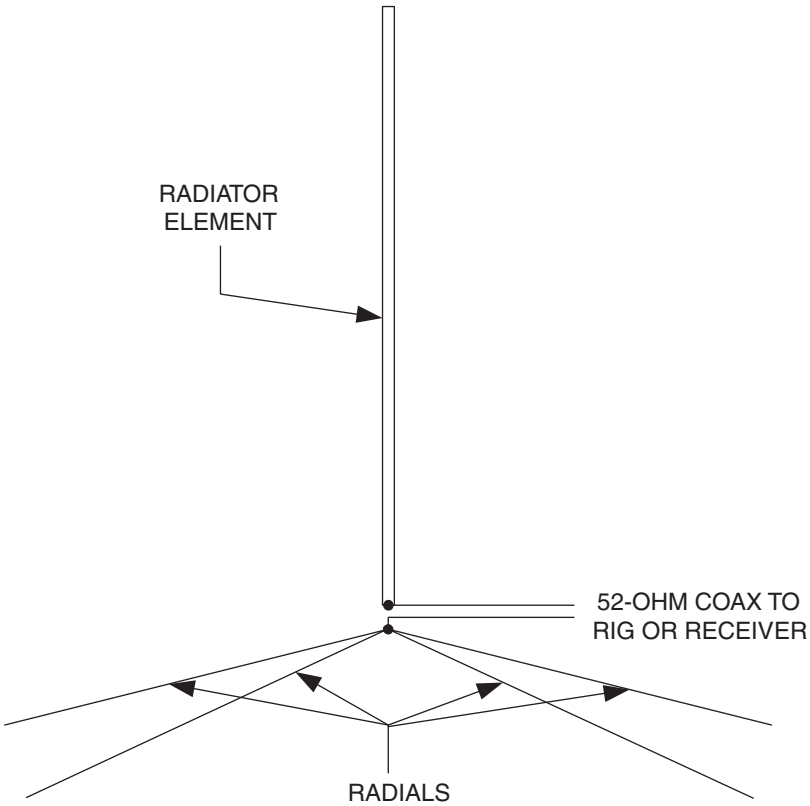

FIGURE 4.9

vertical is mounted on a mast, off ground, the radials are not optional – they are mandatory. In that case, use four to sixteen radials arranged in a circular pattern around the base of the radiator element.

Connect the system so that the radiator element is connected to the coaxial cable center conductor, and the radials are connected to the shield of the coaxial cable. Because the feedpoint impedance of the vertical antenna is 37 ohms, use of 52-ohm coax will result in a VSWR of only 50/37 = 1.35:1. In the case where the vertical has a substantially lower impedance (as low as 2 ohms!), use a broadband transformer between the coaxial cable and the antenna.

FOLDED MARCONI 'TEE' ANTENNA

The antenna shown in Figure 4.10 is popular for receiving and transmitting on the lower bands (< 7 MHz) when space for antennas is a bit limited.

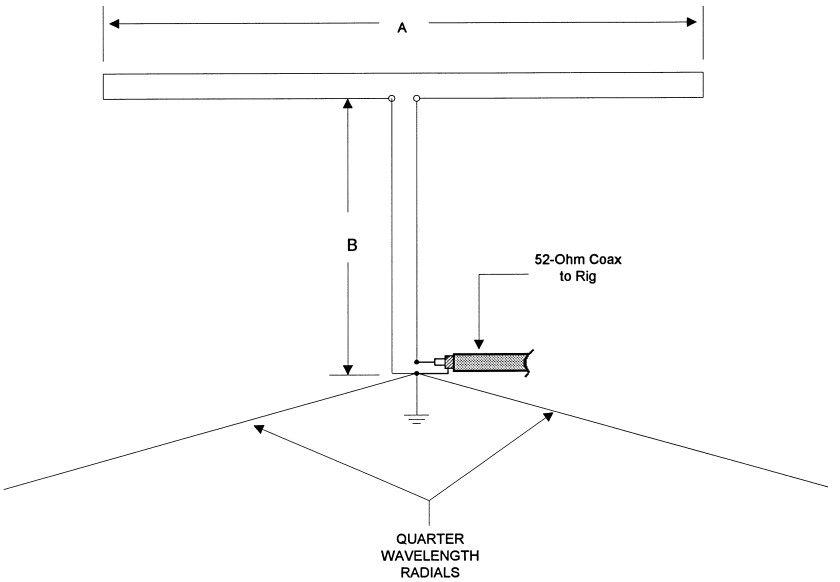

FIGURE 4.10

Although it can still take a lot of space at the lowest frequencies, it is quite a bit shorter than a half-wavelength dipole for the same frequencies.

Two pieces of 300 or 450 ohm twin-lead are used to make this antenna (*A* and *B* in Figure 4.10). The *A*-section is the main radiator element, and it has a length of

$$A_{\text{meters}} = \frac{82}{F_{\text{MHz}}} \text{ meters}$$

Note that section *A* is built like a folded dipole. At the ends of the twin-lead the two conductors are shorted together. At the center point of section *A* one of the two conductors is cut to accept the two conductors of the twin-lead used for section *B*.

Section *B* is vertical, and should come away from section *A* at a right angle. It has a length that is similar to that of *A* except that it is reduced by the velocity factor (VF) of the transmission line:

$$B_{\text{meters}} = \frac{82(\text{VF})}{F_{\text{MHz}}} \text{ meters}$$

For ordinary 300 ohm twin-lead, the length of *B* is $0.82A$.

Note that the conductors making up *A* and *B* form a continuous loop of wire. The coaxial cable is connected such that the shield goes to one lead of *B* and the inner conductor goes to the other conductor. At the top of *B* the two conductors are connected to either side of the cut in section *A*.

As with the other Marconi antennas in this chapter, it is imperative that a good ground be used with the 'tee' Marconi. Otherwise, losses will be too great, and performance will suffer considerably.

Figure 4.11 shows the end-fed Zepp antenna. This antenna has a radiator wire that is half wavelength long at the lowest frequency of operation. It will work on harmonics of that frequency as well as the frequency itself. It will also work on other frequencies if a high VSWR can be tolerated. It is fed by 600-ohm parallel feedline and an antenna tuning unit (ATU). The ATU is used to tune the VSWR to 1:1 at the frequency of operation.

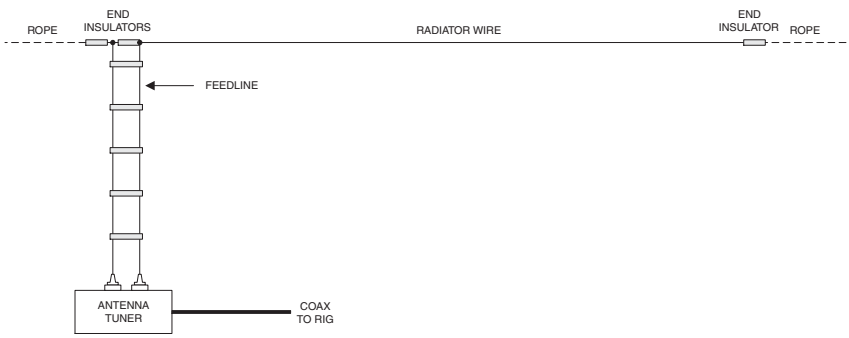

FIGURE 4.11

EWE ANTENNA

The EWE antenna emerged recently as one solution to the low-noise low-band antenna problem. Figure 4.12 shows the basic EWE antenna. It consists of two vertical sections (labeled L1) and a horizontal section (L2). The EWE looks superficially like a Beverage antenna, but it isn't. Like the Beverage it is erected about L1 = 3 meters above the Earth's surface. Unlike the Beverage, it is only L2 = 6.5 meters long at 3.5 MHz. Those dimensions make it affordable for most people.

The far end segment is terminated in an 850 ohm resistor. This resistor should be a carbon composition or metal film resistor, and never a wire-wound resistor.

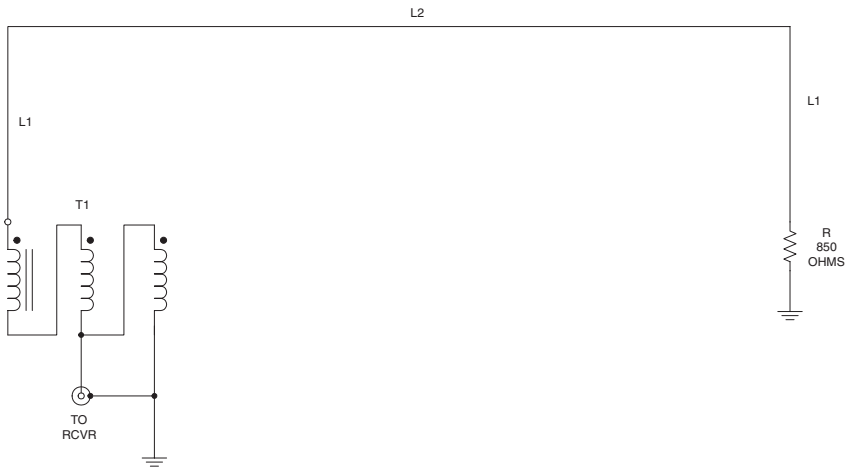

FIGURE 4.12

The receiver end must be matched to the receiver's 50 Ω antenna input impedance. Transformer T1 is provided for this purpose. It has a turns ratio of 3:1 to provide the 9:1 impedance ratio required to match the 450 Ω antenna impedance to the 50 Ω receiver impedance. A powdered iron toroid core made of -2, -6 or -15 material will be sufficient. A suitable transformer can be made using a T-50-15 (red/white) core. Use about 20 turns of any size enameled wire.

The azimuthal and elevation patterns for the Koontz EWE antenna are shown in Figures 4.13, 4.14, 4.15 and 4.16. These patterns were simulated from the *Nec-WIN Basic* software available from Nittany-Scientific. The patterns in Figures 4.13 and 4.14 are based on the Sommerfield-Norton standard ground model, with the azimuth being seen in Figure 4.13 and the elevation in Figure 4.14. The same types of pattern are seen for a 'real' ground based on suburban soil and are shown in Figures 4.15 (azimuth) and 4.16 (elevation).

REVERSIBLE EWE

The EWE antenna can be made reversible by using a system such as Figure 4.17. The feedpoint and termination circuits are co-located at the receiver. Transformer T1, coil L1, resistor R1 and DPDT switch S1 are installed in a shielded metal box. The outputs of the box (i.e. center terminals of the DPDT switch) are connected to the bases of the vertical (L1) sections of the EWE antenna. According to one source, the simple resistive termination

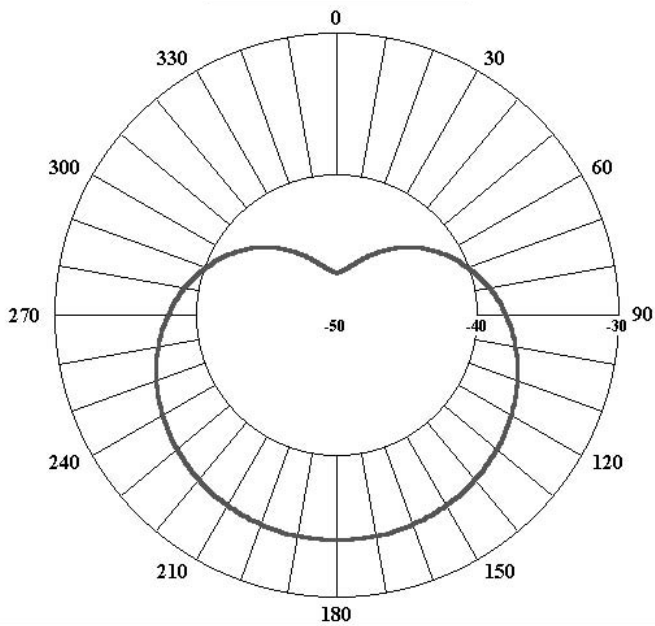

FIGURE 4.13 Low-Noise RX Antenna

was not sufficient, so they added an inductive reactance in series with a resistance. This is the method used on Beverage antennas to make a steerable null, and that effect is seen on the EWE as well.

DUAL EWE ANTENNA

Figure 4.18A shows a modification of the EWE antenna that permits switchable bi-directionality. Four EWE antennas are arranged in north–south (N–S) and East–West (E–W) directions. The feedpoints (A, B, C and D) are connected to a switch circuit such as shown in Figure 4.18B. The directivity of the antenna is controlled by opening and closing the four switches (S1–S4).

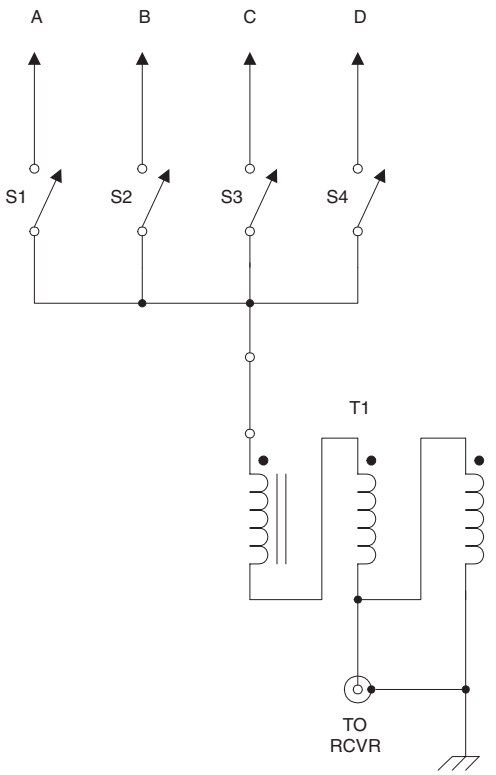

FIGURE 4.18B

CHAPTER 5

Doublets, dipoles, and other Hertzian antennas

A **doublet** antenna is any of several forms of **dipoles** (*di* – 'two') that are balanced with respect to ground. In other words, neither side of the antenna feedline is grounded. These antennas are fed in the center, which point will be either a current node or voltage node depending on the design of the particular antenna. Perhaps the most common form of dipole is the half-wavelength ($\lambda/2$) center-fed dipole, which can be fed with ordinary 75 ohm coaxial cable. It is so popular that when people use the word 'dipole' in an unqualified sense, it is the $\lambda/2$ center-fed version that is meant. Although dipoles can be made of either wire or tubing, the most common practice is to make them out of wire, especially antennas at the lower end of the high-frequency (HF) spectrum. Above about 14 MHz, however, it becomes increasingly practical to make these antennas of aluminum tubing.

DIPOLE RADIATION PATTERNS

When one uses the term 'dipole' in the common sense it is usually understood that the antenna being discussed is the half-wavelength doublet. One reason for this practice is the widespread popularity of that particular dipole. But the practice is actually erroneous because the dipole can be any size up to about two wavelengths (although some would argue that any balanced antenna, even longer than two wavelengths, is a dipole, I demur on grounds that longer antennas begin acting like the **long-wire** antenna and its relatives). Figure 5.1 shows the effect of different wavelength dipoles on the azimuthal radiation pattern of the antenna.

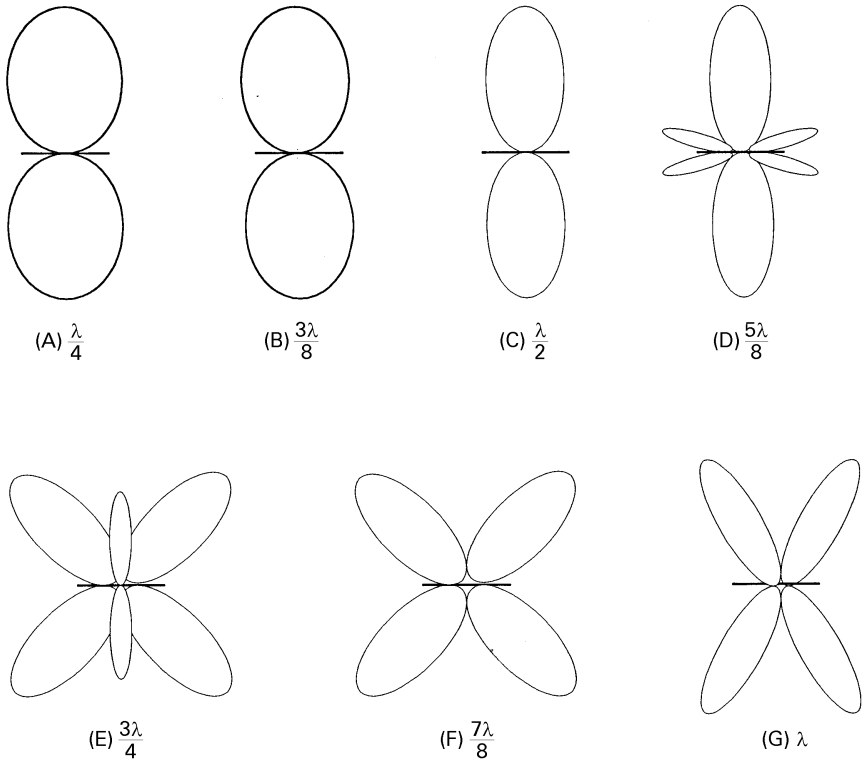

FIGURE 5.1

At $\lambda/4$, $3\lambda/8$, and $\lambda/2$ the azimuthal pattern is the classic figure '8' that is commonly associated with dipoles. The principal difference in these patterns is the particular shape (width, etc.) of the pattern, which varies with antenna size. At $5\lambda/8$ wavelength, the figure '8' persists, but becomes narrower and minor lobes begin to appear. To a receiver, these sidelobes represent responses in directions that may not be desired, and for transmitters it represents wasted energy. At $3\lambda/4$, the pattern blossoms into a four-lobe 'clover leaf' with significant minor lobes. This pattern is seen in ham radio when a half-wavelength 40 m (7 MHz) dipole is used at 15 m (21 MHz). The same physical length that is $\lambda/2$ at 7 MHz is $3\lambda/4$ at 21 Mhz. At $7\lambda/8$ wavelength the minor lobes disappear, and at 1λ the pattern thins out a bit but retains the clover leaf shape.

HALF-WAVELENGTH DIPOLE

It is often the case that a half-wavelength dipole is the first antenna that a new ham operator or short-wave listener will put up. These antennas are low

cost, easy to build, and have a delightful tendency to work well with only a little muss and fuss. They are thus well suited to the newcomer.

Figure 5.2A shows the basic half-wavelength dipole. It consists of a half-wavelength radiator ('B') that is cut into two sections ('A') which are each a quarter-wavelength long. The feedpoint is the middle of the half-wavelength, and for this size dipole the feedpoint is a current node. The feedpoint impedance is therefore a minimum, and the dipole makes a good match to 75 ohm coaxial cable.

It is commonly assumed that the feedpoint impedance of the dipole is 73 ohms, but that is a nominal value which is only true at certain heights above the ground. As can be seen in Figure 5.2B, the actual impedance is a function of the height of the dipole, and at a certain height it converges to 73 ohms. At other heights it can vary from a very low impedance (near zero ohms) up to about 110 or 120 ohms.

The reason for the impedance situation is shown in Figure 5.2C. This graph shows the distribution of voltage and current along the length of the antenna element. Note that the current peaks at the feedpoint and drops to a zero at the ends. The voltage, on the other hand, peaks at the two ends and drops to a minimum at the feedpoint. One of the principal differences between different dipole designs is the issue of whether they are voltage fed or current fed.

The element lengths (in meters) of the half-wavelength dipole would normally be found from $150/F_{\mathrm{MHz}}$ for the overall length, and $75/F_{\mathrm{MHz}}$ for each quarter-wavelength segment. However, because of the velocity factor effects of the length–diameter ratio (which is high for wire HF antennas), and the capactive end effects, a small foreshortening occurs, making the actual lengths closer to

$$B_{\mathrm{meters}} = \frac{143}{F_{\mathrm{MHz}}} \text{ meters}$$

$$A_{\mathrm{meters}} = \frac{71.5}{F_{\mathrm{MHz}}} \text{ meters}$$

These lengths are still only approximate, although in many cases they will be right on the money. There is nonetheless a possibility of needing to lengthen or shorten the antenna if an exact resonant frequency is needed. This is done by either noting the voltage standing wave ratio (VSWR) for the minima being at the desired resonant frequency, or by the feedpoint impedance being close to the design value.

The standard dipole is fed in the center with coaxial cable. For installations really on the cheap, ordinary lamp cord (alternating current wiring) can be used, as it looks like 75–100 ohm parallel transmission line to the antenna. However, except for receiver and the lowest power transmit

operations, it is definitely not recommended. Even receiver operators will fare better with coaxial cable because it has superior noise immunity.

In the usual installation, the dipole will have a center insulator to support the middle ends of the two sections, and to provide the connection spot for the transmission line. The outer ends of the two sections will be supported by end insulators and rope or heavy twine tied to a mast, roof top, or convenient tree. Antenna and radio shops sell special center insulators that provide strain relieved coaxial connections for the transmission line and solder points for the antenna elements.

To BALUN or not to BALUN, that is the question

The BALUN transformer is used to convert between balanced and unbalanced loads. In the context of the dipole, the feedpoint is balanced with respect to the ground, while the transmitter output is unbalanced with respect to the ground. What this means in plain language is that an unbalanced load has one side grounded, while a balanced load is not grounded. Some BALUN transformers also provide impedance transformation, with 4:1 being the most commonly seen. This means that a load of R across the output ports of the transformer is reflected back to the input so that 'looking into' the transformer it will seem like a load of $R/4$. This is the transformer used to reduce 300 ohms from television-style twin-lead to 75 ohms for coaxial cable.

It is common practice to use a 1:1 BALUN transformer at the feedpoint of the half-wavelength dipole antenna (Figure 5.3), even though it provides no impedance transformation (and none is needed). The BALUN transformer balances the load, causing equal but opposite phase currents to flow in the two conductors, and thereby reduces radiation from the transmission line. The effect of the feedline radiation is to distort the radiation pattern. Figure 5.4 shows the effect on the pattern, at least in simplified form. Figure 5.4A shows the 'normal' pattern, which is what we saw in Figure 5.1C. But radiation from the feedline, and unbalanced current flow, tends to cause the nulls to fill in and the main lobes to reduce a bit (Figure 5.4B). In some cases, the afflicted pattern is a lot more distorted than shown in Figure 5.4B, which is a highly simplified case. When a BALUN transformer is used, however, the resultant pattern will look a lot nearer the ideal than the distorted version, and the dipole will perform as expected.

The use of the BALUN in the half-wavelength dipole is one of those controversial things that radio enthusiasts debate seemingly endlessly, but there is no real controversy. The simple fact is that half-wavelength dipoles work better in practical situations when a 1:1 BALUN is used to interface the coaxial cable transmission line to the antenna feedpoint. The only excuse to not use a BALUN, in my not so humble opinion, is the economic one.

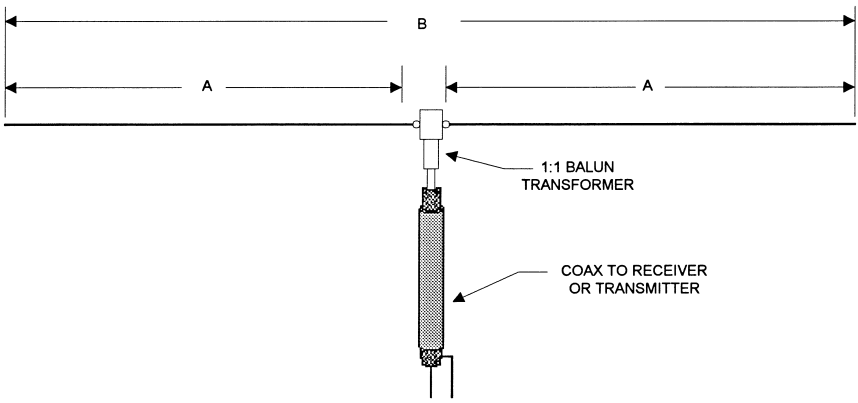

FIGURE 5.3

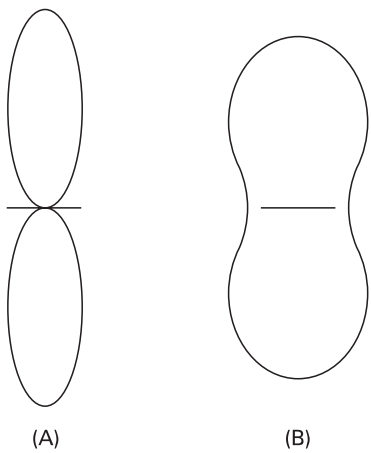

FIGURE 5.4

There were, after all, periods in my life when even so low a priced item as an HF BALUN was very dear indeed, so I used an end insulator at the feedpoint instead (once I even used a discarded toothbrush as a center insulator – and it even lasted a month or two before it broke).

MULTIBAND AND WIDE-BAND HALF-WAVELENGTH DIPOLES

The half-wavelength dipole is a resonant antenna, so it works best only on and near the center design frequency. The classic figure '8' pattern is found only at this frequency and certain lower frequencies (for which the antenna is $\lambda/4$ or $3\lambda/8$). The antenna also provides performance at odd integer

harmonics of the design frequency, but with a multilobed pattern (see Figure 5.1 again). But there are some things that can be done to accommodate the multiband interests of typical radio hobbiests. For one thing, we could put up a different dipole for each band. But even if you have the space, the installation would look like an aerial rat's nest of wires, and it requires switching the feedlines at the rig or receiver to change bands. Not a good idea, actually.

The other approach is shown in Figure 5.5: connect dipoles for different bands to the same transmission line. One can get away with this because the feedpoint impedances of the dipoles are very high except at their resonant frequency, so do not materially affect the feedpoint impedance of whichever dipole is in use at any given time. In Figure 5.5, dipole A1–A2 works at the highest band, B1–B2 works at a middle band, and C1–C2 works at the lowest-frequency band. One precaution is to ensure that none of the dipoles is cut to a frequency that is an odd integer multiple of the resonant frequency of one of the other dipoles. If, for example, you make C1–C2 cut to 7 MHz, and A1–A2 cut for 21 MHz, then the half-wavelength 21 MHz dipole A1–A2 will be in parallel with the $3\lambda/4$ wavelength 21 MHz operation of A1–A2. The low impedances will be in conflict and the pattern will be bizarre. Note, however, that $3\lambda/4$ operation means that proper selection will yield six-band operation from this 'three-band' antenna.

A certain precaution is needed when the multiband dipole is connected to a radio transmitter. Many of the HF amateur radio bands are harmonically

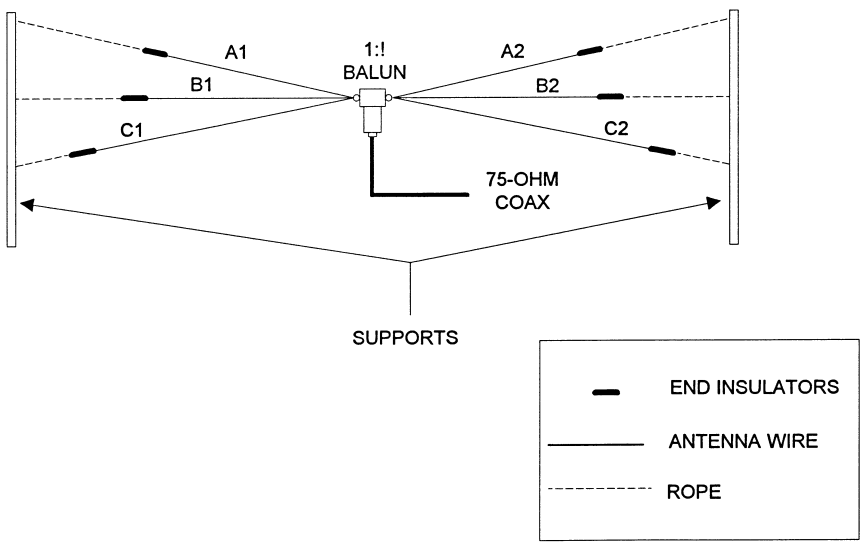

FIGURE 5.5

related. This was done, I am told by some old timers, because in the 'golden oldie' days, trapping harmonics was not as easily done as today, and amateur transmitter harmonics would fall into another amateur band, rather than onto a commercial band or public safety band. If one of the other dipoles is cut to a harmonically related band, then that harmonic looks into a resonant antenna and will radiate efficiently. If you use this type of antenna, then be certain to use a low-pass filter with a cut-off between the two bands, or use an antenna tuning unit that is not a high-pass filter (as some are), or otherwise make sure that your transmitter is harmonic free.

Figure 5.6 shows a method for producing a very wide-band dipole. This particular version was designed for use by radio science observers who listened for radio emissions from the planet Jupiter in the 16–26 MHz short-wave band. These sounds are rather strong, and can appear anytime Jupiter is above the horizon, day or night. Although a beam antenna would have been more useful in this project, the small college physics department who needed it was unable to afford a proper array, so had to make do with a simple dipole.

The idea in this design is to parallel connect three half-wavelength dipoles with overlapping frequency responses. In this particular case, the antennas were cut for 18, 21, and 24 MHz. Some amateur radio operators will use this type of antenna, but with only two dipoles, with one cut for a frequency one-third the way through the band and the other at two-thirds the way through the band. For example, in the 15 m band (21.0–21.450 MHz), the low-end antenna is cut for 21.15 MHz and the high-end antenna for 21.3 MHz.

Figure 5.7 shows how this antenna works. In Figure 5.7A we see the frequency response of a single-dipole antenna. This curve plots VSWR versus frequency. The lowest point on the VSWR curve is the resonant frequency of the antenna, and is hopefully where you designed it. Note that the VSWR climbs fairly rapidly as you get away from the resonant frequency. In Figure 5.7B we see the effect of overlapping the VSWR versus frequency curves of three antennas designed for adjacent segments of

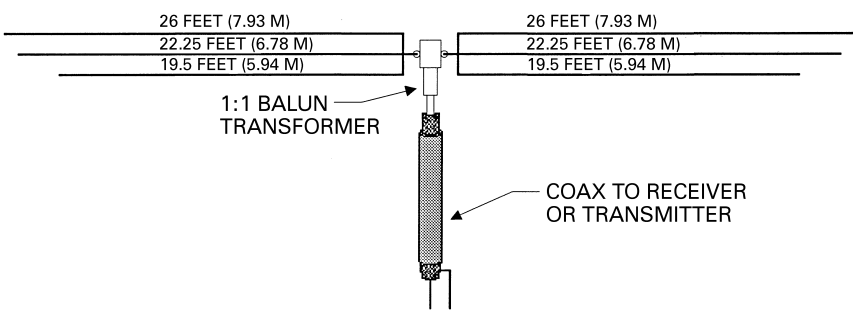

FIGURE 5.6

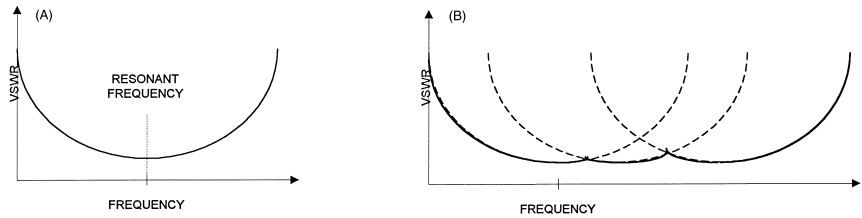

FIGURE 5.7

the band. The overall VSWR seen by the antenna is basically the lowest point on the composite curve (although there is some interaction in real antennas!).

FOLDED DIPOLES

The **folded dipole** antenna (Figure 5.8) has a wider bandwidth than the common dipole, although at the expense of a little constructional complexity. This antenna consists of a loop of wire made from a half-wavelength section of twin-lead or parallel transmission line. The most common form of folded dipole uses 300 ohm television twin-lead for the antenna element. Note that the two conductors of the twin-lead are shorted together at both ends of the radiator. The feedpoint is formed by breaking one of the two conductors at the midpoint. The feedpoint impedance of this antenna is just under 300 ohms, so it makes a good match to another piece of 300 ohm twin-lead used as a transmission line.

The overall length of the folded dipole is found from the same equation (see above) as a regular half-wavelength dipole. There may be a small amount of additional foreshortening due to the velocity factor of the twin-lead, so this length may be a tad long for the desired frequency. You can adjust to the desired frequency by trimming the same amount off of each end while monitoring the VSWR to determine the resonant frequency.

If you want to use coaxial cable to feed the folded dipole, then place a 4:1 BALUN transformer at the feedpoint. This transformer reduces the feedpoint impedance from near 300 ohms to near 75 ohms, and so makes a good match to 75 ohm coaxial cable (e.g. RG-59 or RG-11).

The folded dipole made of twin-lead can be used with moderate amounts of radio frequency (RF) power in transmitting stations, and all receiving stations, but one has to be a bit careful as power levels increase. I recall one 40 m folded dipole excited with around 300 W of RF that got uncomfortably hot to the touch after a few minutes of CW operation.

Folded dipole construction always looks easier in books than it is in real life. The problem is that the conductors used in 300 ohm twin-lead are small, and not intended to support any weight or sustain under wind forces (which

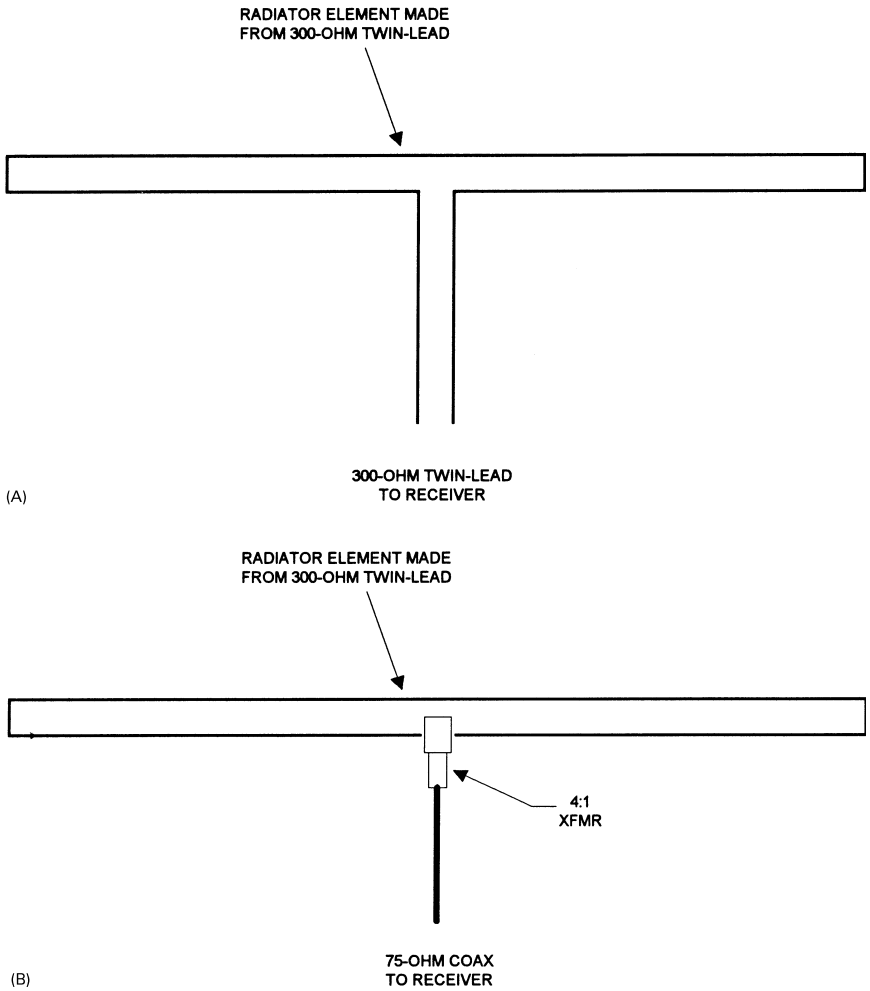

FIGURE 5.8

can be larger than most of us imagine because an antenna has a large 'sail area' in wind). As a result, folded dipoles usually break and come down either at the feedpoint or one of the two ends. The solution is to make fittings such as shown in Figure 5.9 for the center (Figure 5.9A) and ends (Figure 5.9B).

The folded dipole fittings of Figure 5.9 are made of an insulating material. I have seen similar devices made of hardwood salvaged from flooring, and then coated in polyurethene or varnish to protect against rain. Others use Plexiglass, Lexan, or other materials. I have even seen one commercial folded dipole center insulator made of nylon, but it seems to have disap-

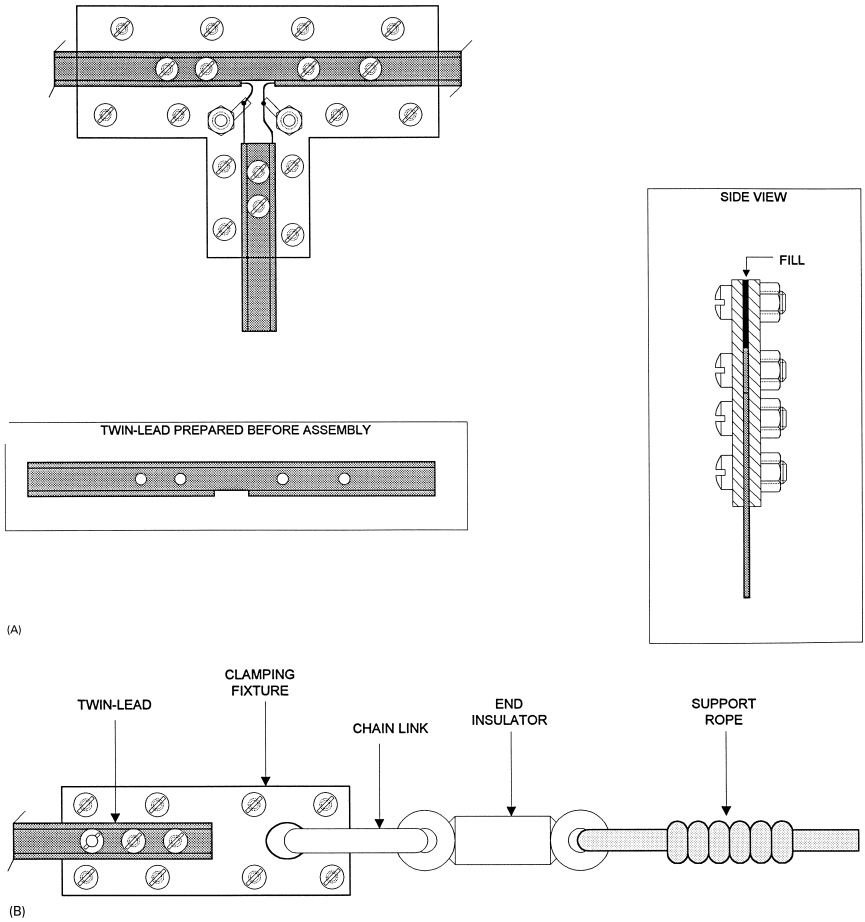

FIGURE 5.9

peared from the marketplace. In Figure 5.9A, the wire connections are soldered to solder lugs attached to brass machine screws. All other screws and nuts are made of nylon to minimize interaction with the antenna. Note in Figures 5.9A and 5.9B that holes are cut into the insulation of the twin-lead, and nylon machine screws are passed through both these holes and mating holes cut into the mounting device; matching hex nuts on the other side secure the screw (see side view inset to Figure 5.9A). This keeps the twin-lead from slipping out of the block, or at least delays the day when failure might occur.

The screw holes in the twin-lead (see inset to Figure 5.9A) can be made with an ordinary paper hole punch, although one has to squeeze a bit hard on the better grades of twin-lead.

INVERTED-'VEE' DIPOLE

The **inverted-'vee' antenna** (Figure 5.10) is a dipole that is supported in the center from a mast or other support, with the ends drooping toward the ground. As with other forms of dipole, the ends are supported using end insulators and rope. But instead of finding a convenient high spot to support the ends, the rope is tied off to a ground level support, or a stake driven into the ground if none exists. Keep in mind, however, that only the type of tent pegs that are intended for high-wind areas (i.e. the type with prongs) should be used. Otherwise, drive a long stake into the ground. The wires of this antenna have a rather large sail area, and the forces could easily pull out the ground supports over time.

The inverted-'vee' antenna is fed in the center with 75 ohm coaxial cable and a 1:1 BALUN transformer. In some cases, you will find that 52 ohm coaxial cable is a better match. The angle between the radiator elements at the top of the mast should be 90–120°. The directivity is based on the figure '8' of a dipole, but with considerable filling in of the nulls off the ends.

The length of the wire elements can be a quarter wavelength each (a half wavelength overall), or any odd integer multiple of a quarter wavelength. Because of the sloping of the elements, the actual length is of the order of 5–6% longer than for an equivalent horizontal dipole at the same frequency. The quarter-wavelength element lengths are found from

$$L_{\text{meters}} = \frac{76}{F_{\text{MHz}}} \text{ meters}$$

As with all antennas, the actual lengths required will be found experimentally using the calculated figure as a starting point.

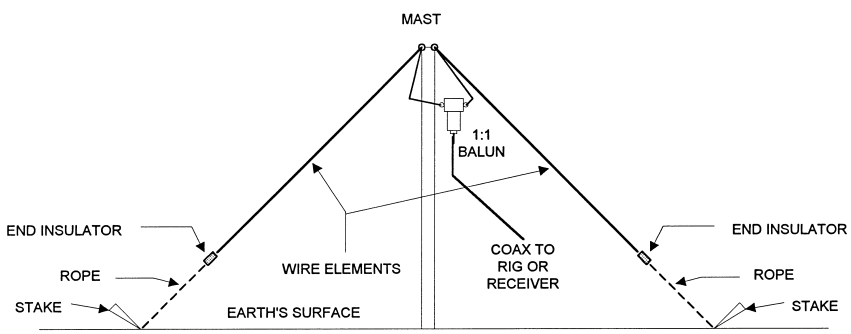

FIGURE 5.10

SLOPING DIPOLE

The **sloping dipole** (Figure 5.11) is a half wavelength dipole. Like the inverted-'vee', this dipole slants from a support (mast, tree, rooftop) to the ground. Unlike the 'vee', however, the sloping dipole has the entire half wavelength in one sloping element. The length of each quarter-wavelength element is found from the same equation as for the inverted-'vee'.

VERTICAL DIPOLE

A refinement of the sloping dipole is the vertical dipole shown in Figure 5.12. Like all verticals, the azimuthal pattern of this antenna is omnidirectional if nothing distorts it. The vertical dipole antenna works especially well in locations where there is limited space, and the desired frequencies are in the higher end of the HF spectrum. Lower-frequency vertical dipoles can be accommodated if a support of sufficient height is available. The lengths of the quarter-wavelength elements are found from $150/F_{\mathrm{MHz}}$, although this length will almost certainly need trimming to find the actual length.

The feed shown in Figure 5.12 is a direct feed with 75 ohm coaxial cable. If you wish to substitute a 1:1 BALUN, however, feel free. Indeed, it is recommended.

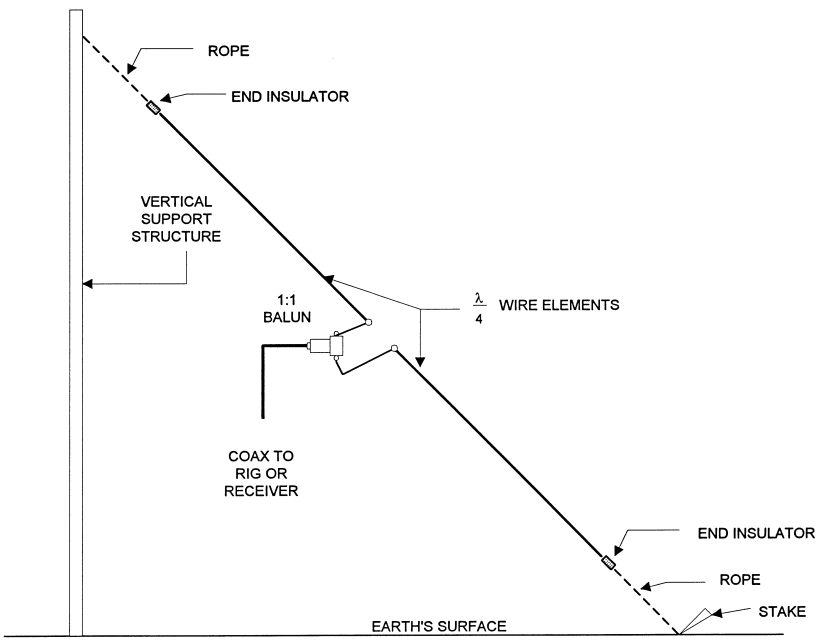

FIGURE 5.11

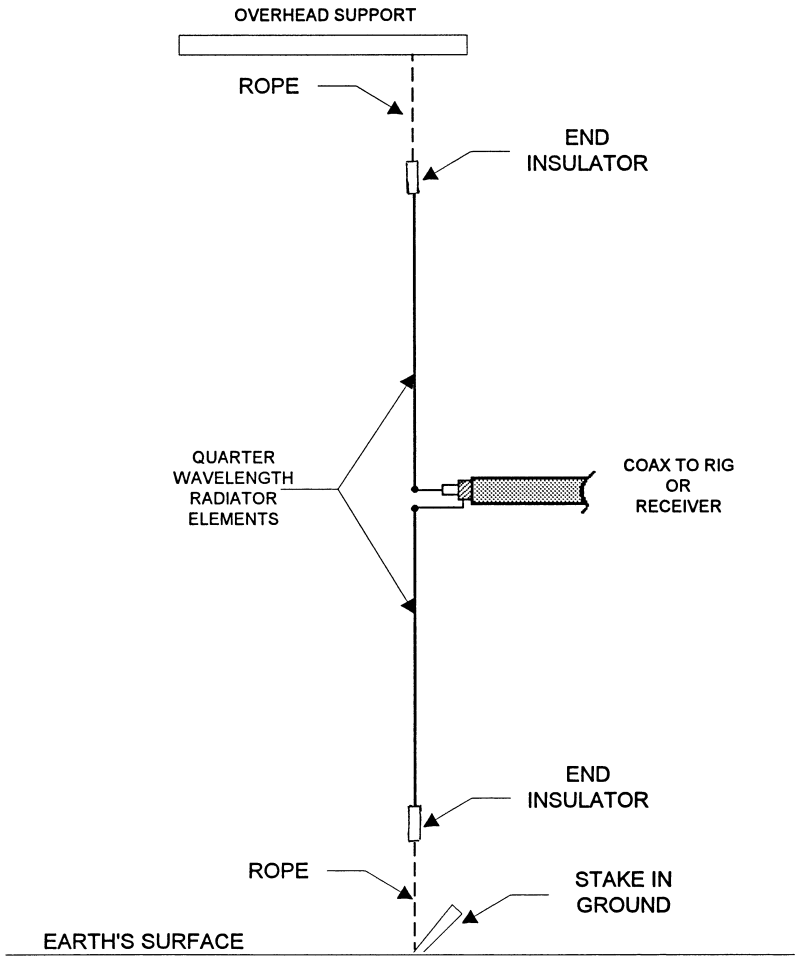

FIGURE 5.12

DELTA-FED DIPOLE

Most of the dipoles shown thus far are fed with coaxial cable. The **delta-fed half-wavelength dipole** (Figure 5.13) uses parallel feedline (either open line or 450 ohm twin-lead) and a delta match scheme. The feedline is non-resonant, and must be connected to an antenna tuning unit that has a balanced output. The lengths are found from

$$A_{\text{meters}} = \frac{142}{F_{\text{MHz}}} \text{ meters}$$

$$B_{\text{meters}} = \frac{54}{F_{\text{MHz}}} \text{ meters}$$

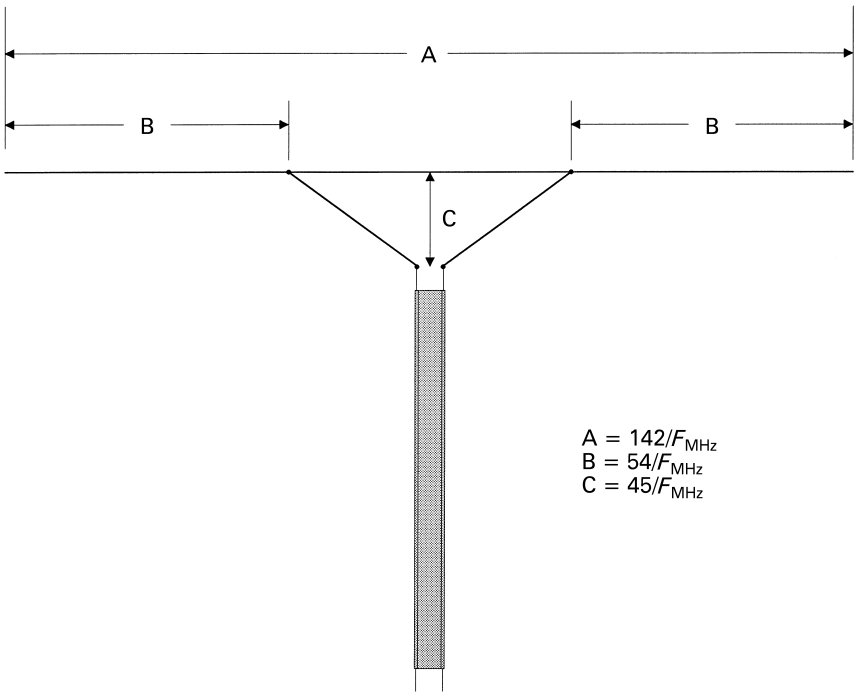

FIGURE 5.13

$$C_{\text{meters}} = \frac{45}{F_{\text{MHz}}} \text{ meters}$$

The delta-fed dipole was very popular prior to World War II, and still finds some adherents.

BOW-TIE DIPOLE

Figure 5.14 shows the 'bow-tie dipole' wide-band antenna. It is not quite like the wide-band antenna shown in Figure 5.6 because both wires in both elements are cut to the same frequency. Wide-band operation is achieved by spreading the ends of the two wires in each element approximately 11% of the total length. Length L (in meters) is found from $127/F_{\text{MHz}}$, and the spread width $W = 0.11L$. For a frequency of 4.5 MHz, therefore, the overall length of the antenna is $127/4.5 = 28.22$ m, so $W = 0.11 \times 28.22 = 3.1$ m. The bandwidth of the antenna is achieved because spreading the ends supposedly controls impedance excursions that would normally occur when the frequency departs from resonance.

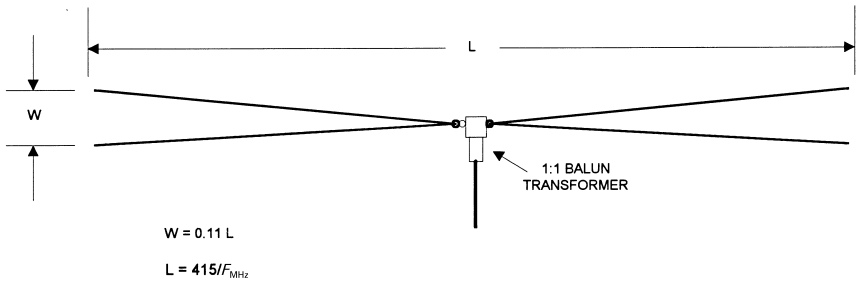

FIGURE 5.14

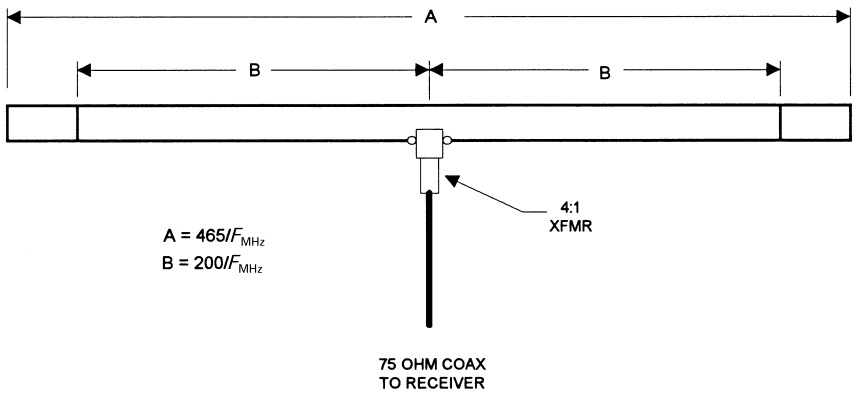

FIGURE 5.15

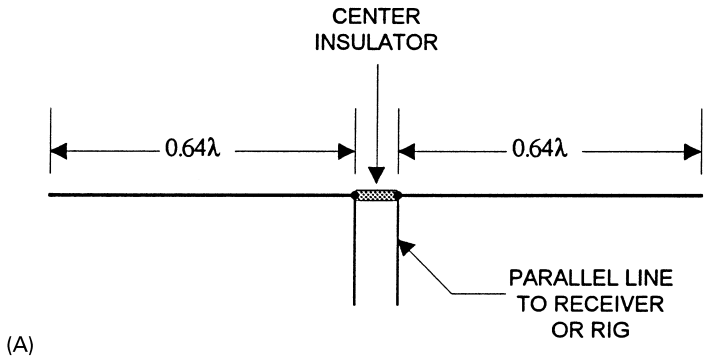
WIDER BANDWIDTH FOLDED DIPOLE

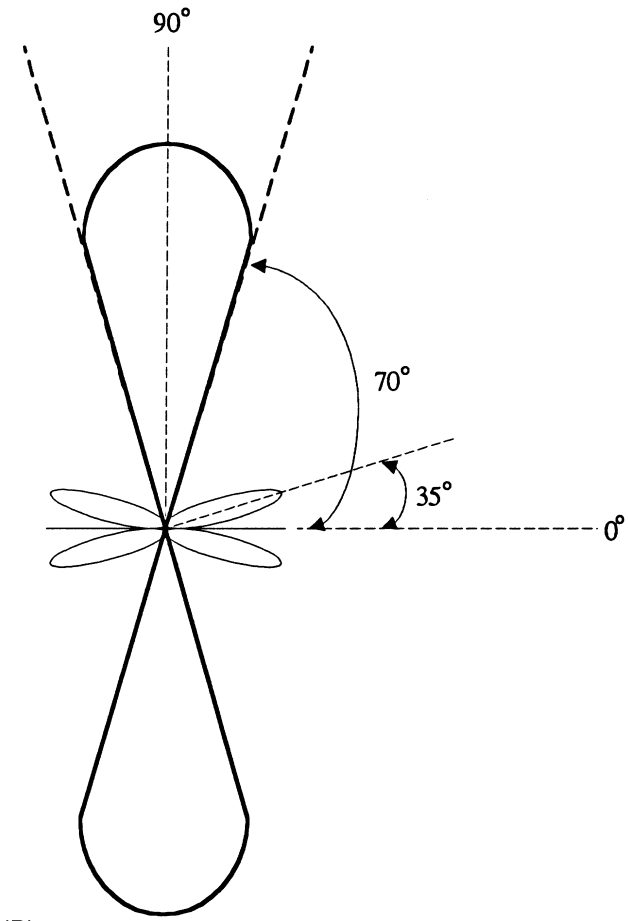
Figure 5.15 shows a wider bandwidth folded dipole antenna. This antenna is made from 300 ohm twin-lead. Like all folded dipoles, the parallel conductors are shorted at the ends, and one conductor is broken at its center to accommodate either a 300 ohm twin-lead feedline to the receiver, or a 75 ohm coaxial cable coupled to the antenna through a 4:1 BALUN transformer. In the antenna of Figure 5.15, however, there is a difference from the normal folded dipole format: shorts are placed between the two conductors at very critical distances (B) from the feedpoint. The overall length (A) of the folded dipole is given by $142/F_{\mathrm{MHz}}$, while the distance between the inner shorts (B–B) is $122/F_{\mathrm{MHz}}$, i.e. the distance from the feedpoint to each inner short is $61/F_{\mathrm{MHz}}$.

DOUBLE EXTENDED ZEPP

The double extended Zepp antenna (Figure 5.16A) is a dipole in which the overall length is 1.28λ, and each element is 0.64λ. It provides about 3 dB



(A)



(B)

FIGURE 5.16

gain over a dipole. The azimuthal pattern (Figure 5.16B) is a narrowed figure '8' with sidelobes appearing at $\pm 35^\circ$ from the line along the antenna length.

The length of each 0.64λ element is found from

$$L_{\text{meters}} = \frac{163}{F_{\text{MHz}}} \text{ meters}$$

This antenna must be fed with parallel line connected to an antenna tuning unit with a balanced output. However, if you build a one-eighth wavelength matching section from 450 ohm twin-lead, then you can reduce the impedance to 150 ohms. The length of the 450 ohm twin-lead matching section is

$$L_{\text{meters}} = \frac{31.4}{F_{\text{MHz}}} \text{ meters}$$

The impedance looking into the matching section is 150 ohms, so using 75 ohm coaxial cable results in a 2:1 VSWR. However, if a 4:1 BALUN transformer is provided, then the impedance is transformed to $150/4 = 37.5$ ohms. If 52 ohm coaxial cable is used with this scheme, then the VSWR $= 52/37.5 = 1.4{:}1$.

MULTIBAND TUNED DOUBLETS

An antenna that was quite popular before World War II with ham operators and short-wave listeners is still a strong contender today for those who want a multiband antenna, provided that the bands are harmonically related. Figure 5.17 shows the **multiband tuned doublet** antenna. This antenna consists of a nominal half-wavelength wire radiator that has a physical length (in meters) of $145/F_{\text{MHz}}$, where F_{MHz} is the *lowest* frequency (expressed in megahertz) of operation. Note this difference: many antennas are designed for the center frequency of the band of interest, while this one is designed for the lowest frequency. The antenna will perform well on harmonics of this frequency, and will perform at least somewhat on other frequencies as well if a higher VSWR can be tolerated. This situation is seen for receiver operators, but is often a limiting case for transmitter operators.

The feed of this antenna is through a quarter-wavelength matching section made of 450 ohm twin-lead transmission line. The length of the quarter-wavelength section is $73/F_{\text{MHz}}$. Although one may get away with replacing the heavier 450 ohm line with lighter 300 ohm line, it is not appropriate to replace the line with coaxial cable and a 4:1 BALUN as is done in other antennas. The reason for this is that the twin-lead forms a set of tuned feeders, so is not easily replaced with an untuned form of line.

The lengths for typical antennas of this sort are given in Table 5.1.

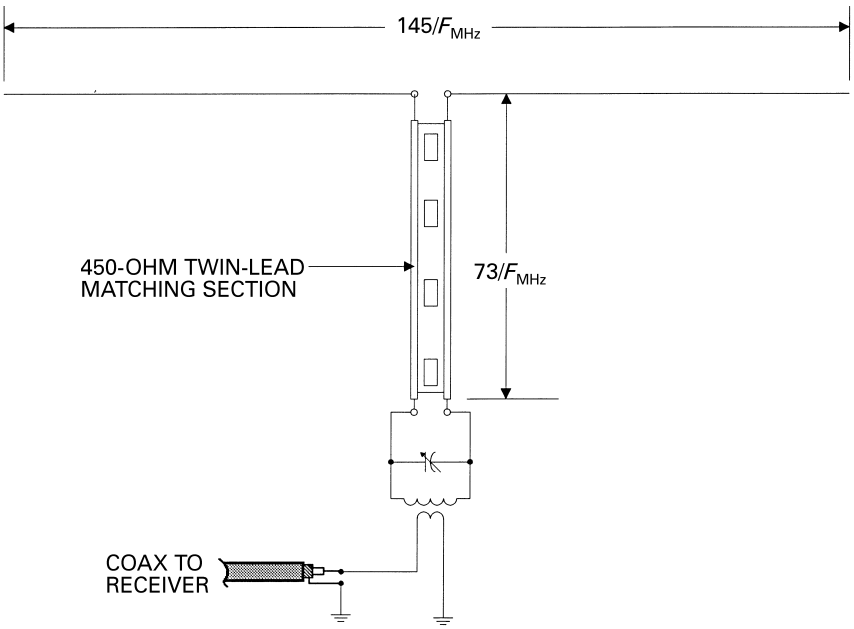


FIGURE 5.17

TABLE 5.1

Lower frequency (MHz)	Radiator element (m)	Matching section (m)
3.5	41.43	20.86
5.0	29.00	14.60
7.0	20.71	10.43

One consequence of this configuration is that a balanced antenna tuner is needed at the feed end of the matching section. The version shown here is a parallel resonant LC tank circuit that is a transformer coupled to a low-impedance link to the receiver or transmitter. The inductor and capacitor for this tuner should be designed so that they have a reactance of about 600 ohms at every frequency required. This may mean a tapped or variable inductor, or bandswitched inductor, as well as a variable capacitor. Commercial antenna tuners can also be used for this application.

THE G5RV ANTENNA

The G5RV antenna (Figure 5.18) is controversial for several reasons. One reason is the originator of the antenna. The name 'G5RV' is the call-sign of the claimed originator, Louis Varney, a British ham operator. Others claim

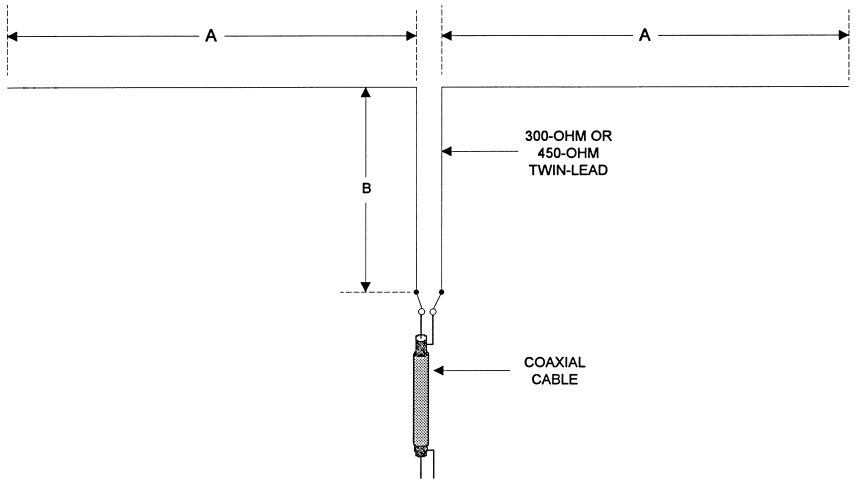

FIGURE 5.18

that the G5RV antenna is nothing but a 1930s or 1940s vintage design by Collins Radio for the US military. However, the similarities between the Collins antenna and the G5RV are, it seems to me, at best a case of 'further development' or 'co-invention,' rather than something more sinister. Because of the obvious differences between the two antennas, I prefer to continue the credit due to G5RV.

Another reason for the seeming controversy over the G5RV is perhaps the 'NIH syndrome' (not-invented-here). The G5RV is more popular in Europe than in the USA. In my own experience, the G5RV tends to be built in the US by antenna experimenters, and most of those who I have talked to are happy with the results.

Still another controversy is over whether, or how well, the G5RV works. One reviewer of one of my other antenna books (*Joe Carr's Receiving Antenna Handbook*, Universal Radio) stated that he 'wish(es) the G5RV would just go away.' The same reviewer stated that it would be better to just put up a 'dipole of the same size.' Wrong! The dipole is a single-band resonant antenna, whereas the G5RV will work on several harmonically related bands. The G5RV has two poles, but it does not exactly fit into the same category as the half-wavelength dipole.

PHYSICAL STRUCTURE OF THE G5RV

The G5RV antenna looks like a dipole, to be sure, but its length is considerably longer. Unlike many multiband antennas, the G5RV is not cut to

the lowest frequency of operation, but rather to the middle frequency. For an HF ham band antenna, one designs it for 20 m (14 MHz).

Like the dipole, the G5RV is fed in the center. Unlike the dipole, a matching section made of 450 or 300 ohm twin-lead transmission line (450 ohm is preferred) is connected between the antenna feedpoint and the 75 ohm coaxial cable. The length of each radiator element (A) is

$$A = \frac{220}{F_{\text{MHz}}} \text{ meters}$$

While the length of the matching section (B) is

$$B = \frac{146V}{F_{\text{MHz}}} \text{ meters}$$

A is the length of each radiator element, B is the length of the 450 ohm matching section, F_{MHz} is the middle frequency of operation, and V is the **velocity factor** of the twin-lead (typically 0.82 for twin-lead and 0.99 for open-wire parallel line).

In case you do not like to do arithmetic, the calculations have already been done for the HF ham bands: $A = 15.55$ meters ($2A = 31.1$ m overall), and $B = 10.37$ m for open-wire transmission line and 8.38 m for 300 or 450 ohm twin-lead. There is some argument over these figures, but they are regarded by many hams who have actually used the antenna as a good trade-off.

If you want more technical details on the G5RV, Louis Varney, the inventor, has written about the antenna in a number of publications. Varney gives the basis for operation of the G5RV antenna at 3.5, 7, 10, 14, 18, 21, 24, and 28 MHz. The VSWR on each band is a bit different, and Varney recommends the use of a transmatch or similar coaxial-to-coaxial antenna tuning unit between the transmitter and the input to the coaxial cable transmission line.

There is a possibility of an unbalanced line condition existing that causes some radiation from the feedline – and for transmitters that can cause television interference (TVI) and other forms of unpleasantness. The solution to this problem is to wind the coaxial cable into an in-line choke at the point where the coaxial cable connects to the twin-lead or parallel line matching section. This is done by winding the coaxial cable into a 15 cm diameter coil of 10 turns right at the feedpoint. The coiled coaxial cable can be secured to the center insulator by tape, string, or some other mechanism.

BALUNS ON RECEIVER ANTENNAS?

Above I mentioned a reviewer who did not like the G5RV antenna. The same reviewer stated that he did not believe that 1:1 BALUN transformers are useful on half-wavelength dipole receiving antennas. My calm, professional, well-considered response is: *rubbish*! The purpose of using a 1:1 BALUN (which after all provides no impedance transformation) is twofold. First, as in the transmit case, the BALUN prevents radiation from the transmission line. Perhaps the reviewer was thinking of TVI as the reason for avoiding feedline radiation. But, as ample test chamber evidence shows, the radiation from the feedline tends to distort the figure '8' azimuthal pattern. When a BALUN is used, the currents are balanced, and the radiation pattern is restored. And guess what? Antennas are reciprocal in nature – they work the same on receive as on transmit.

The second reason is that the receiver antenna feedline may pick up strong signals from powerful local stations. Other hams and AM broadcast band stations are particular problems. Any large signal at the input may challenge even the best receiver front-end, but if the receiver design is in any way mediocre in the dynamic range department (and many are!), then the signals picked up on the dipole transmission line shield can overload the front-end of the receiver. Using a 1:1 BALUN transformer between the antenna feedline and the radiator elements balances out the currents and seriously reduces the amount of signal seen by the receiver input.

LINEAR LOADED WIDE-BAND DOUBLET

Figure 5.19 shows an antenna that superficially resembles both the folded dipole and the G5RV, but is actually a wide-band antenna with a linear loading section between the radiators. The overall length of the main radiator elements is $146/F_{\mathrm{MHz}}$ meters, while the linear loading element is $133/F_{\mathrm{MHz}}$ meters long. The radiator elements are separated about 30.5 cm, with the linear loading element placed in the middle, 15 cm from each element. The linear loading element is placed horizontally about the mid-point of the antenna. The spreaders can be ceramic, or made of any insulating material. In one variant that I built, ordinary wooden dowels (1 cm diameter) were used, although I am not too sure it will weather well unless treated with some kind of coating.

This antenna is fed through 'any' length of 450 ohm twin-lead, but practical advice from several people who have actually built this antenna suggest that 'any' should be read as 'one-fifth to one-half the length of the radiator elements.' A 9:1 BALUN transformer is connected to the feedpoint, and coaxial cable routed to the receiver.

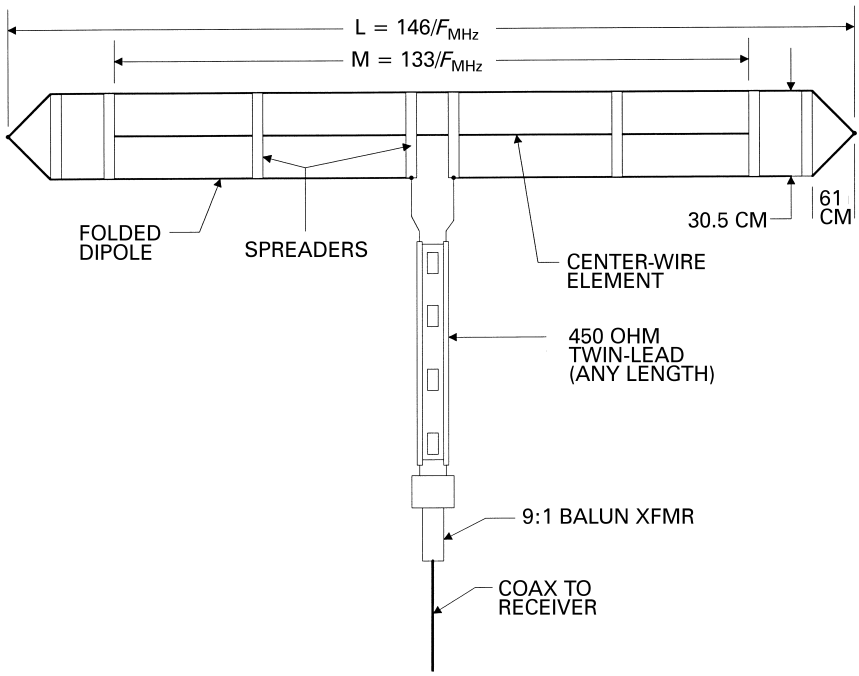

FIGURE 5.19

One practical problem with this antenna is that it tends to flop over because it is top heavy. Two solutions present themselves. First, do not tie off the ends in a single rope, but rather attach two ropes to the supporting structure at each end. Second, tie rope or fishing line from the bottom radiator at each end to a supporting structure below, or to stakes in the ground. One fellow used fishing weights for this purpose. The weights were attached to the bottom radiator element at the far ends.

THE AUSSIE BROAD-BAND HF DOUBLET FOR RECEIVERS

One of the problems with most of the antennas in this chapter is that they work on a single resonant frequency, and a narrow range of frequencies around it. Some of them will work over relatively wide bandwidths, but the coverage is nonetheless limited with respect to the entire HF spectrum. The Aussie doublet shown in Figure 5.20 is a receive antenna with a VSWR less than 2.5:1 over the entire 3–30 MHz range of the HF band.

This antenna is rather large, being 40 m long and 1.8 m wide, so requires some space to erect. Also, the two conductors of each segment are separated by insulating spacers. One approach to making these very long (1.8 m) spacers is to use PVC plumbing pipe or small size lumber. Even then, the

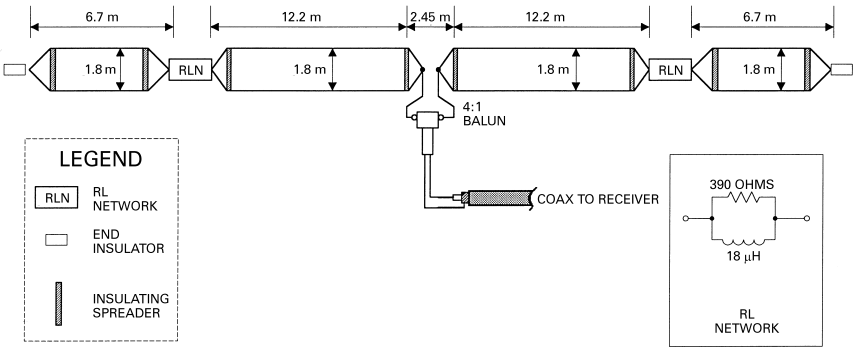

FIGURE 5.20

antenna will tend to flop over and lay flat unless rope moorings to the ground are provided along the bottom conductor.

Part of the broad-banding effect is provided by the two-wire design and their spacing, but much of it is also provided by a pair of RL networks ('RLN' in Figure 5.20). Each network is a 390 ohm resistor in parallel with an 18 μH inductor. It is these components that limit the use of this antenna for transmitting, although moderate powers can be accommodated if a suitable non-inductive, high-power resistor and a suitably designed inductor are provided.

THE CAPACITOR-TUNED WIDE-BAND DIPOLE

Dipole antennas are resonant and so will operate effectively over a relatively narrow band, as well as the third harmonic of that band. It is possible to broaden the response of the antenna by inserting a variable capacitor at the feedpoint (Figure 5.21). This capacitor should have a maximum value of 500 pF, although 730 and 1100 pF have been successfully used. The latter two values represent the values obtained when two or three sections of a 365 pF broadcast variable capacitor are used (receive only). For transmitting, a wide air gap capacitor ('transmitting variables') or vacuum capacitor should be used.

The best solution for using this antenna is to mount the capacitor at the feedpoint inside of a weatherproof housing, and then use a low-voltage, low-RPM direct-current (DC) motor to drive it. Voltage to the motor can be supplied through a separate wire, using the coaxial cable shield as the DC return line. In another scheme, it is also possible to use the coaxial cable center conductor to carry the DC (with the shield acting as the return), but it is necessary to separate the motor and signal line with an RF choke at both

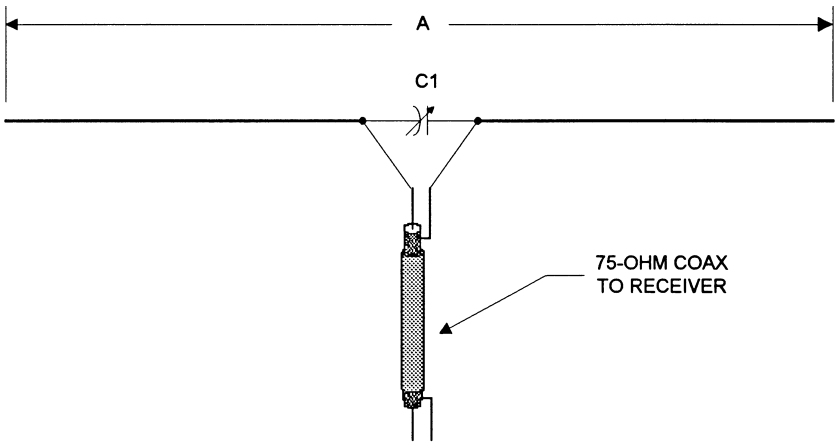

FIGURE 5.21

ends of the transmission line. IT IS VERY IMPORTANT TO USE LOW-VOLTAGE DC FOR THIS JOB. DO NOT USE AC POWER MAINS VOLTAGE!

THE INDUCTOR-LOADED SHORTENED DIPOLE

At low frequencies, dipole antennas can take up a large amount of space. At 75/80 m ham bands, for example, a half-wavelength dipole is 41 m long; at 5 MHz, the length is still 28.5 m. This fact of physics can ruin the plans of many radio enthusiasts because of space limitations. There is, however, a method for making a dipole one-half the normal size. Figure 5.22 shows a dipole that is one-half the size of the normal half-wavelength dipole, even though it simulates the electrical half wavelength.

An antenna that is too short for its operating frequency offers a capactive reactance component to the impedance at the feedpoint. In order to tune out this impedance the opposite form of reactance, inductive reactance, is placed in series with each radiator element. Although the inductors can be placed anywhere along the line, and the overall length can be any fraction of a 'full-

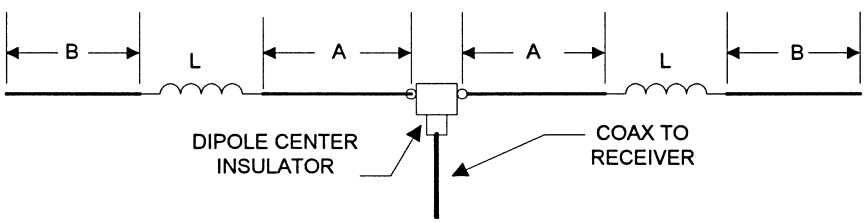

FIGURE 5.22

size' half-wavelength, the design gets a bit messy. A compromise is found by limiting our selections: (1) the overall length is one-half the normal length; and (2) the inductors are placed at the center of each element. If these rules are followed, then we have a shot at making this antenna with only a small amount of discomfort in the math zone. In this limited case, the reactance of each coil is 950 ohms in the middle of the band of interest. The procedure is as follows:

(a) Calculate the overall length of the elements: $L_{\text{meters}} = 37.5/F_{\text{MHz}}$. This is the overall length of the half-size antenna.
(b) Divide the number obtained in step (a) by 2. This is the length of each segment of wire (A or B). In our limited case, the assumption is that $A = B$, but in some other cases this assumption might not be true.
(c) Calculate the inductance required to produce a 950 ohm reactance at the design frequency:

$$L_{\mu\text{H}} = \frac{X_{\text{L}} \times 10^6}{2\pi F_{\text{MHz}}}$$

Antennas do not give up convenience for free, however. The price of this antenna design is narrower bandwidth.

MORE MULTIBAND DIPOLES

The shortened inductively loaded dipole of Figure 5.22 can be used on two bands by increasing the reactance of the coil to 5500 ohms at the middle frequency of the highest band. For example, you can make a 75/80 m plus 40 m dipole. The inductor in this case serves not only to foreshorten the antenna's overall length, but also acts as an RF choke to the higher-frequency band. In that case, the sections labelled A in Figure 5.22 are for the higher-frequency band, while $A + B$ is for the lower-frequency band. Approximations of the lengths are found from

$$A = \frac{74}{F_{\text{HI(MHz)}}} \text{ meters}$$

$$B = \frac{4.64}{F_{\text{LO(MHz)}}} \text{ meters}$$

In this antenna, the sections A act like a regular half-wavelength dipole at the higher frequency, while the sections $A + B$ act like a shortened inductively loaded dipole at the lower frequency. You are well advised to leave extra space on the B-sections for adjustments. This antenna tends to be narrower in bandwidth on the lower band, so may require some fiddling with lengths to achieve the desired resonance.

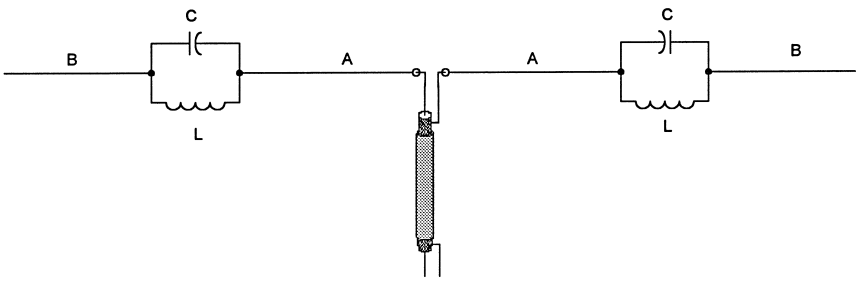

FIGURE 5.23

Another approach to multibanding is shown in Figure 5.23. This antenna is called a **trap dipole** because it uses a pair of parallel resonant LC networks to trap the higher frequency. A parallel resonant network presents a high impedance to signals at its resonant frequency, but a low impedance to frequencies removed from resonance. Like the antenna above, the sections marked A are a half-wavelength dipole at the higher frequency, while the $A + B$ sections form a near-half wavelength at the lower frequency. These lengths are approximated by the normal half-wavelength equations, although some adjustment is in order due to the effects of the trap. The traps consist of an inductor (L) and capacitor (C) in parallel. At resonance, $X_L = X_C = 370$ ohms.

MULTIBAND RESONANT ANTENNAS: MULTIBAND TUNED DOUBLET

An antenna that was quite popular before World War II is still a strong contender today for those who want a multiband antenna, provided that the bands are harmonically related. Figure 5.24 shows the multiband tuned doublet antenna. It consists of a nominal half wavelength wire radiator. The antenna will perform well on harmonics of this frequency, and will perform at least somewhat on other frequencies as well if a higher VSWR can be tolerated.

The feed of this antenna is through a matching section of 450 ohm twin-lead transmission line. Although one may get away with replacing the heavier 450 ohm line with lighter 300 ohm line, it's not appropriate to replace the line with coaxial cable and a 4:1 BALUN as is done in other antennas. The reason for this is that the twin-lead forms a set of tuned feeders, so is not easily replaced with an untuned form of line. One consequence of this configuration is that a balanced antenna tuner is needed at the feed end of the matching section. The version shown here is a parallel

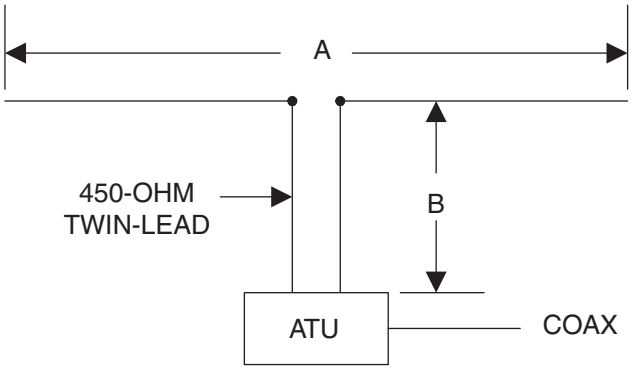

FIGURE 5.24

resonant L-C tank circuit that is transformer coupled to a low impedance link to the receiver.

The antenna is a half wavelength long at the lowest frequency of operation, and the twin-lead is a quarter wavelength long, or an odd integer multiple of quarter wavelengths. The lengths are:

$$A = \frac{144}{F_{\text{MHz}}}$$

$$B = \frac{73}{F_{\text{MHz}}}$$

This antenna depends on an antenna tuning unit (ATU) to be effective, unless the transmitter has a balanced output that can handle the high impedance. The ATU needs to be the type that has a balanced output, rather than the coaxial cable 'line flattener' variety.

THE TILTED, CENTER-FED TERMINATED, FOLDED DIPOLE

Figure 5.25 and the following figures show the *tilted, center-fed terminated, folded dipole* (TCFTFD) antenna, which is a special case of a loop antenna and a folded dipole antenna. The inventor, Navy captain G.L. Countryman (W3HH), once called it a 'squashed rhombic' antenna. The antenna is a widely spread folded dipole, and is shorter than a conventional folded dipole. It must be mounted as a sloper, with an angle from its upper vertical support of 20 to 40°.

The feeding of the antenna is conventional, with a feedpoint impedance close to 300 Ω. A 75 Ω coaxial cable is connected to the bottom half of the antenna through a BALUN transformer that has a 4:1 impedance ratio.

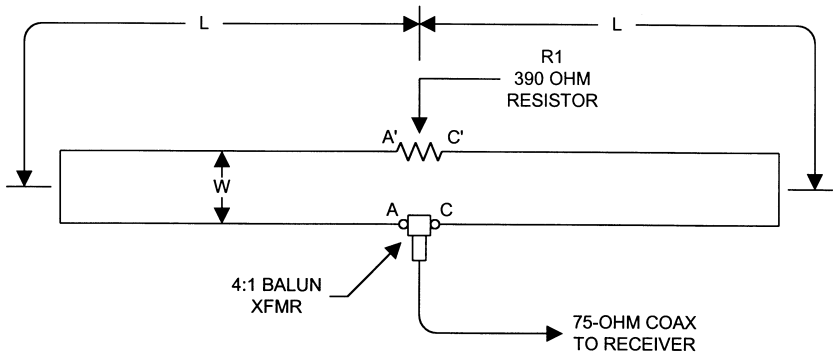

FIGURE 5.25

At the top side of the antenna, the 'feedpoint' is occupied with a termination resistor of 370 to 430 Ω (390 Ω, 1 or 2 watts, makes a good compromise for receiving antennas).

The spread (W) of the antenna wire elements is found from:

$$W = \frac{2.99}{F_{\text{MHz}}}$$

where W is the width of the antenna in meters (m) and F_{MHz} is the frequency in megahertz.

The spreaders are preferably ceramic, strong plastic, or thick-walled PVC pipe. The spreaders can be made of wood (1 × 2 stock or 1-inch dowels) for receive antennas if the wood is properly varnished against the weather.

The overall length of the antenna is calculated a little differently from most antennas. We need to calculate the lengths from the *feedpoint to the middle of the spreaders*, which is also the length from the middle of the spreaders and the terminating resistor. These lengths are found from:

$$L = \frac{54.3}{F_{\text{MHz}}}$$

where L is the length in meters (m) and F_{MHz} is the frequency in megahertz.

Four sections of wire, each with a length defined by the equation above, are needed to make this antenna.

The height of the upper antenna support is determined by trigonometry from the length of the antenna from end-to-end (not the length calculated for D, but approximately twice that length), and the angle. For example, at 7 MHz the lengths are 7.76 meters, and the spreaders are 0.47 cm. Thus, the overall physical length, counting the two element lengths and half of both spreader lengths, is [2 × 7.76 meters – (2 × 0.5)] meters, or 16.52 meters. If the angle of mounting is 30°, then the antenna forms the hypotenuse of a 60/30 right angled triangle. If we allow two meters for the lower support, then the upper support is:

$$\text{height} = 2 + L\cos Q$$
$$= 2 + (16.52\cos 60) = 10.26 \text{ meters}$$

This antenna has a low angle of radiation, and at a tilt angle of 30° (considered ideal) it is nearly omnidirectional.

The termination resistor can be mounted on a small piece of plastic, or alternatively, as shown in Figure 5.26, it can be stretched across the end insulator in the manner of the inductors in the previous section. Use a 390 Ω, 2 watt resistor for this application.

Figure 5.27 shows the installation of the antenna. The upper support and lower support are made of wood, or some other insulating material. There are ropes tying the ends of the antenna to the supports. Detail of the spreaders and end insulators are shown in Figures 5.28 and 5.29, respectively.

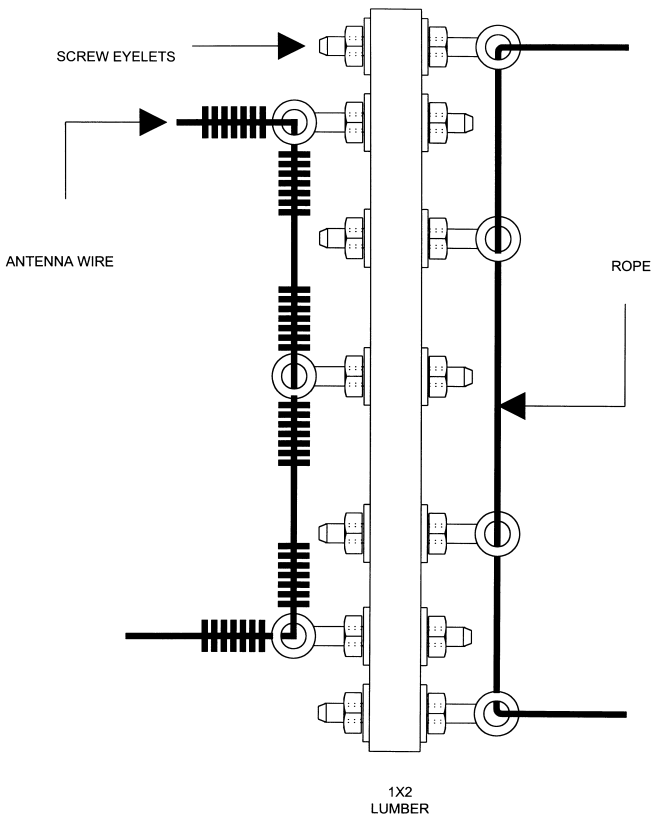

FIGURE 5.29

CHAPTER 6

Limited space antennas

Sometimes at night, when things are well and all is right in the universe, I dream. I dream of owning (or at least renting from a radio enthusiast landlord) about 500 hectares of flat land good for farming. Not that I intend to do any farming (unless 'antenna farm' counts), but good farmland is moist and composed of enough conductive minerals to make a very good radio frequency (RF) ground for antennas!

Dreams are fun to indulge, but on awakening one finds the sometimes harsh nightmare of antenna construction on the limited estates that most of us can afford. And I have lived in some tight spots. In my novice days, living in my parents' home, the lot was respectable by American suburban standards, but was criss-crossed with alternating-current (AC) power lines to both our house and the houses of two neighbors. That problem sharply limited the area open to safe antenna erection. The student boarding house where I lived in college had a sympathetic landlady (who in any event was too poor of sight to notice an antenna short of a beam and tower) was on a shallow, narrow city lot with few possibilities below 20 m (and even that band strained the antenna constructor's imagination). After being married, I lived in an apartment and then a small house of my own for a number of years – all of which were limited spaces. Even with my present home, which seems a mansion compared to our first house, my ability to put up full size antennas is a testament to my wife's tolerant attitude. So what to do?

Fortunately, there are some things that can be done to accommodate the limited space situation. Nearly all of these schemes use some form of com-

pensation antenna, and as a result do not work as well as the full-sized equivalent. The TANSTAAFL principle reigns supreme: '*there ain't no such thing as a free lunch*.' Whenever one attempts to reduce the size of an antenna for any given frequency, the result is that something else falls down a bit: gain, directivity, impedance, efficiency, bandwidth, or all of the above. While these factors may lead one to a depressed sense of gloom and doom, that is not the best attitude. The correct way to view the situation is not comparing the limited space antenna to a full size antenna, or the best in class, but rather to whether or not it allows you to operate at all. After all, a 10 m long, end-fed inductor loaded Marconi draped out of an upper-story window may not work as well as a 75 m dipole, 25 m in the air, but it works well enough to make contacts.

SOME OBVIOUS SOLUTIONS

Not all limited space antenna choices are bad. For example, one could restrict operations to the upper bands, i.e. those above 21 MHz and into the very high-frequency (VHF) region. I know one fellow who was a 300+ country DXCC award holder who operated only on the 15 m ham band because of space limitations (he lived on a small $\frac{1}{12}$ hectare lot). He was able to erect a 15 m two-element quad beam that worked quite well. Another fellow earned his DXCC as a newly licensed amateur (when operating skills are presumedly undeveloped as yet) with a 50 W kit-built transmitter and a 10–15–20 m trap vertical mounted on the roof of a four-story apartment building. It can be done.

The vertical antenna is a decent solution for many people. A full-sized 40 m (7–7.3 MHz) vertical is only 10 m high, and that is right at the legal limit or 10.7 m in my county for an installation that does not need mechanical inspection by the local government. Adding a switchable loading coil at the base of that antenna would also allow 75/80 m operation, especially if an antenna tuning unit is provided.

Modern trap verticals are also a good bet. Several commercially made verticals allow operation over the 40 m band through 10 m and are only 6.5 m tall when mounted on the ground. A good set of radials makes this antenna reasonably efficient. The only drawback is that the omnidirectional pattern makes interference rather constant. The half-wavelength bottom-fed ham-band verticals currently on the market are quite decent DX antennas.

Another obvious solution is to use any of several inductor loaded antennas such as the loops and shortened dipoles shown elsewhere in this book. Some of these antennas can be quite useful. Also, I once operated with a pair of commercial coil-loaded mobile antennas mounted back to back to form a kind of dipole. Did it work well? No! But it worked well enough for me to rack up a lot of DX using an old Heath HW-101 transceiver.

I have also used commercial mobile antennas as fixed verticals. In one case, right after we moved into our first home, I mounted a Hustler mobile antenna for 20 m on the window sill of the upstairs bedroom that served as my office (until the kids started coming along). A pair of radials out of the window, sloping to a fence, completed the 'ground' side of the antenna. It worked rather well, actually. Later on, I added 15 and 40 m coils using one of those attachments that allow three coils to coexist on the same base mast. It worked very well at 15 m and 20 m, and passably well at 40 m.

SOME OTHER SOLUTIONS

Figure 6.1 shows Marconi (Figure 6.1A) and Hertzian (Figure 6.1B) antennas for use in limited space situations. In the Marconi version, the antenna wire is mounted to lay flat on the roof, and then (if possible) to an attachment point on a support such as a mast or convenient tree. The Hertzian version is a dipole, preferably a half wavelength (if you want to use coaxial feed), positioned such that the feedpoint is in the middle of the roof line.

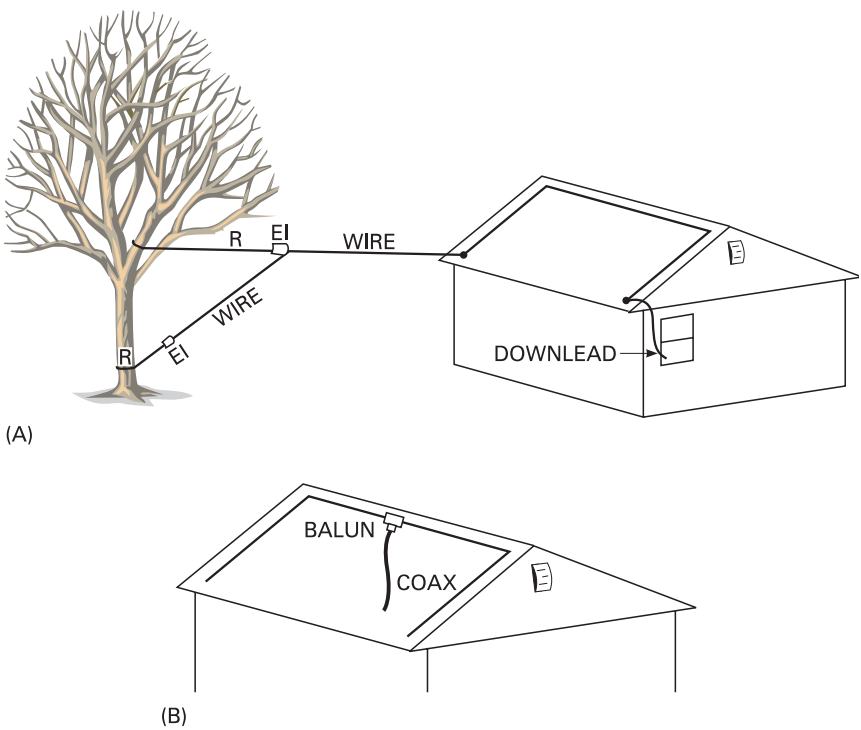

FIGURE 6.1

The idea in building these antennas is to put as much wire in the same direction as possible, but do not worry too much if the goal is not met. The real goal is to get on the air or use your receiver, depending on your interests.

Another solution is the loop antenna shown in Figure 6.2. The best loop is one that is a full wavelength on the lowest frequency of operation, but any convenient loop can be made to work at least part of the way. This is especially true if tuned parallel feeders and a decent antenna tuning unit (ATU) are used.

All of these antennas can be used either on the outside of the roof, or inside the attic. In neither case, especially the latter, would you want to try it on a roof that has a copper or aluminum base. That approach is not used on residential properties much anymore, but if you have an older dwelling the roof may well be copper covered.

Mounting the wire can be a bit of a problem, especially when the antenna is on the outside of the roof. What seems to be the best way is to use nail-in or screw-in stand-off insulators attached to the wooden roof. This works well only when you can seal it against rain water seeping in. Water will wick along the threads, and rot the wood – leading to leaks and expensive repairs. A better approach would be to design a wooden fixture attached to the soffits or overhang in a way that prevents extensive damage. Inside the attic, however, one can easily use standoffs, but they must be attached to a roof rafter (Figure 6.3), rather than the roof covering. A screw thread that penetrates to the outside surface will allow as much water damage (or more) than a thread going the other way.

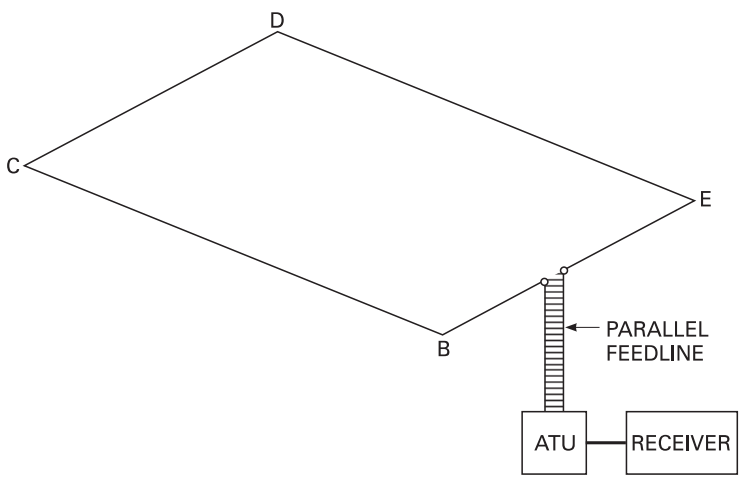

FIGURE 6.2

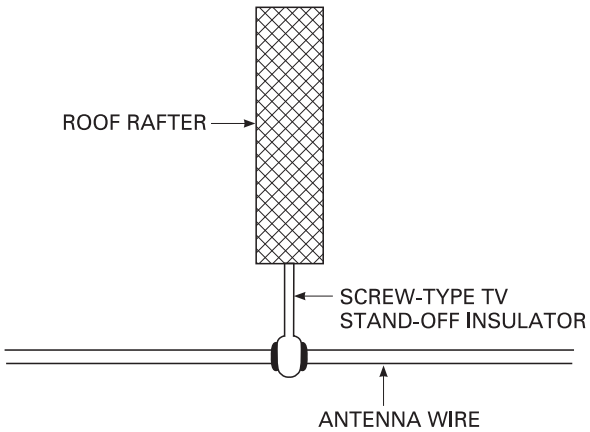

FIGURE 6.3

Marconi and Hertzian antennas may not be as good a choice as the loop because they tend to have high voltages at the ends. Use of even moderate RF power levels could cause an arcing situation that represents a fire hazard. As a result, even with the loop, if the antenna is used with a transmitter the power level should be limited.

These ideas work especially well for people with restrictive local ordinances that make decent antennas unworkable, or nasty neighbors, or restrictive covenants in their deed (and a militant homeowners association board that enforces them!). Some situations allow an antenna such as that shown in Figure 6.1A or Figure 6.1B as long as it is not visible from the street.

Zig-Zag Dipoles

The antenna purist would probably roast me over a slow fire like a marshmellow for suggesting some approaches to the limited space problem. Figure 6.4 is especially suited to drawing the ire of the pure. But it also works passably well for people with limited space. This antenna uses a zig-zag path for the dipole elements. Try to put as much wire in one direction as possible, and wherever possible make the pattern symmetrical. Although the angles shown in Figure 6.4 are acute, any angle can be used. Of course, the closer the pattern is to the regular straight dipole installation, the better it will work.

The antenna shown in Figure 6.4 is seen from the side, i.e. a ground view. The zigging and zagging can be in any direction in three-dimensional space,

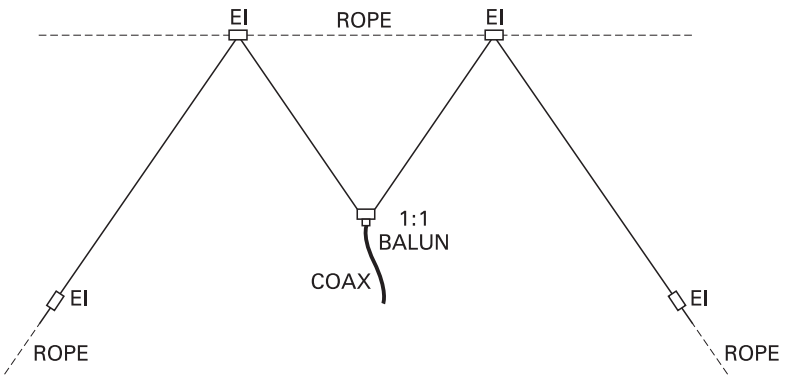

FIGURE 6.4

however. Some combinations will not work well, but others will work well enough to get you on the air.

You will find that the pattern suffers when this is done, but again the goal is to get you on the air – not to produce a perfect antenna. Also, expect to use a 'line flattening' antenna tuner to wash away the sins of the voltage standing wave ratio (VSWR).

Linearly Loaded 'Tee' Antenna

The traditional method for loading an antenna that is too short is to put a coil in series with one or all elements. In the 'tee' antenna in Figure 6.5, however, a different approach is used: **linearly loaded elements**. This antenna has been popular with low-band operators and receiver users who lack the tremendous space required for proper antennas at those frequencies. The overall length of the element (A) is usually around $\lambda/3$, and the spacing between the three segments (B) is about 25 cm (a little more or a little less can be accommodated by the design). The vertical portion of the antenna (C) is a quarter-wavelength single wire, and is fed at the bottom by parallel tuned transmission line.

The critical lengths are

$$A = \frac{50}{F_{\text{MHz}}} \text{ meters}$$

$$B = 25\,\text{cm}$$

$$C = \frac{75}{F_{\text{MHz}}} \text{ meters}$$

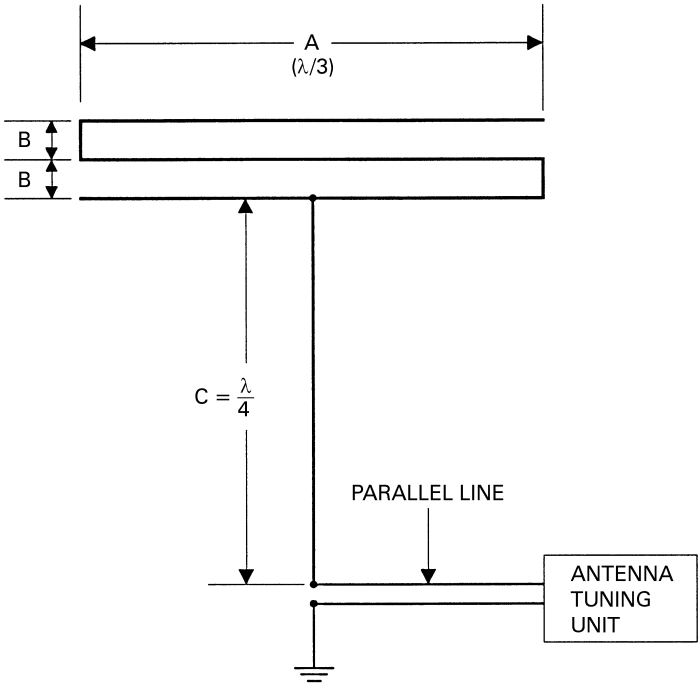

FIGURE 6.5

The Right-Angle Marconi

Figure 6.6 shows a simple quarter-wavelength Marconi antenna that can be used with 52 or 75 ohm coaxial cable. The antenna consists of two wire sections, each $\lambda/8$ long, erected at right angles to each other. The right-angle Marconi (sometimes laughingly called 'half-Hertzian') produces both a vertically and horizontally polarized signal. This method of construction reduces the linear property needed for the antenna by half, so is more accessible to a larger number of people.

Shortened Hertzian Radiators

The zig-zag dipole shown earlier is only one possibility for reducing the size of a Hertzian antenna. The antenna of Figure 6.7 is a species of zig-zag doublet, but is a little less random in its construction than the previous antenna of this sort. The overall length is $\lambda/2$, but the two $\lambda/4$ elements are bent into right-angle sections of $\lambda/12$ (vertical) and $\lambda/6$ (horizontal). The antenna is fed with open-wire parallel line operated as tuned feeders.

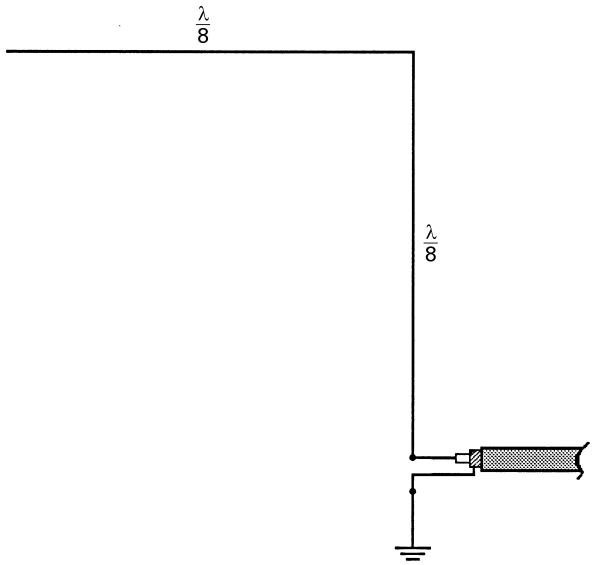

FIGURE 6.6

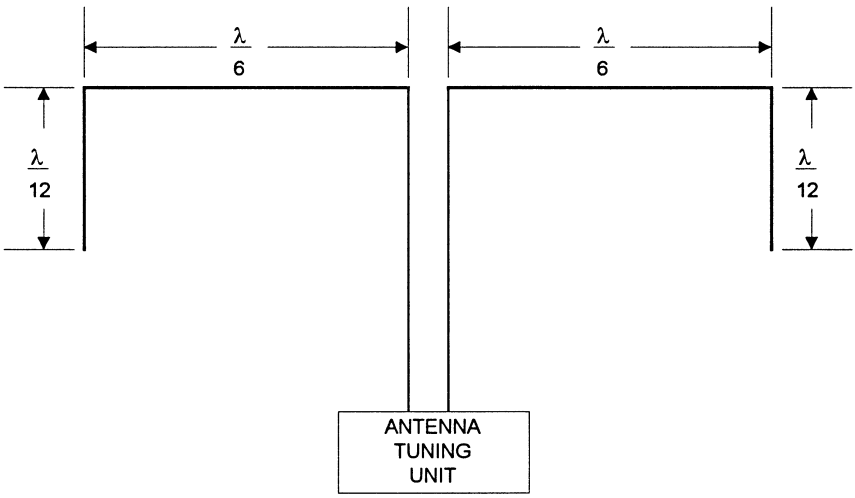

FIGURE 6.7

The antenna in Figure 6.8 looks like a folded dipole, and on one hand that is exactly what it is. The antenna length is cut for $\lambda/4$ at the lowest frequency of operation. At the second harmonic of this low band the antenna acts like a folded dipole, while at the lower frequency it is a species of 'tee' antenna. It is fed with open-wire tuned feeders. If you want to

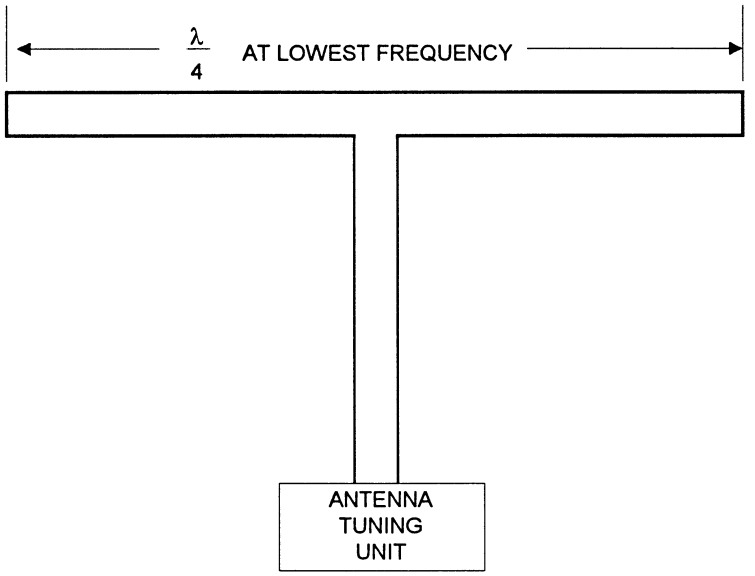

FIGURE 6.8

operate it only one band (the lower band), and wish to use coaxial cable, then a quarter-wavelength matching stub can be provided, and the antenna driven with a 4:1 BALUN transformer.

The doublet antenna in Figure 6.9 is a bit longer than $5\lambda/8$, and is fed by coaxial cable through a shorted matching stub and a 4:1 BALUN transformer. The overall length (B) of the radiator element is

$$B = \frac{102}{F_{\text{MHz}}} \text{ meters}$$

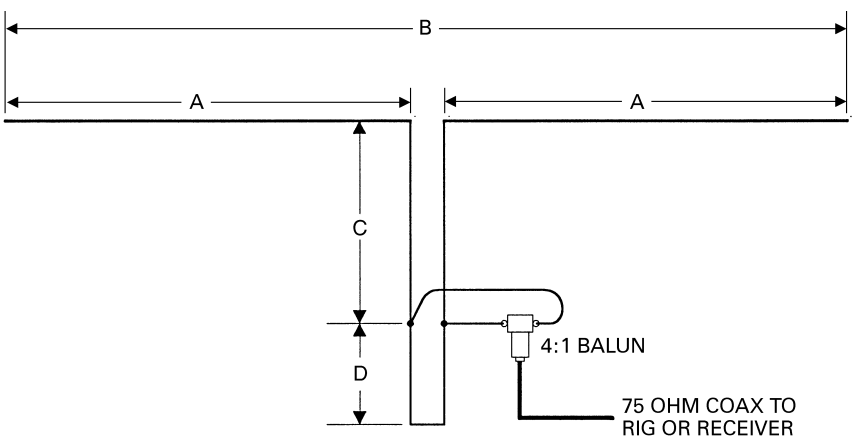

FIGURE 6.9

The matching stub consists of a length of parallel open-wire transmission line, divided into two segments either side of the feedpoint. The dimensions of the two segments are

$$C = \frac{32}{F_{\text{MHz}}} \text{ meters}$$

$$D = \frac{8.8}{F_{\text{MHz}}} \text{ meters}$$

The tap point on the stub represented by these lengths will provide a good match to 300 ohm twin-lead, or to 75 ohm coaxial cable if a 4:1 BALUN transformer is provided.

The extended folded dipole shown in Figure 6.10 uses 300 ohm twin-lead for the folded dipole section (A) and single conductor wire for the vertical extensions (B). The length overall of section A is found from

$$A = \frac{123}{F_{\text{MHz}}} \text{ meters}$$

While the vertical sections are

$$B = \frac{9.2}{F_{\text{MHz}}} \text{ meters}$$

The antenna of Figure 6.10 can be fed with 300 ohm twin-lead, but this requires the antenna tuning unit to have a balanced output. Alternatively, you can feed it with 75 ohm coaxial cable if a 4:1 BALUN transformer is provided at the interface between the coaxial cable and the antenna feedpoint.

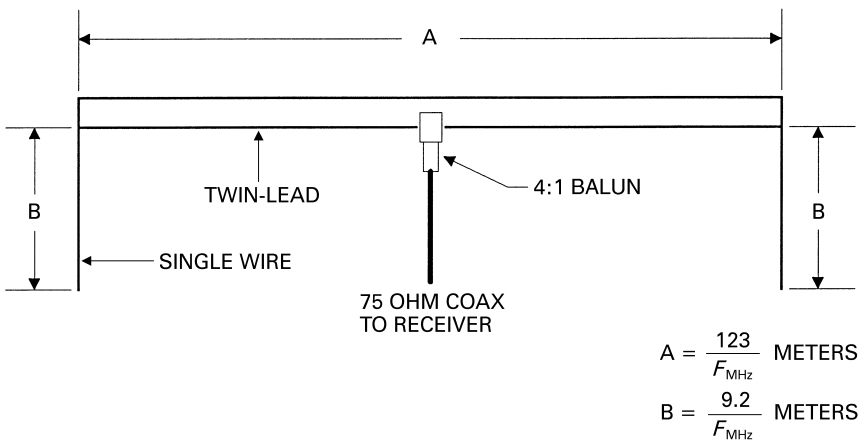

FIGURE 6.10

Limited Space Radial Layout

Radials are quarter-wavelength (usually) pieces of wire connected to the ground side of a transmission line at the antenna. These radials can be on the surface, under the surface, or elevated, depending on the particular antenna. The radials are used to form a **counterpoise ground**, i.e. an artificial ground plane. It is seen by the antenna as essentially the same as the ground.

By the way, the preferred 'ground level' configuration is buried, rather than on the surface, because it prevents injury to people passing by, either from RF burns or stumbling over the fool wire. But what do you do in the limited space situation?

A representative solution is shown in Figure 6.11. The radials shown in textbooks are straight, and that is the preferred configuration. But if you do not have the space, then you need to use some variant of the two paths shown in Figure 6.11. The radial can either go around the perimeter of the property, or zig-zag back and forth in either a triangle or rectangle pattern (the latter is shown here). I have even tacked radials to the baseboard of a student boarding house room (not recommended over a few watts of QRP power levels).

Imagination, a bit of engineering, some science, and a whole lot of luck make radio operations from limited space situations possible – or at least a lot easier.

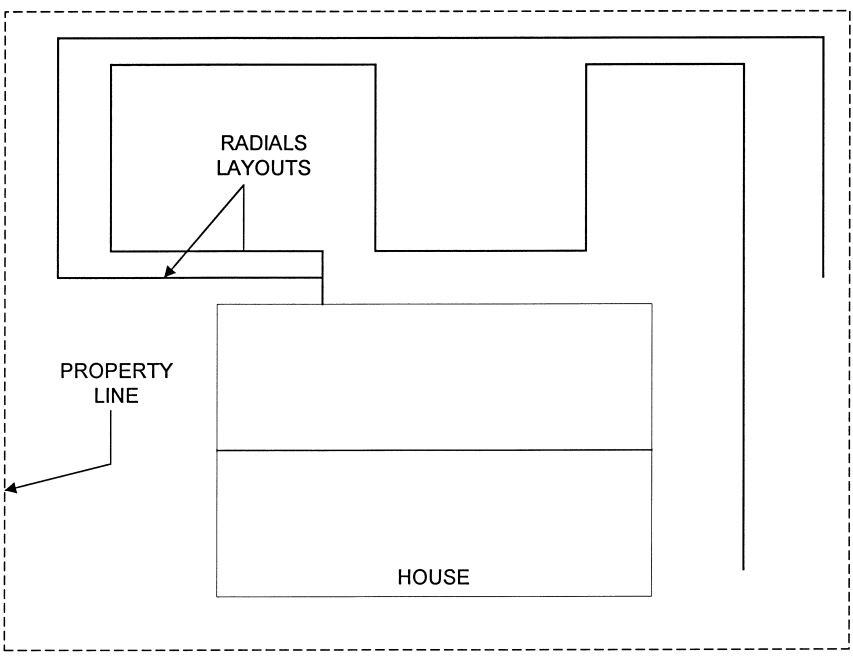

FIGURE 6.11

CHAPTER 7

Large loop antennas

There are two basic classes of loop antennas: **small loops** and **large loops**. The small loop antenna has an overall length that is less than about 0.18λ. Large loop antennas, on the other hand, have overall lengths larger than 0.5λ, and some of them are two or more wavelengths. The small loops are used for radio direction finding and for certain AM broadcast band reception problems. The topic of this chapter is the large loop antenna, of which several varieties for both transmitting and receiving are covered. We will also look at some in-between size loops that I have dubbed 'smaller large loops' to distinguish them from small radio direction finding loops.

QUAD LOOPS

The quad loop antenna (Figure 7.1) is perhaps the most effective and efficient of the large loop antennas, and it is certainly the most popular. The quad loop consists of a one wavelength loop of wire formed into a square shape. It provides about 2 dB gain over a dipole. The views in Figure 7.1 are from the horizontal perspective looking at the broad side of the loop. The azimuthal radiation pattern is a figure '8', like a dipole, with the directivity in and out of the page.

The quad loop can be fed in either of two ways. Figure 7.1A shows the feed attached to the bottom wire segment, and this produces horizontal polarization. The same polarization occurs if the feedpoint is in the top

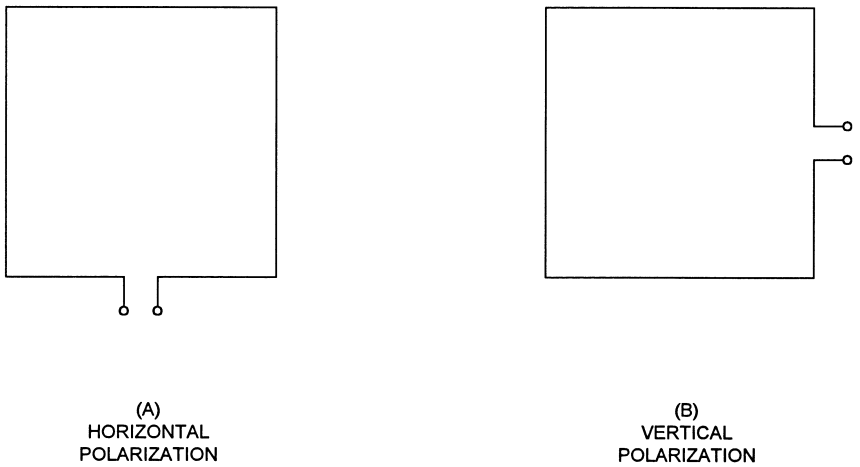

FIGURE 7.1

horizontal segment. If the feed is in either vertical segment (Figure 7.1B) then the polarization will be vertical.

The elevation pattern is shown in Figure 7.2. This pattern is found when the top horizontal segment of the loop is quarter wavelength from the ground. The directivity is in and out of the page. Note that there are two sets of lobes, one horizontally polarized (a minor lobe) and two vertically polarized. These lobes are derived by taking a slice out of the three-dimensional pattern that would be seen as a figure '8' pattern from above.

The overall length of the wire used to make the loop is found from

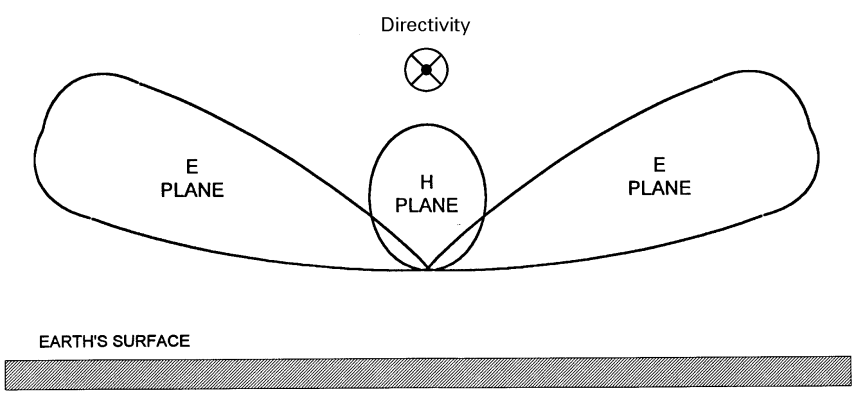

FIGURE 7.2

$$L_{\text{meters}} = \frac{306.4}{F_{\text{MHz}}} \text{ meters}$$

Examples of wire lengths for loops of various frequencies are given in Table 7.1. Each side is one-fourth of the total wire length.

There are several methods for constructing the quad loop. If you want a fixed loop, then it can be suspended from insulators and ropes from convenient support structures (tree, mast, roof of a building).

If you want to make the loop rotatable, then use a construction method similar to that of Figure 7.3A. This method uses a plywood **gusset plate**, approximately 30 cm square, to support a set of four **spreaders**. The gusset plate can be attached to a mounting pole or rotator pole with U-bolt clamps. Details of the gusset plate construction are shown in Figure 7.3B. The four spreaders are held to the gusset plate with two to four small U-bolts. The gusset plate is held to the mounting mast with two or three large U-bolts. In both cases, be sure to use a substantial size U-bolt in order to prevent breakage (use stainless steel wherever possible).

The spreaders can be made of wooden dowels at very high frequency (VHF). I have even seen larger cylindrical wooden dowels (2–3 cm diameter) used for quad loops in the upper end of the HF spectrum. For all other HF regions, however, you can buy fiberglass spreader specially manufactured for the purpose of building quad loops or quad beams. At one time, it was popular to build the quad loops from bamboo stalks. These were used as the core on which carpet was rolled, and carpet dealers would sell them for a modest price or even give them away. Today, however, carpet manufacturers use hard cardboard tubes for the roller, and these are unsuitable for building quad loops. Bamboo stalks of the right size (2.5–4 m) have all but disappeared from the marketplace.

The quad loop can be fed with coaxial cable, although it is a good idea to use a 1:1 BALUN transformer at the feedpoint if only coaxial cable is used. The impedance match is not exact, and a voltage standing wave ratio

TABLE 7.1

Center frequency (MHz)	*L* (overall length) (m)	*L*/4 (each side) (m)
3.75	81.70	20.43

(VSWR) will be found. The feedpoint impedance is of the order of 100 ohms, so the VSWR when 75 ohm coaxial cable is used is only 100/75, or 1.33:1. Some people use a coaxial cable impedance matching stub between the quad loop feedpoint and the coaxial cable to the rig or receiver. Such a stub, called a **Q-section**, is made of 75 ohm coaxial cable, and is a quarter wavelength long. The coaxial cable to the rig or the receiver in that case is of 52 ohms.

To make an electrical quarter-wavelength matching stub you must shorten the physical length by the value of the velocity factor of the coaxial cable used for the matching section. For example, suppose we are building a quad loop for 14.25 MHz. A quarter wavelength in free space is $75/14.25 = 5.26$ m. But if polythene dielectric coaxial cable (velocity factor (VF) = 0.66) is used, the physical length required to make an electrical quarter wavelength is $5.26\,\text{m} \times 0.66 = 3.472$ m. If polyfoam dielectric coaxial cable (VF = 0.82) is used for the matching section, then the required physical length is 4.31 m.

QUAD LOOP BEAMS

The basic quad loop is bidirectional (figure '8' pattern). If you want to make the loop unidirectional, it can be built into a beam antenna by adding a second loop as either a **reflector** (Figure 7.4A) or **director** (Figure 7.4B). The reflector and director elements are not directly excited by the transmitter, and are therefore called **parasitic elements**. The reflector is slightly larger than the main loop (called the **driven element**), while the director is slightly smaller. The overall wire sizes are found from

Reflector:

$$L_{\text{Ref}} = \frac{315}{F_{\text{MHz}}} \text{ meters}$$

Driven element:

$$L_{\text{DE}} = \frac{306}{F_{\text{MHz}}} \text{ meters}$$

Director:

$$L_{\text{Dir}} = \frac{297}{F_{\text{MHz}}} \text{ meters}$$

Spacing between elements:

$$S = \frac{60}{F_{\text{MHz}}} \text{ meters}$$

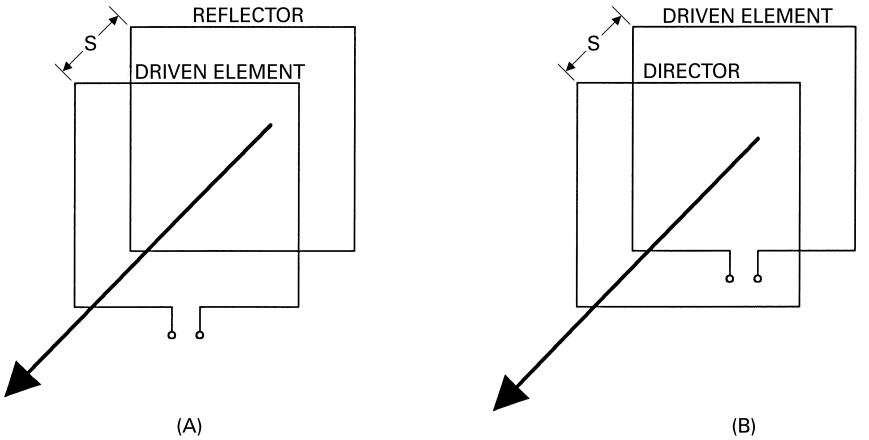

FIGURE 7.4

The directivity of the two-loop beam is always in the direction of the smallest element, as seen by the arrows in Figure 7.4, and the forward gain will be about 7 dBd (9.1 dBi), while the front-to-back ratio will be up to 25 dB (the actual value depends on the spacing of the elements).

The quad loop beam has a tradition that goes back to just before World War II. The missionary short-wave radio station HCJB in Quito, Ecuador was experiencing problems with its Yagi beam antennas. There was a constant corona discharge off the ends of the elements because the tips are high-voltage points. At lower altitudes than Quito's Andes location, these antennas do not exhibit the problem, but at altitude the arcing was severe enough to create a constant (and expensive) maintenance problem for the engineers. They invented the quad beam to solve the problem. The reason is that the feed method puts the high-voltage nodes in the middle of the vertical segments. It takes a much higher voltage to cause corona arcing from the middle of a cylindrical conductor than off the ends, so the problem was eliminated.

Ham operators and some commercial stations quickly picked up on the quad beam because it offered a relatively low-cost method for obtaining directivity and gain. In addition, the quad beam is believed to work better than the Yagi beam in installations that are close to the Earth's surface (e.g. less than a half wavelength).

The quad antennas shown here are two-element designs. Three and more elements can be accommodated by using both a reflector and a director, or any combination of multiple directors or reflectors. It is common practice (but by no means totally necessary) to use one reflector and as many directors as are needed to accomplish the desired number of

elements. Each element added to the array will increase the gain and narrow directivity. The feedpoint impedance is around 60 ohms, so it makes a reasonably good impedance match to both 52 and 75 ohm coaxial cable.

DELTA LOOPS

The delta loop (Figure 7.5) gets its name from the fact that its triangular shape resembles the upper-case Greek letter *delta* (Δ). These three-sided loops are made with a full-wavelength piece of wire, each side of the equilateral triangle being one-third wavelength long.

Three different feed schemes are shown in Figure 7.5, but all three of them attach the feedline at an apex of the triangle. The antenna in Figure 7.5A is fed at the top apex, that in Figure 7.5B is fed at bottom apex, while that in Figure 7.5C is fed at one of the side apexes (either right or left could be used).

The overall length (in meters) of the wire used to make the delta loop is found from $306.4/F_{\mathrm{MHz}}$ only if the antenna is mounted far enough from the ground and surrounding objects to simulate the elusive 'free space' ideal. But for practical delta loops a nearer approximation is found from $285/F_{\mathrm{MHz}}$. The actual size will be between the two values.

A delta loop built for 9.75 MHz is shown in Figure 7.6. The overall formula length of the wire is 29.23 m, with each side being 9.74 m. The transmission line to the rig or receiver is 52 ohm coaxial cable. There is a coaxial quarter-wavelength impedance matching section ('Q-section') between the antenna feedpoint and the line to the receiver or rig. The Q-section is made from 75 ohm coaxial cable.

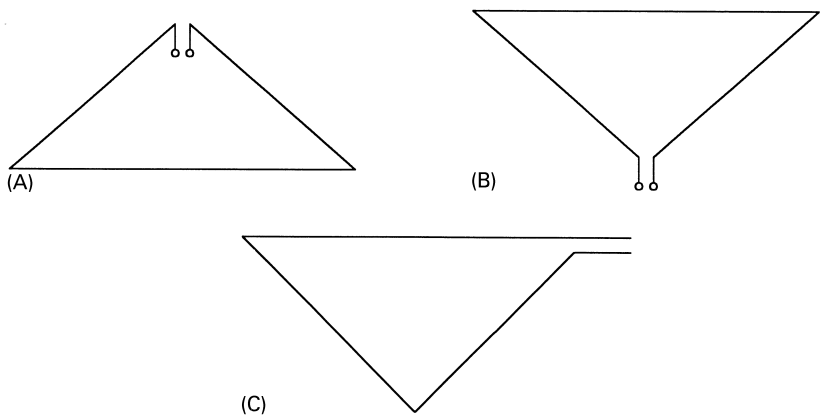

FIGURE 7.5

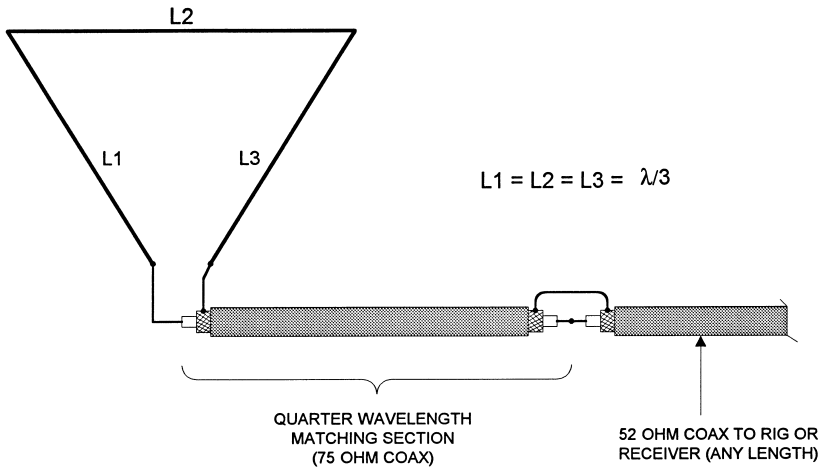

FIGURE 7.6

The physical length of the Q-section is reduced from the free space quarter wavelength ($75/F_{\mathrm{MHz}}$ m) by the VF, to ($75 \times \mathrm{VF})/F_{\mathrm{MHz}}$ m. At 9.75 MHz, if polythene coaxial cable is used (VF = 0.66) the length of the section is 5.1 m, but if polyfoam coaxial cable (VF = 0.82), then it is 6.3 m.

'ON-THE-CHEAP' ROOM LOOP

There are many situations where short-wave antennas cannot be installed without great pain and suffering, or where landlords, building managers, and other sundry unsympathetic types refuse to permit outdoor antennas. If you have a wall inside the building that will allow erection of a normal quad loop (as shown above), then there is no reason why you cannot attempt it (unless you are inside a metal frame or metal sided building!). I have seen cases where ham operators running relatively low-power levels (50–100 W) used full-wave quad loops mounted on the wall from floor to ceiling. In fact, one fellow sent me a photo of his installation where there were two adjacent quad loops on two walls that were at right angles to each other. By feeding them both along the vertical edge in the corner he was able to switch directions with a simple double-pole double-throw (DPDT) heavy duty switch. It seemed like a good solution for anyone who finds messy wire an acceptable wall decoration.

Another solution is to use a room loop antenna such as that in Figure 7.7. Although shown here as a horizontal delta loop, it can also be square or rectangular. The 'on-the-cheap' room loop is mounted on the ceiling of the room. The wire can be suspended from the type of hooks used to hang planters and flower pots. I have even seen cases where the sort of hooks

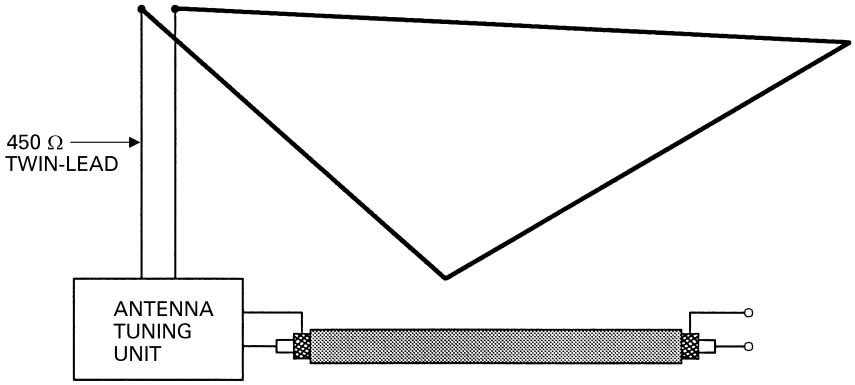

FIGURE 7.7

used to mount pictures on the walls were used on the ceiling to support the antenna wire.

The loop size is adjusted to fit the room, and is essentially a random length as far as any particular frequency is concerned. The feedline is 300 ohm, 450 ohm or parallel open feedline run vertically down the wall at the operating position to a balanced antenna tuning unit.

This antenna works well for receiving sites, and can be used for low-powered transmitters, but it should not be used for higher power transmitting. Also, it is probably prudent to use insulated wire for the antenna element.

INDOOR 'MIDDLE-EAST ROOM LOOP' ANTENNAS

There are many reasons why someone might want to build a room loop antenna. For some people, the problem is one of unsympathetic landlords, while in other situations there are problems in the layout of the property that limit antennas. In the USA, most new housing developments impose legally binding restrictive convenants that forbid the use of outdoor antennas on the deeds of houses sold. In some countries, short-wave radio antennas are limited because of political considerations. The antenna design in Figure 7.8 was sent to me via one of my magazine columns by a reader in a Middle-Eastern country that severely restricts both external antennas and the bands which short-wave receivers can pick up. He is limited to models that receive 4–7 MHz in addition to only a 200 kHz portion of the AM broadcast band and a 2 MHz segment of the FM broadcast band (what paranoia those politicians must have!). He also felt that it was necessary to not call attention to himself by erecting the short permitted outdoor antennas because, as a foreign worker, he is already somewhat suspect,

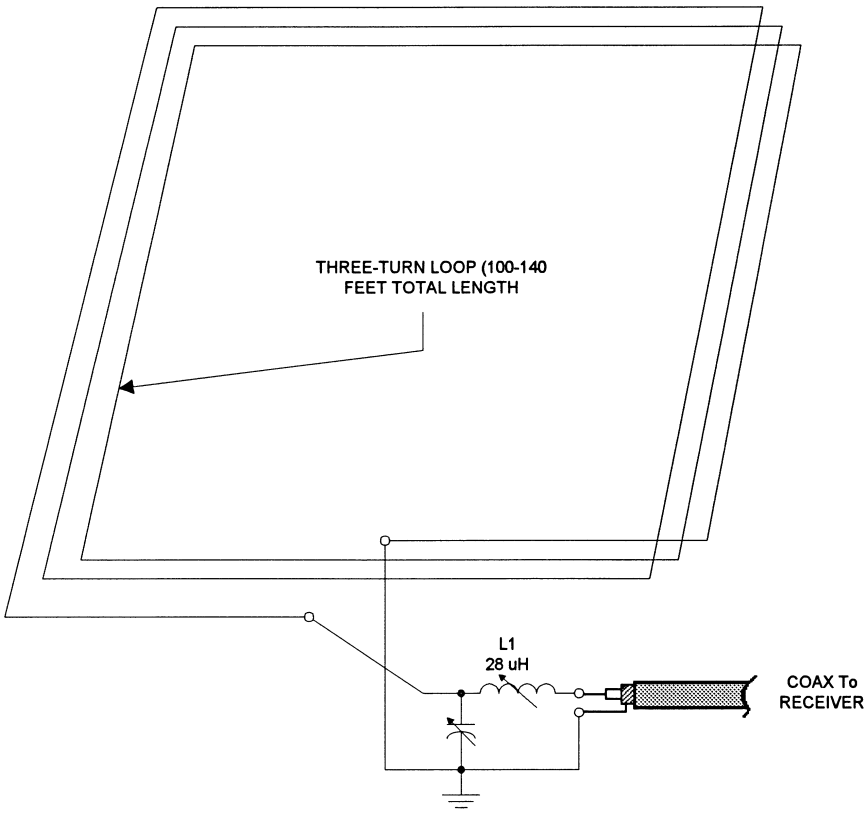

FIGURE 7.8

and believed that a substantial external antenna might label him as some sort of intelligence agent.

He claimed that this antenna worked quite well. The loop consists of 30–40 m of insulated wire (e.g. No. 22 hook-up wire) wound around the room to form three or four loops (the figure assumes a square room). My correspondent mounted the loop at the intersection of the ceiling and the walls. The windings were closely wound with little or no spacing between the windings.

The chap who sent me this design used an antenna tuner consisting of a shunt 365 pF broadcast variable and a 28 μH series inductor (i.e. a classic L-section tuner of the sort used by many radio amateurs and short-wave listeners). From some of my experiences during my student days (when I lived in student boarding house rooms), the antenna tuner might be purely optional for receiver operators. Try connecting your receiver directly to the loop using ordinary coaxial cable.

If you have some means for measuring the antenna impedance or VSWR, then make the measurement for the frequencies of interest before committing yourself to building or buying a tuner. Another option that will eliminate the antenna tuner, especially if you confine the use of the antenna to a small segment of the HF spectrum, is to use a BALUN or other form of impedance transformer at the feedpoint. This option becomes less viable as the frequency coverage required increases because the feedpoint impedance will vary all over the place with changes in frequency.

I cannot as yet recommend this antenna for transmitting above the purely QRP level (a few watts), so do not try it except at your own risk.

The directivity of this antenna is a bit uncertain because it will change with frequency. I found no problems using similar loops in my boarding house room, but common sense suggests that the azimuthal and elevation patterns will be quite different at the various bands throughout the HF short-wave bands.

A MULTIBAND SWITCHABLE DELTA LOOP

Wire antennas are among my favorites because they are low cost, reasonably well behaved, and can easily be erected and then torn down as the experimenting urge hits. Alternatively, if the urge to experiment is not something that hits you very often, or if you prudently lay down and let it pass when it does, then wire antennas are still (normally) easy to erect and are reasonably robust against the elements. They last a long time with reasonable maintenance. As might be expected of a book that deals with wire antennas, we take a look at quite a few different wire antennas. This time, we are going to look at two multiband delta loop antennas based on both the G4ABS and the N4PC designs. These antennas produce gains of the order of 4–8 dB, depending on the band of operation.

Multiband Loop 1

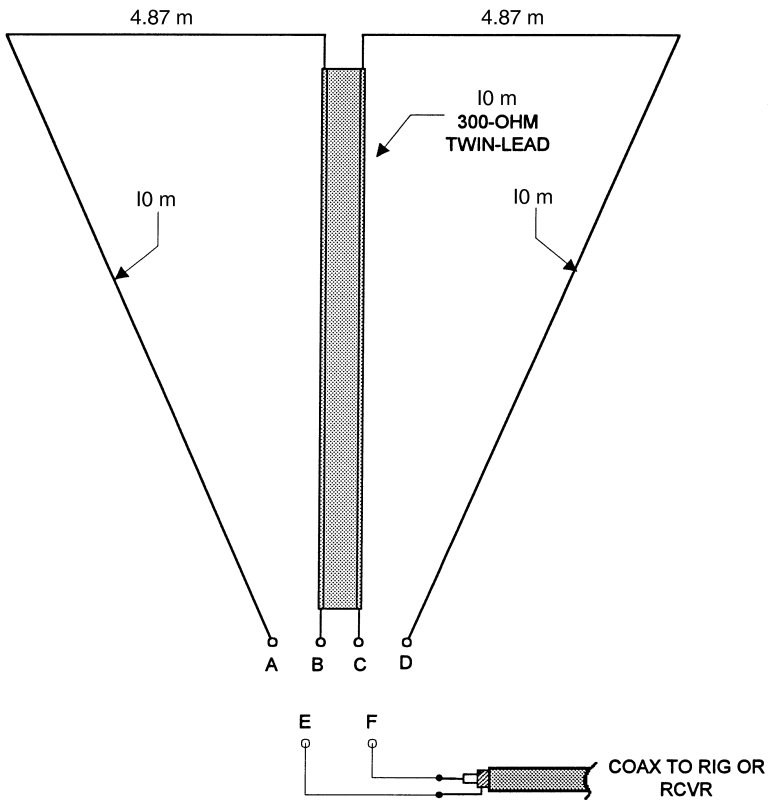
The first loop antenna works on 3.5, 7, 14 and 28 MHz, and is constructed of No. 14 antenna wire and a 10 m piece of either 300 or 450 ohm twin-lead transmission line. With slight modification, it will also work on a series of bands starting at 5 MHz and proceeding up through the HF short-wave band.

Figure 7.9A shows the multiband delta loop antenna design. There are four sections to this antenna. Two sloping side sections are made of No. 14 antenna wire, and are 10 m long. The top section is 9.75 m of No. 14 antenna wire, but is cut in the center to form two equal-length sections. Hanging from the center of the top section is a vertical section made of twin-lead transmission line (10 m).

To make this antenna work on the international short-wave bands rather than the ham bands, multiply these dimensions by 0.7. This is an example of dimensions scaling. It can be done by taking the ratio of the frequencies, and multiplying the resultant factor by the lengths. Scaling only works if all of the lengths are treated in this manner.

The two sloping side sections and the vertical section are brought to a connector board made of an insulating material such as ceramic, Plexiglas or even dry wood (if it can be kept dry and low power levels are used). We will take a look at the connection schemes for the different bands in a moment.

The antenna is supported in a manner similar to a dipole or any other wire antenna. The cut at the center of the top section, with its connections to the vertical section, are supported by an end insulator. The ends of the top half sections are supported by end insulators and ropes to nearby structures, just like a dipole. In some cases, a 10 m or higher wooden mast might be used to support the center of the top section. In that case, the vertical section



(A)

FIGURE 7.9

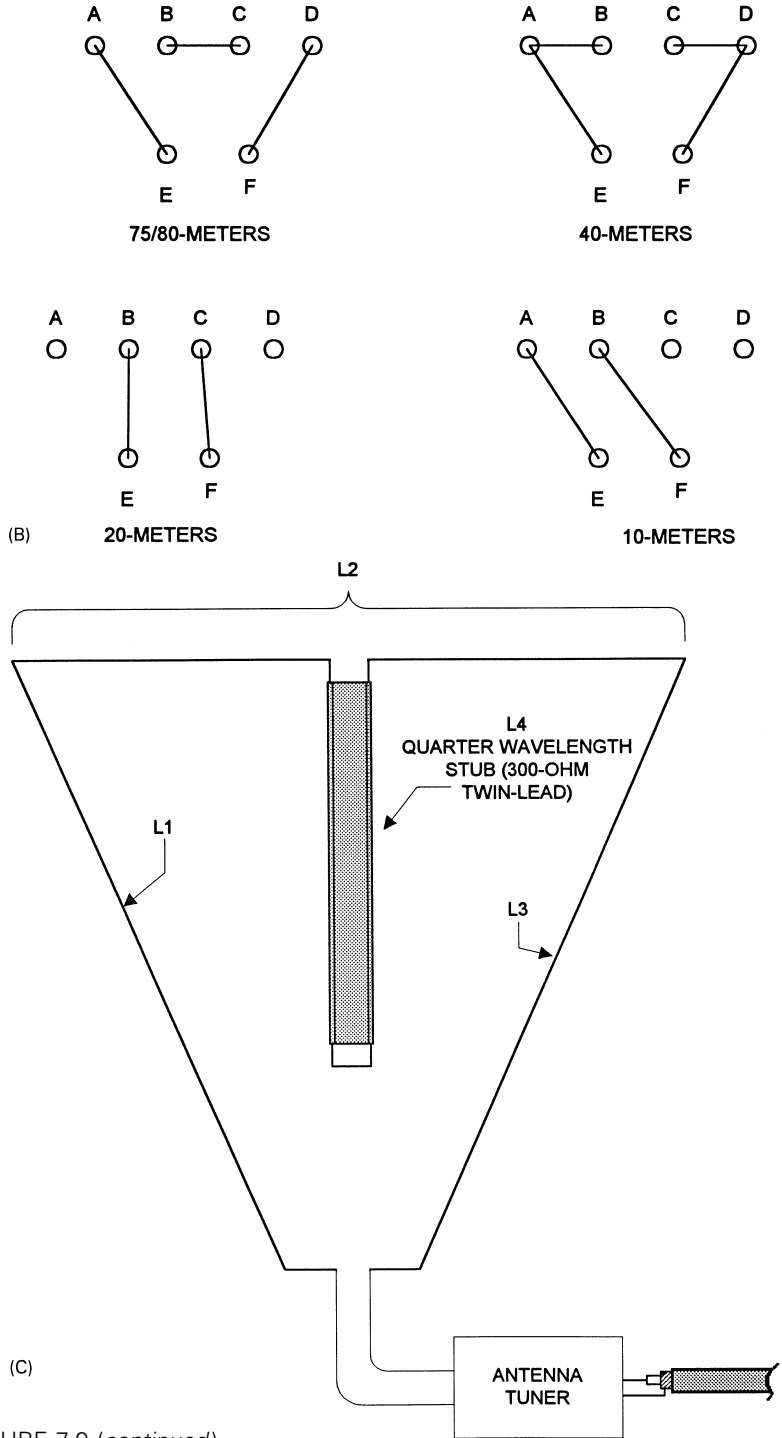


FIGURE 7.9 (*continued*)

can be tied to it, improving its mechanical support. In addition, the connections board (used for band changing) can be mounted close to its base.

Figure 7.9B shows the connections scheme to make the antenna work on the four different bands (which, you will undoubtedly notice are the harmonically related HF bands). All connections go to stand-off insulators, labeled A, B, C, D, E, and F. The cheapest way to use these connection points is to manually connect a shorting wire between the appropriate terminals. People with a bit more money to spend might want to get some coaxial relays, radio frequency relays, or vacuum relays in order to perform the switching. For receiver and very low-power transmitter applications, the connectors can be five-way binding posts that accept a banana plug. The shorting could be done with short (very short!) pieces of wire tipped at each end with the banana plugs. The connections scheme is as follows:

(1) To make the antenna work on the 75/80 m bands (3.5–4.0 MHz), short B–C, A–E, and D–F.
(2) To make the antenna work on 40 m (7.0–7.3 MHz), short B–A–E and C–D–F.
(3) To make the antenna work on 20 m (14.0–14.35 MHz), short B–E and C–F.
(4) To make the antenna work on 10 m (28.0–29.7 MHz) short A–E and B–F.

My impression of the multiband delta loop is that it works about as well as a dipole, and is generally bidirectional. However, the pattern does seem to change considerably from band to band (which is to be expected). I do not want to say much about how it changes because propagation effects are so different on the four bands that it would take a very long time of observing signals to get a good idea of what the pattern looks like. Any statement about patterns, other than it appears to change from band to band, would be unwise without extensive modeling or some actual measurements.

Multiband Loop 2

The other form of multiband loop is shown in Figure 7.9C. This design uses a full-wave loop with the balanced feedline connected at one of the apexes of the triangle, and a quarter-wavelength stub. Both the stub length and the overall length (L + L2 + L3) are calculated at the *highest* frequency of operation. It will operate over three bands that are harmonically related (e.g. 3.5/7.0/14.0 MHz, or 5/10/15 MHz, etc.). The overall length in meters is found from $(L1 + L2 + L3) = 615/F_{MHz}$, while the stub is $60/F_{MHz}$ (assuming that the usual form of twin-lead is used, which has a VF of 0.82). Both of these antennas produce patterns broadside from the loop

plane, although both the azimuthal and elevation radiation patterns vary from one band to another.

DOUBLE-DELTA LOOP

The double-delta loop antenna (Figure 7.10) consists of a back-to-back pair of large horizontal delta loops fed 180° out of phase with each other. The view shown is a plan view, i.e. as seen from above. The far corners of the two delta loops are connected together by a 180° phase-reversing harness made from a length of 450 ohm twin-lead or parallel ladder line. The 180° phase reversal is achieved by twisting the twin-lead over on itself once (and only once).

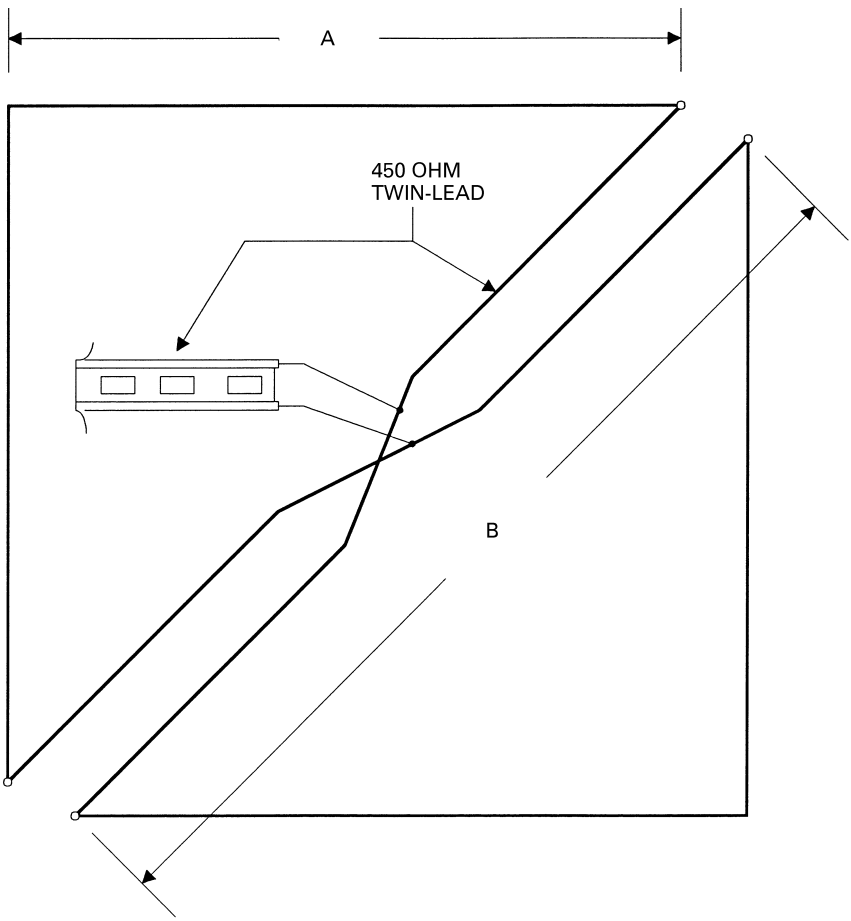

FIGURE 7.10

The feedline to the receiver or its antenna coupler is another piece of 450 ohm twin-lead connected to the mid-points of the two conductors of the 180° phasing harness. This transmission line will make a decent if not perfect match to receivers that have a balanced input. Use of a 4:1 BALUN transformer at the feedpoint will drop the impedance to about 112 ohms, which is not too bad a match for 75 ohm coaxial cable. On the other hand, if you want a near-perfect match, then opt instead for a 9:1 BALUN transformer and connect the receiver using 52 ohm coaxial cable. There are several forms of 9:1 BALUN transformer on the market, but are sometimes hard to find except by mail order. If such a transformer is not available, then you will have to build it yourself (which is not too great a chore).

The length of each of the four sides of the double-delta loop is about a quarter wavelength, and is found from

$$A = \frac{66}{F_{\text{MHz}}} \text{ meters}$$

Let us look at some examples: a 60 m band antenna cut for 5 MHz and a 31 m band antenna cut for 9.75 MHz (assume I did the arithmetic on my calculator, with the results tabulated below):

F (MHz)	Meters
5.00	13.20
9.75	6.77

The delta loop antenna is well regarded because it performs similarly to the quad loop, but is somewhat easier to install when the site only has a single high point. A friend of mine in Ireland uses a tall tower for his 20 m beam antenna. The tower becomes the upper support for a 75/80 m delta loop made of wire.

SMALLER LARGE LOOPS

The loops in this section are physically smaller than the one-wavelength loops of the previous sections. Few of them will work as well as the full-size loops, but they will work passably well, and can be installed at sites that will not accommodate the larger variety. I call them 'smaller large loops' to distinguish them from the small loops used in radio direction finding.

Half-wavelength loop

The half-wavelength loop is $\lambda/8$ on each side, and is one-half the size of the full-wavelength quad loop discussed earlier. There are two configurations for this loop. The closed-loop version (Figure 7.11A) transmits and receives in the direction opposite the feedpoint, while the open-loop variety (Figure 7.11B) transmits and receives in the oppposite direction.

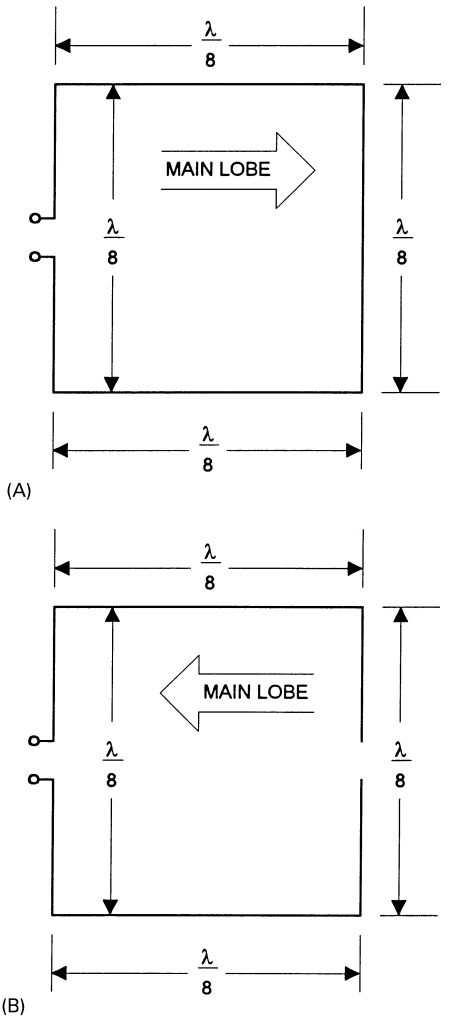

FIGURE 7.11

The two half-wavelength loops differ not just in the direction of radiation but also in the feedpoint impedance. The antenna in Figure 7.11A (closed-loop version) is fed at a voltage node, while the current node is in the middle of the opposite segment. As a result, the feedpoint impedance is several kilo-ohms. This means that a matching stub, impedance transformer or some other means of reducing the impedance is necessary. The open-loop variety (Figure 7.11B) forces the current to be a minimum at the open-circuit point, which means that the current maximum (and voltage minimum) occurs at the feedpoint. The open-loop version can be directly fed with coaxial cable.

These antennas are lossy, so have a poor front-to-back ratio (≈6 dB) and no gain over a dipole. Indeed, the gain is −1 dBd. Of course, if you want to make it seem like a better antenna, then quote the gain over isotropic, which is about +1.1 dBi.

Inductor-loaded smaller large loop

Figure 7.12A shows a less-than-full-size loop that is inductively loaded to lower the resonant point. The overall length of the wire used to form the loop is found from

$$A = \frac{180}{F_{\text{MHz}}} \text{ meters}$$

Each side is one-fourth this length. Note that the loop is a bit larger than a half wavelength.

The inductor should have a reactance of about 2500 ohms at the frequency in the middle of the band of operation. For example, if you build the antenna for reception in the 31 m band (e.g. 9.75 MHz), then the overall length of the antenna is 180/9.75 = 18.46 m, and each side is 4.62 m long.

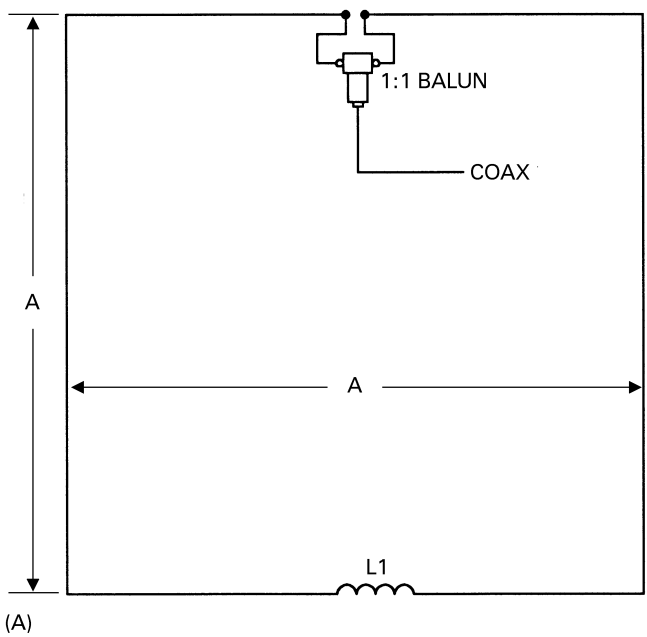

FIGURE 7.12

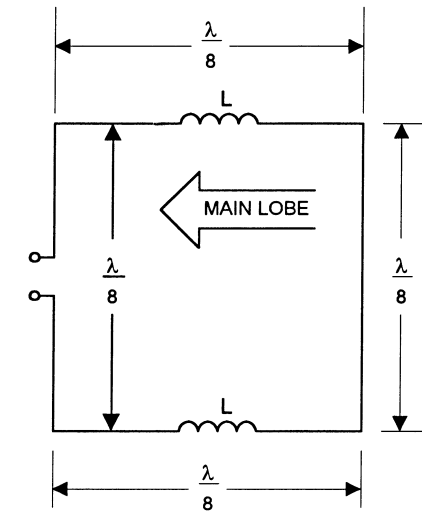
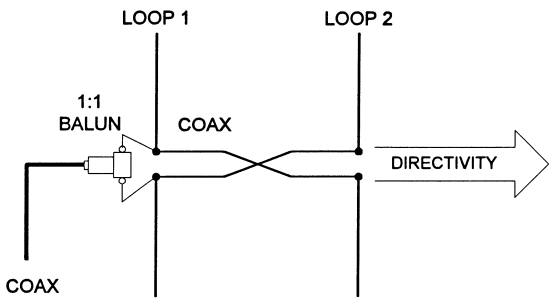


(B)



(TOP VIEW)

(C)

FIGURE 7.12 (*continued*)

The coil inductance required can be found from:

$$L_{\mu H} = \frac{400}{F_{MHz}} \text{ microhenrys}$$

For the 9.75 MHz example antenna, the value of the inductance required is (400/9.75 MHz) = 41 μH.

For receiver sites, the inductor can be a small toroid core coil. For example, if the 2.5 cm red core T-106-2 is used, then 55 turns of small diameter wire are required to make the inductor.

The antenna is not recommended for transmitting above the lowest power levels. Even at modest power levels (e.g. 100 W), a solenoid wound

air core coil should be of the order of 4–5 cm diameter with wire in the No. 14 size.

The antenna is fed at the mid-point of the side opposite the inductor. A 1:1 BALUN transformer is used to interface the feedpoint to 52 or 75 ohm coaxial cable.

A variation on the theme is the half-wavelength loop shown in Figure 7.12B. It is a tad smaller than the previous inductor load loop. In this case, the inductance is split into two inductors, and are placed at the mid-points of the segments adjacent to the segment containing the feedpoint. The coils in this variety should have a reactance of 360 ohms, making the inductance

$$L_{\mu H} = \frac{57}{F_{MHz}} \text{ microhenrys}$$

Both of these antennas can be used in a beam array by placing two identical loops facing each other (Figure 12.7C), and separated by a spacing of

$$S_{meters} = \frac{33}{F_{MHz}} \text{ meters}$$

The two antennas are fed in-phase, so there are two methods of attaching the transmission line. If you want to use parallel line or 450 ohm twin-lead, then connect the phasing harness straight across and connect the transmission line to the mid-point. But if you wish to use coaxial cable, then feed the antenna as shown in Figure 12.7C, using a 1:1 BALUN transformer. The 450 ohm twin-lead phasing harness between the elements should be twisted over on itself once, as shown.

The diamond loop

The diamond loop antenna is shown in Figure 7.13. This antenna is a shortened, flattened quad loop consisting of two equilateral triangles back to back. The length of each side, plus the height (dashed line) of the two principal apexes, is found from

$$L_{meters} = \frac{70}{F_{MHz}} \text{ meters}$$

In order to feed this antenna with coaxial cable, a 4:1 BALUN transformer is used between the coaxial cable and the feedpoint of the antenna.

Half-delta loop

The antenna in Figure 7.14 achieves a smaller size by being grounded. It is essentially one-half of a full-wave delta loop, with the other half being 'imaged' in the ground. The wire forms a right triangle, with the vertical

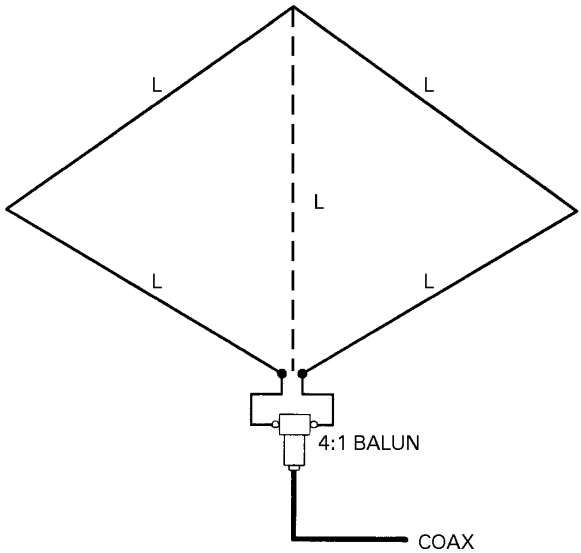


FIGURE 7.13

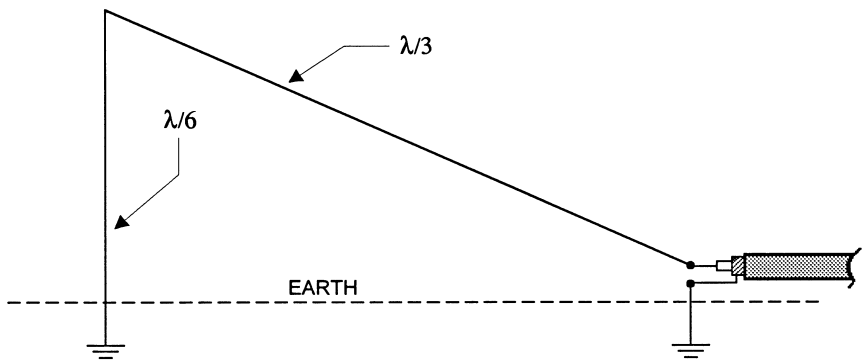

FIGURE 7.14

section being $\lambda/6$ and the sloping section being $\lambda/3$. These lengths are found from

$$\frac{\lambda}{3} = \frac{102}{F_{\text{MHz}}} \text{ meters}$$

and

$$\frac{\lambda}{6} = \frac{61}{F_{\text{MHz}}} \text{ meters}$$

The antenna is inherently unbalanced with respect to ground, so can be fed directly with 52 ohm coaxial cable.

Two-band compact loop

Most of the loops discussed thus far are basically monobanders, unless multiple loops are built on the same frame and fed in parallel. The loop in Figure 7.15, however, operates on two bands that are harmonically related to each other. For example, if FL is the lower band, and FH is the higher band, then FH = 2 × FL.

The overall length of the loop is a half wavelength, but it is arranged not into a square but rather into a rectangle in which the horizontal sides are twice as long as the vertical sides, i.e. the horizontal elements are a quarter wavelength and the vertical sections are one-eighth wavelength. The section lengths are

Horizontal:

$$L_{\text{hor}} = \frac{75}{F_{\text{MHz}}} \text{ meters}$$

Vertical:

$$L_{\text{ver}} = \frac{37.5}{F_{\text{MHz}}} \text{ meters}$$

In both equations, the frequency is the center frequency of the lower band of operation.

The vertical stub is made of 600 ohm parallel open-wire transmission line, although 450 ohm twin-lead could also be used. The length of the stub is found from the same equation (above) as the vertical segment if open-wire line is used. If twin-lead is used, then multiply that distance by the velocity factor of the transmission line.

The coaxial line is a Q-section made of 75 ohm transmission line. It is cut to a quarter wavelength of the upper band, i.e. twice F_{MHz} used in the calculations above.

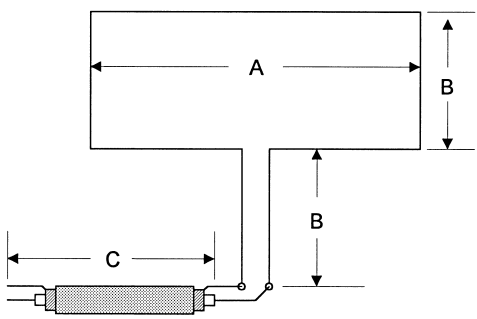

FIGURE 7.15

THE BI-SQUARE REALLY LARGE LOOP

The bi-square loop in Figure 7.16 is twice as large as the quad loop discussed earlier in this chapter. The overall length of the wire is two wavelengths, so each side is a half wavelength long. The overall length is calculated from

$$L_{\text{meters}} = \frac{585}{F_{\text{MHz}}} \text{ meters}$$

While each side is:

$$L_{\text{meters}} = \frac{146.25}{F_{\text{MHz}}} \text{ meters}$$

The bi-square antenna can be used on its design frequency, and also at one-half of its design frequency (although the patterns change). At the design frequency, the azimuthal pattern is a clover leaf perpendicular to the plane of the loop, and is horizontally polarized. At one-half the design frequency the radiation is vertically polarized, and the directivity is end fire.

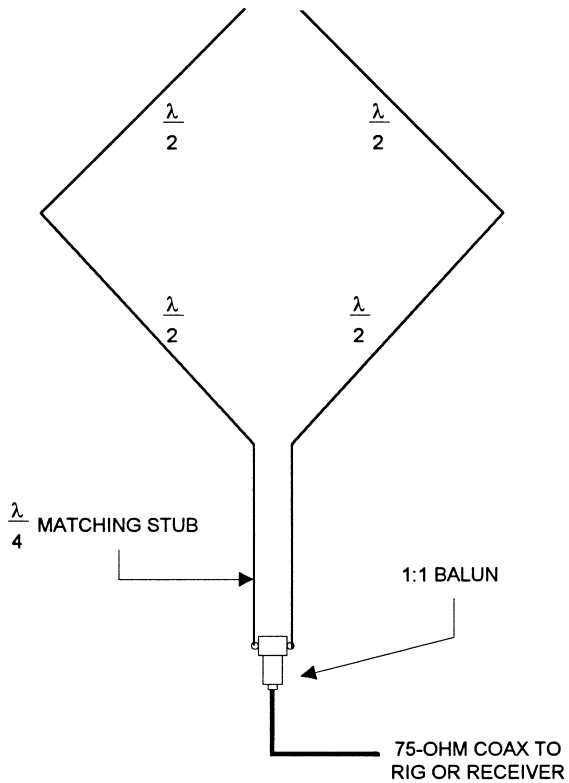

FIGURE 7.16

VHF/UHF QUAD BEAM ANTENNA

Figure 7.17 shows a VHF/UHF quad beam with four elements. Although it's technically possible to build such a beam for a lower frequency than VHF, it is not too practical because of mechanical considerations. But at VHF and UHF frequencies the dimensions of the elements become less large, and therefore more manageable. These dimensions are:

Reflector:

$$L_{\mathrm{REF}} = \frac{31\,500}{F_{\mathrm{MHz}}}\ \mathrm{cm}$$

Driven element:

$$L_{\mathrm{DE}} = \frac{30\,600}{F_{\mathrm{MHz}}}\ \mathrm{cm}$$

Directors:

$$L_{\mathrm{DIR}} = \frac{29\,700}{F_{\mathrm{MHz}}}\ \mathrm{cm}$$

Spacing between elements:

$$S = \frac{6000}{F_{\mathrm{MHz}}}\ \mathrm{cm}$$

Where all elements lengths are in centimeters (cm).

The antenna can be made of thin or thick wire. In the thin wire (#10 through #18) version, a support such as Figure 7.3 is needed. In the thick wire version, clothes line or other thick wire (#00 to #10) is needed. In that case, it might be possible to erect the antenna without any support other than the boom that holds all four elements.

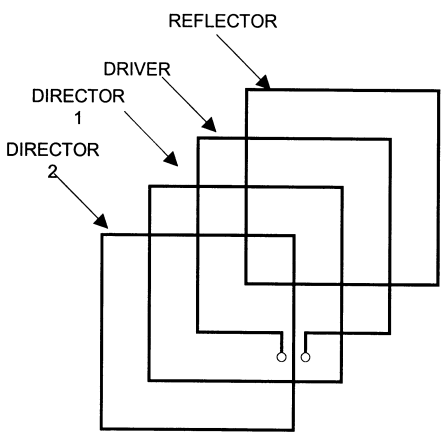

FIGURE 7.17

CHAPTER 8

Wire array antennas

The antennas found in this chapter are any of several array designs that use quarter-wavelength, half-wavelength, or other radiator elements arranged in a fixed array. There are several ways to categorize array antennas. A **collinear array** consists of two or more elements, ranging in length from 0.25λ to 0.65λ (some texts say 1λ), fed such that the currents in the elements are *in-phase* with each other.

Arrays are also classified according to the directivity: **broadside arrays** radiate and receive along a line perpendicular to the plane of the antenna, while **end-fire array**s radiat and receive off the ends of the elements.

The down side of these types of antennas is that many of them require parallel open-line transmission line (although some can use 300 or 450 ohm twin-lead), and impedance matching stubs. But we can handle that problem. Chapter 3 showed what parallel line and the two forms of twin-lead transmission line look like.

Some of the antennas can be fed directly with a 4:1 or 1:1 BALUN transformer and 75 ohm coaxial cable, but in many cases an **impedance matching stub** is needed (see Chapter 11). The BALUN transformers can either be homemade, or store-bought. Although antenna and scanner supplies distributors sell very high-frequency (VHF) BALUN transformers, you can also use television-style BALUN transformers. These may not be called BALUNs on the package, but are recognized by the fact that they have a coaxial 'F' connector at one end, and a piece of 300 ohm twin-lead at the other.

There are several antennas that fit either tightly or loosely into the general category of 'array antennas.' The selection of which antennas to put in this chapter, and which to put in Chapter 5 (dipoles, doublets), was not entirely clear in each case. This ambiguity was especially annoying when looking at antennas such as the double extended Zepp, which I put in Chapter 5. The problem is that antennas such as the double extended Zepp are quite properly called 'array' antennas even though they look suspiciously like doublets (which they are, of course). Other antennas were less difficult to place unambiguously in one chapter or the other.

ARRAY ANTENNAS

The idea in an array antenna is to provide directivity and gain by using two or more antenna elements in such a way that their fields combine and interact to focus the signal in one direction, or a limited number of directions (e.g. bidirectional, like a dipole). Figure 8.1A shows an array not unlike some of those in this chapter. It consists of two half-wavelength dipoles stacked one on top of another a distance (*S*) apart. The view here is broadside from the horizontal direction, so the dipole fed at A1–A2 is positioned above that which is fed at B1–B2.

One requirement of this form of antenna is that the two half-wavelength dipoles be driven in-phase with each other (some other antenna arrays want out-of-phase excitation). That means that the phase of the signal applied to A1–A2 is exactly the same as the phase of the signal applied to B1–B2. This is accomplished with either of the two methods shown in Figure 8.1B and

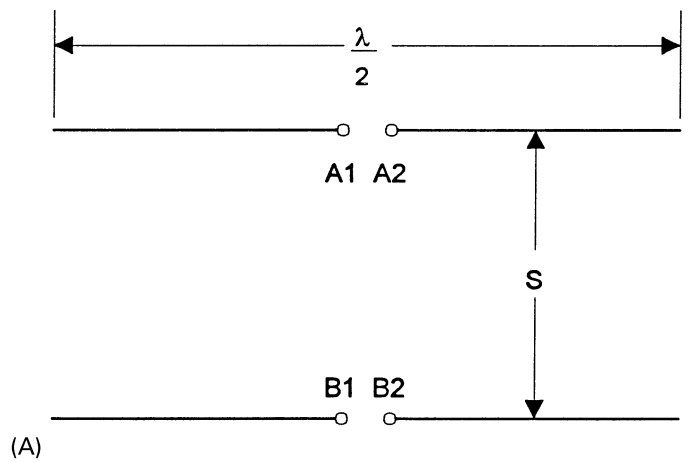

FIGURE 8.1

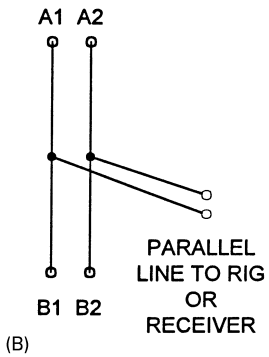
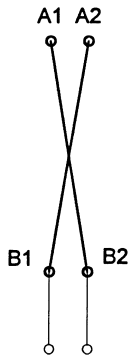
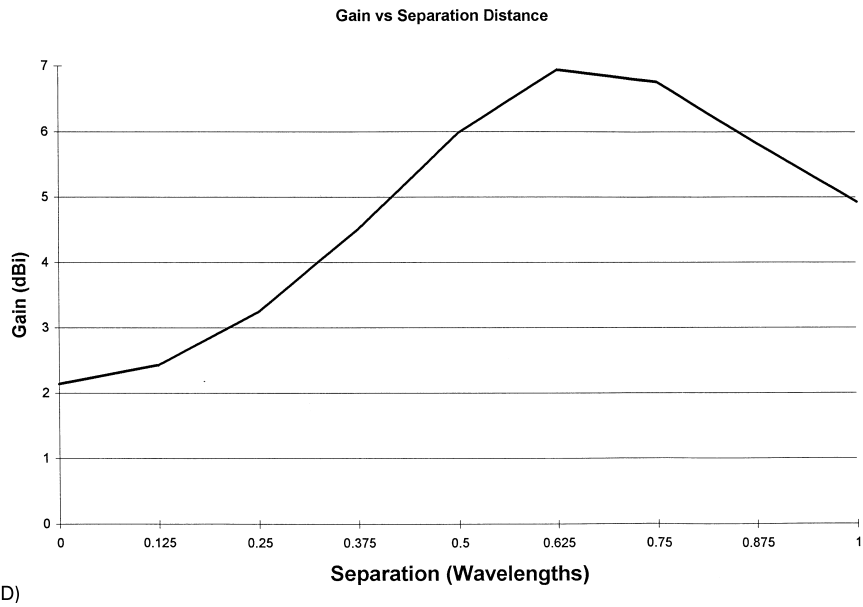


(B)



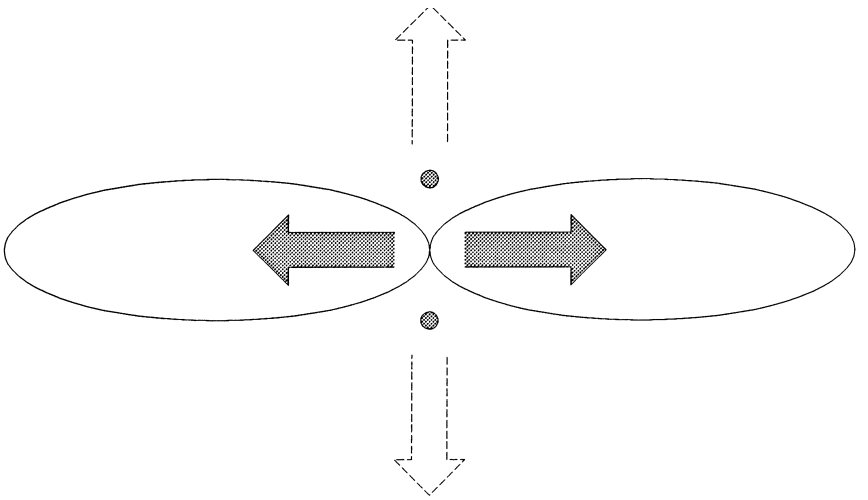
(C)



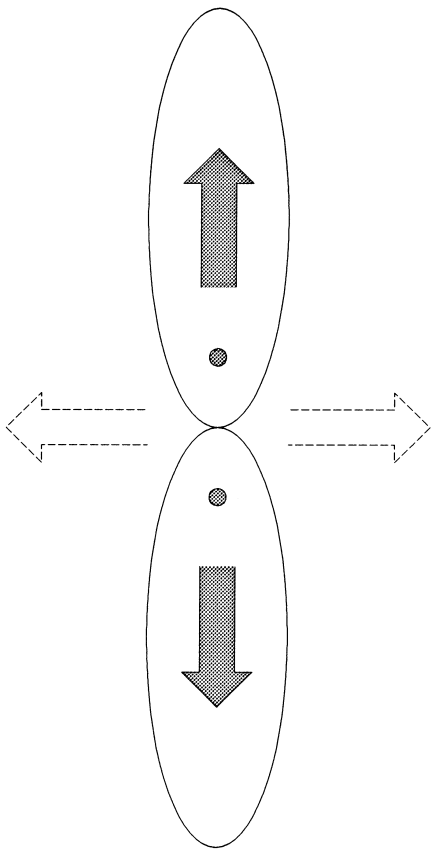
(D)

FIGURE 8.1 (*continued*)

8.1C. In Figure 8.1B, a piece of parallel transmission line is connected between the feedpoints such that A1 is connected to B1, and A2 is connected to B2. Another piece of parallel feedline from the receiver or transmitter is connected at the exact mid-point on the harness between the two dipoles.



(E)



(F)

FIGURE 8.1 (*continued*)

When this is done correctly, the voltages appearing across A1–A2 are exactly the same amplitude and phase as the voltages across B1–B2.

In the method used in Figure 8.1C, the parallel line from the rig or receiver is connected to the feedpoint of one dipole (in this case B1–B2). In order to preserve the 180° phase relationship between the elements, the feedline phasing harness between A1–A2 and B1–B2 must be twisted once such that A1 is connected to B2, and A2 is connected to B1.

The gain realized by stacking the two half-wavelength dipoles in this manner is a function of the spacing (S) between the elements. The approximate gain above isotropic that can be realized is shown in Figure 8.1D (note: to convert to gain above a dipole, subtract 2.14 dB from each value). Note that the gain peaks at about 6.94 dBi (or 4.8 dBd) in the vicinity of $5\lambda/8$ (0.625λ). This is the maximum gain realizable from this configuration. Although it looks good, there are sometimes other factors that deteriorate gain performance, so some experimentation with element spacing is usually in order for those who desire peak performance.

The antenna pattern produced by phased array antennas depends on the nature of the elements, the spacing between them and the ratio of the currents flowing in the elements. In the simple case of two elements spaced a half wavelength apart, we will see the general patterns of Figures 8.1E and 8.1F. These patterns are azimuthal plots as seen from above; the antennas are omnidirectional vertical radiators. The pattern in Figure 8.1E is for the case where the two antenna elements are fed in-phase with each other. The maxima are perpendicular to a line between the two antennas, while the minima are off the ends. Feeding the antennas out-of-phase with each other (Figure 8.1F) flops the pattern over so that the maxima are along the line between the elements, and the minima are perpendicular to this line.

There are a large number of patterns for various spacings and phase angles. The originals were developed in 1929 by a chap named Brown, and published in the USA in *The Proceedings of the Institute of Radio Engineers* (now the Institute of Electrical and Electronics Engineers). Brown's patterns are reproduced in *The ARRL Antenna Handbook* and any of several antenna engineering handbooks. Now let us look at some antennas.

TWO-ELEMENT COLLINEAR ARRAY

One of the simplest forms of gain array antenna is the two-element collinear array (shown in Figure 8.2 as a side view). It consists of two half-wavelength dipoles spaced a half wavelength apart. This antenna gives a gain of 3 dB, and is a broadside array (when viewed from above the pattern is perpendicular to the line between the antenna elements).

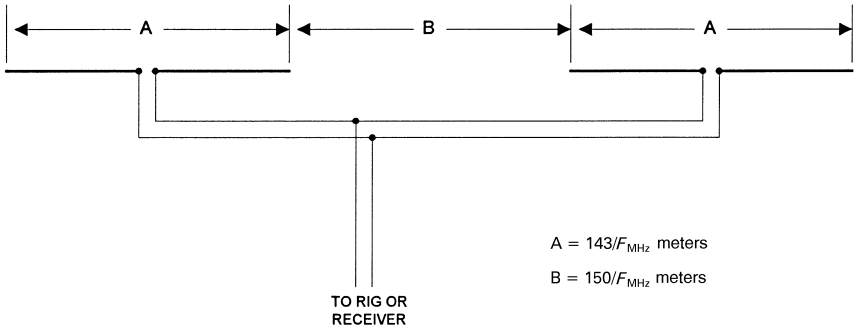


FIGURE 8.2

Each antenna element is a half wavelength, but the actual lengths and the equations used to calculate them are a little different for the HF and VHF/UHF bands.

HF band lengths

On the HF bands (3–30 MHz) the antenna is most likely mounted close to the Earth's surface, so there will be some end-effect reduction of the antenna length due to capacitive coupling. There is also a small reduction (2–3%) due to the velocity factor of the signal in the wire (this is set by the length/diameter ratio of the wire). As a result, the length of the elements is typically reduced 4–5% compared with the free space length. The gap between the dipoles, however, is calculated at the free space value. Thus,

$$A = \frac{143}{F_{\text{MHz}}} \text{ meters}$$

and

$$B = \frac{150}{F_{\text{MHz}}} \text{ meters}$$

Typical lengths for popular bands are given in Table 8.1.

TABLE 8.1

Band (MHz)	*A* (m)	*B* (m)
7.00	20.40	21.43
9.75	14.63	15.40
14.20	10.06	10.55
16.00	8.93	9.39
21.25	6.70	7.07
24.40	5.85	6.16

VHF/UHF band lengths

The physical length of the dipoles for VHF can be calculated from the free space version of the equation because these antennas are typically installed a sufficient number of wavelengths above the Earth's surface that the free space constant is reasonable. Thus, both A and B are the same physical length. These lengths are found as $A_{cm} = B_{cm} = 2324/F_{MHz}$, where F_{MHz} is the frequency in megahertz. Thus, at 150 MHz, the half wavelength is 15.49 cm; at 450 MHz it is 5.16 cm; and at 800 MHz it is 2.91 cm.

The antenna in Figure 8.2 is a little inconvenient in one respect: it requires two transmission lines connected in parallel. This is easily accomplished by using 75 ohm coaxial cable from each antenna element to a 'tee' connector, and then a piece of 52 ohm cable from the 'tee' connector to the receiver. At HF frequencies this antenna can take up a lot of 'footprint' space.

A different solution is shown in Figure 8.3. The antenna elements are separated by only a few centimeters, rather than a half wavelength. The gain drops to 1.6 dB for two elements (although for three elements it is 3 dB, and for four elements it is 4.2 dB). The antenna is fed by 450–600 ohm parallel line or twin-lead. The feedpoint impedance will be as low as 1 kilo-ohm if tubing is used, and up to 4–6 kilo-ohms if wire is used. This is one of those antennas where a matching stub is needed.

The four-element version of the antenna is shown in Figure 8.4 (it is called the **collinear array** or **Franklin array**). This antenna is similar to the two-element version of Figure 8.3, but with an additional half-wavelength element tacked onto the ends. The additional elements are separated by quarter-wavelength **phase reversal stubs**. The stubs are needed to keep the phase of the currents flowing in the outer elements the same as the currents flowing in the center elements. These stubs are made from the same type of

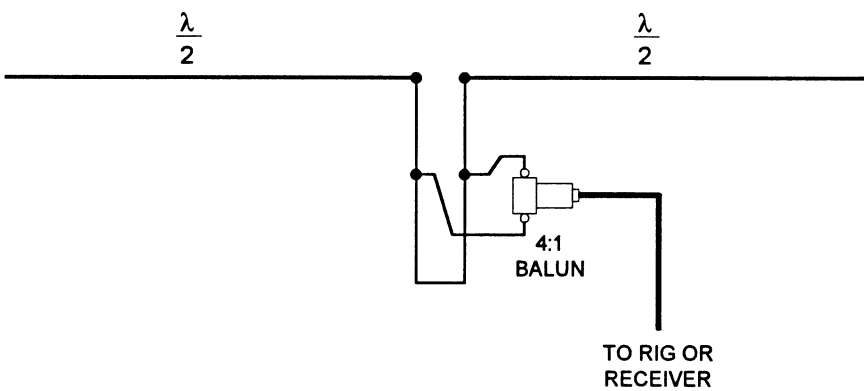

FIGURE 8.3

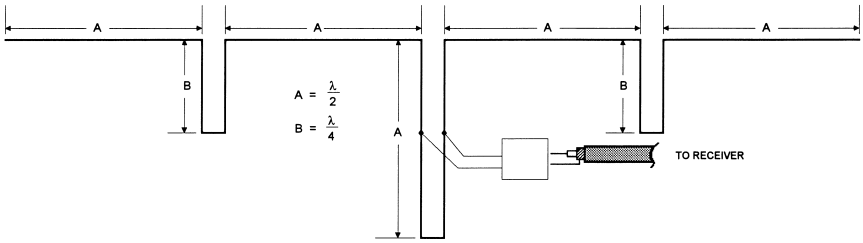

FIGURE 8.4

transmission line as the half-wavelength matching stubs, but are half as long.

Another collinear array is shown in Figure 8.5. This antenna offers 3 dB of gain, and can be fed directly from 75 ohm coaxial cable through a 4:1 BALUN transformer. The antenna consists of three half-wavelength elements, but the center element is fed at the center point (a quarter wavelength from each end). The quarter-wavelength phase reversal stubs are used between the center element and the two outer elements.

FOUR-ELEMENT BROADSIDE ARRAY

A four-element vertical broadside array is shown in Figure 8.6. Although often implemented using aluminum tubing, the array can easily be erected using wire elements as well. This antenna has four half-wavelength elements spaced a half wavelength from each other. Like the antenna above, the radiation direction is perpendicular to the line between the antennas, or in and out of the page.

The antenna elements are fed by a length of 600 ohm parallel line that connects all four together. But notice that the outside elements are fed by reversing the phase. This means that the transmission line must be twisted

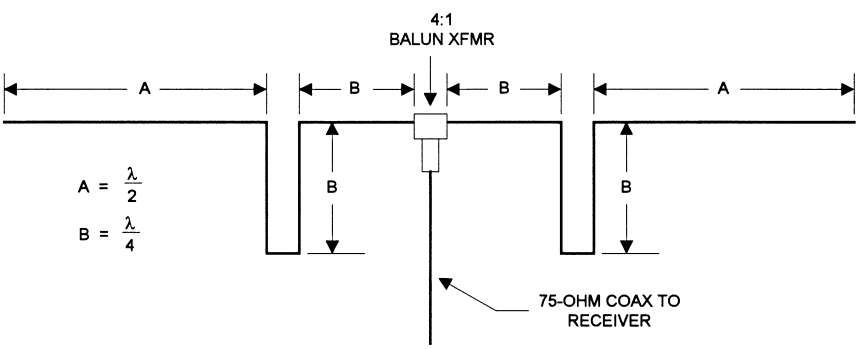

FIGURE 8.5

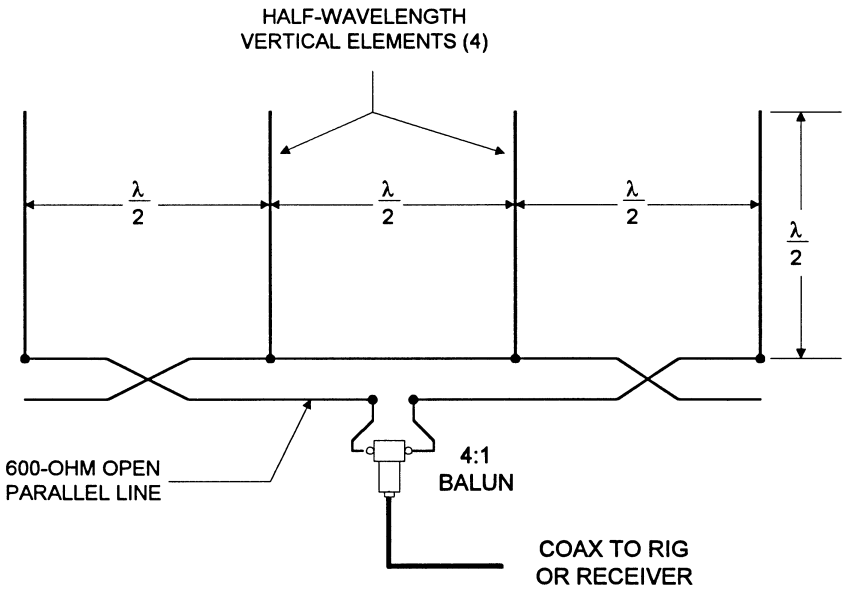

FIGURE 8.6

before being connected to the end elements; the unused conductor is left floating. The feedpoint impedance of this antenna is 200–300 ohms, so it can be fed with either 52 or 75 ohm coaxial cable if a 4:1 BALUN transformer is provided. Gains of the order of 6–8 dB are realized with this antenna.

EIGHT-ELEMENT BROADSIDE ARRAY

The eight-element broadside array shown in Figure 8.7 is built using similar methods to the previous antenna, but with two bays of elements rather than just one. The overall height of the array is one wavelength (although half-wavelength versions can also be built at some cost to gain). As in the previous case, the elements are spaced a half wavelength apart and are fed at their bases through 600 ohm parallel line that is twisted at the ends. Rather than breaking one conductor to connect the feed, this antenna connects the BALUN transformer across the antenna phasing harness wires. Note also that a 1:1 BALUN is used here, rather than a 4:1 device as above. This antenna is capable of as much as 12 dB gain.

THE LAZY-H ARRAY

The lazy-H array is a special case of the doublet array in which the doublets making up the array are one wavelength long (Figure 8.8A), fed in-phase

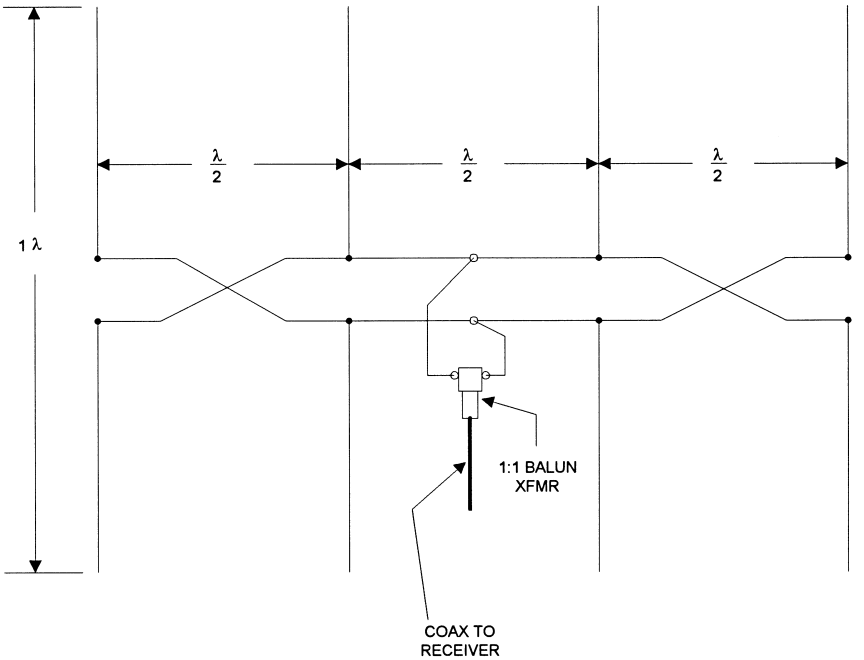

FIGURE 8.7

with each other. The directivity of this antenna is broadside, and so radiates in two directions into and out of the page. This view is as seen from the front or back, so note that the two one-wavelength doublets are stacked one on top of the other.

Gains for the lazy-H antenna vary with the spacing between the doublets (S), and will be as low as 4 dB at $3\lambda/8$ to almost 7 dB at $3\lambda/4$ spacing. The antenna should be installed at least a quarter wavelength above the Earth's surface.

The two doublets in the lazy-H must be fed in-phase with each other. When the feed arrangement is as shown in Figure 8.8A, i.e. with the feedpoint in the center, the transmission line phasing harness is connected straight across (no twisting). If only single-band operation is anticipated, then the feedpoint impedance will be a reasonable match to 75 ohm coaxial cable; a 1:1 BALUN transformer is used to connect the coaxial cable to the phasing harness. For multiband operation, however, it is necessary to use tuned feeders to an antenna tuning unit.

An alternative feed scheme is shown in Figure 8.8B. In this arrangement, the feedpoint is at the feedpoint of one of the doublets, rather than in the center of the harness. In order to preserve the in-phase relationship, the

harness must be twisted once as shown. The feedpoint impedance is around 3000 ohms, so a quarter-wavelength matching stub is needed in order to effect a reasonable match to the coaxial transmission line. Again, for multiband operation tuned feeders are advisable.

CURTAIN ARRAYS

The curtain arrays in this section are variations of the broadside arrays. The antenna shown in Figure 8.9 is a small **Sterba curtain array**, larger versions of which are often used by high-power international short-wave broadcasters. It can be fed with either 300 ohm twin-lead, or with 75 ohm coaxial cable if a 4:1 BALUN transformer is provided at the feedpoint.

The Sterba curtain antenna can be built of wire or aluminum tubing, although the wire option is probably the most popular at HF, and tubing at VHF. An advantage of these antennas is that they can be built for frequencies in the 6–7 MHz range (where wire construction is preferred), if you have enough room, and also well into the VHF region (in which case aluminum tubing construction is preferred).

The signal is bidirectional, and is broadside to the array (in and out of the page). Gain is of the order of 6 dB, although it rises with added numbers of sections.

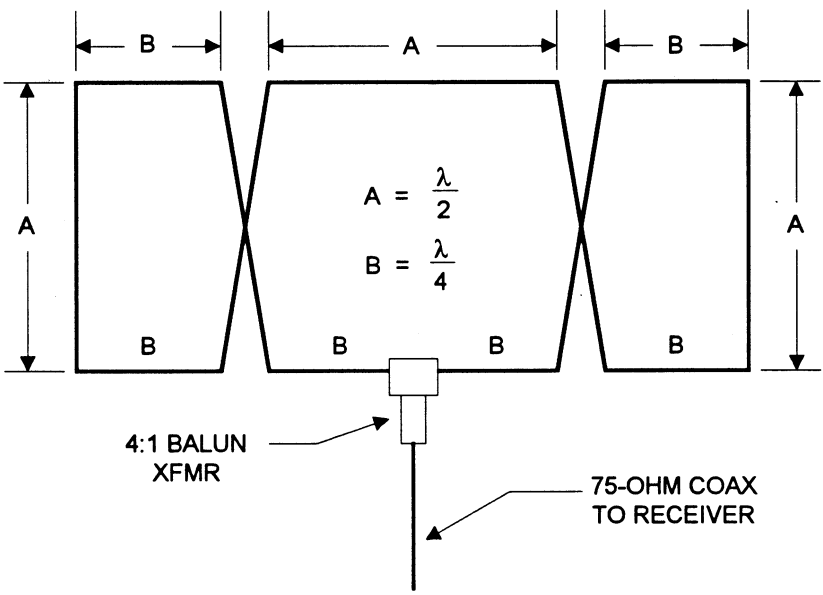

FIGURE 8.9

The antenna in Figure 8.10 (our micro-Sterba) uses elements of two different lengths ($\lambda/2$ and $\lambda/4$), labelled A and B. These lengths can be calculated from

$$A = \frac{149}{F_{\text{MHz}}} \text{ meters}$$

$$B = \frac{A}{2}$$

At 16 MHz, these lengths work out to be $A = 9.31$ m, $B = 4.66$ m; at 162 MHz, $A = 0.92$ m and $B = 0.46$ m.

The horizontal distance between horizontal elements should be 10.2–15 cm. In wire antennas, an ordinary end insulator placed between two elements will usually suffice.

The Sterba curtain concept can be extended by adding sections, which of course also increases gain. The version shown in Figure 8.10 provides gain up to 8 dB, and is basically a pair of the previous antennas back to back. The feedpoint is matched using a quarter wavelength stub and a 1:1 BALUN transformer. As with the other antennas, this is a broadside array.

The multisection Sterba curtain array shown in Figure 8.11 uses five loops, and is fed at the end with 300 ohm twin-lead (or a 4:1 BALUN connected to 75 ohm coaxial cable). Gain will be up to 9 dB or so, but at the cost of a lot of space (each A-section is a half wavelength long).

The **Bruce array** is shown in Figure 8.12. This type of array is built using a long wire folded and fed in such a manner that the current nodes (i.e. points of high current) are in the centers of the vertical elements, while the

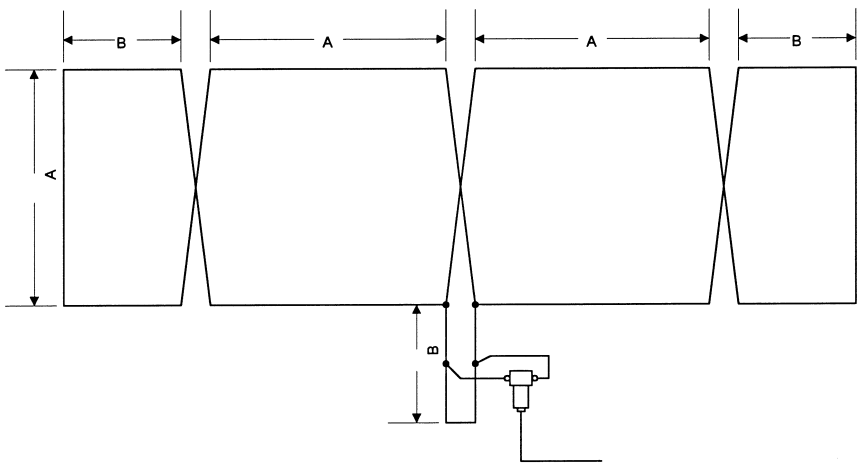

FIGURE 8.10

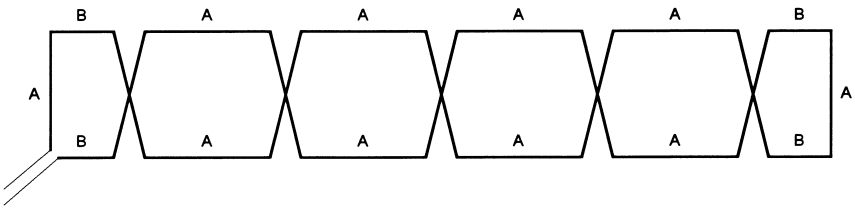

FIGURE 8.11

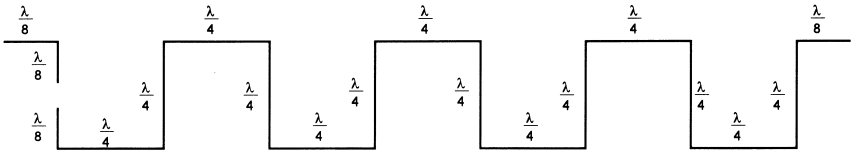

FIGURE 8.12

voltage nodes (points of low current) are in the centers of the horizontal elements. About 9 dB can be achieved with this antenna.

A variant Bruce array is shown in Figure 8.13. This antenna consists of two cross-connected sections, each of which are made of quarter-wavelength elements. The feedline is connected at the points marked X1–X2. The impedance at this point is around 700–800 ohms. If a 9:1 BALUN transformer is used, then this point can be fed with 75 ohm coaxial cable with only a small voltage standing wave ratio (VSWR), assuming single-band operation. It is also possible to feed this antenna on a single band with a quarter-wavelength matching stub, along with a 1:1 BALUN transformer. If you want to operate on two harmonically related bands, however, tuned feeders and an antenna tuner are required.

'SIX-SHOOTER' ARRAY

The array shown in Figure 8.14A is sometimes called the 'six-shooter' because it consists of six half-wavelength elements. In structure it is much

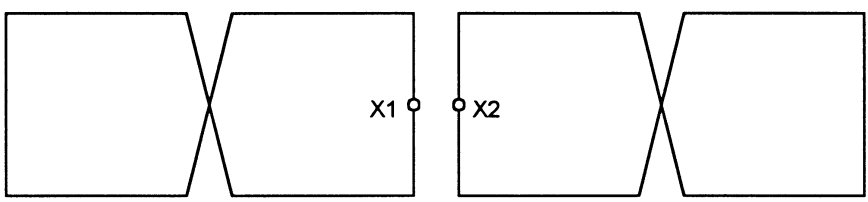

FIGURE 8.13

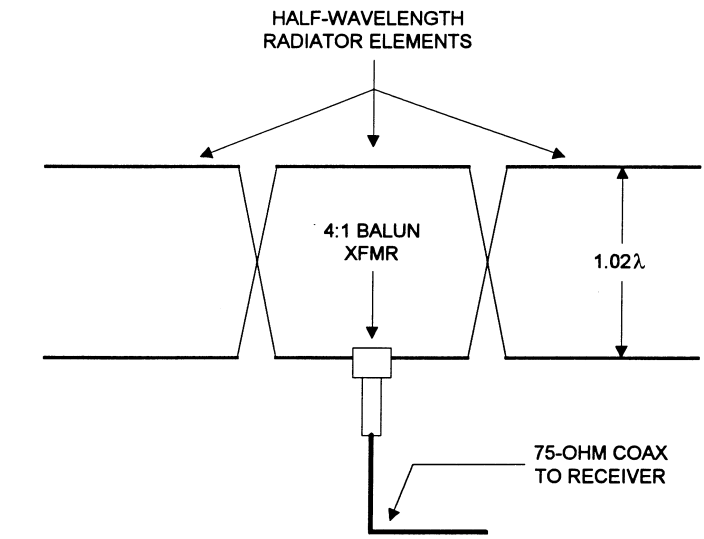
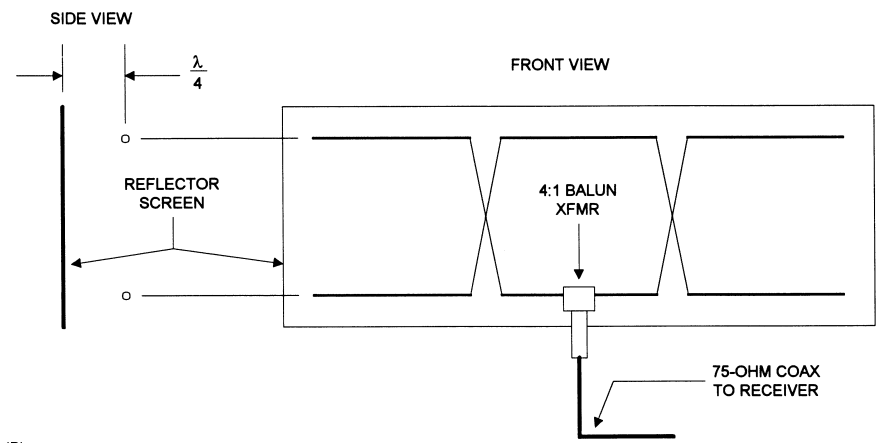
like the Sterba curtain shown earlier, with the end elements open circuited rather than connected together. This antenna is capable of gains between 7 and 8 dB.

The lengths of the elements in Figure 8.14A are calculated as shown in the figure. The horizontal elements are each calculated from

$$L_{\text{meters}} = \frac{145}{F_{\text{MHz}}} \text{ meters}$$



(A)



(B)

FIGURE 8.14

While the vertical separation between the two rows of horizontal elements is calculated from

$$L_{\text{meters}} = \frac{296}{F_{\text{MHz}}} \text{ meters}$$

These antennas are relatively easy to construct of either wire or tubing, and should be considered whenever you want gain on the cheap.

Like other broadside arrays, the 'six-shooter' is bidirectional, and sends or receives signals in and out of the page as you view the drawing. One variant that I saw on a 10 m amateur radio band 'six-shooter' is shown in Figure 8.14B. In this version, a screen is placed a quarter wavelength behind the antenna. Signals traveling toward the screen from the antenna are reflected back toward the antenna element. Because the spacing is a quarter wavelength, the signal reflected arrives back at the antenna in phase, so reinforces the signal going in the other direction. A gain improvement of 3 dB over the gain of the unscreened version is realized.

The screen can be almost any form of reflective plane. Although one could use sheets of copper or aluminum, this approach is not the best for most purposes. The reason is that the reflector then has a tremendous 'sail area' and so will be susceptible to wind problems. A better solution might be to use metal window screening (if you can still get it), or 'chicken wire' (i.e. the kind of wire used to screen chicken coops). Alternatively, one could also create an effective screen by connecting wires in a square matrix, provided that the gaps are only a small fraction of a wavelength (i.e. $\ll \lambda/8$).

THE BOBTAIL CURTAIN ARRAY

The bobtail curtain (Figure 8.15) is something of a favorite in the HF short-wave bands (with both listeners and ham operators) when very low angles of radiation are required. A low angle is the desired condition for maximizing the distance received by any given antenna (a good 'DX' antenna has an angle of radiation that barely kisses the horizon). The bobtail curtain fits this requirement rather nicely. Although it is easiest to construct for the upper HF bands, it is not beyond reason for many sites for 75/80 m band amateur radio operation or 60 m band short-wave activity.

The bobtail curtain consists of three quarter-wavelength radiators (*B*) connected at their tops by half-wavelength sections (*A*). Because the antennas are a quarter wavelength, the proper lengths are of the order of 19.82–21.34 m for the 75/80 m band and 14.63 m for the 60 m band. For the 13 m band, on the other hand, the lengths of the vertical radiators are only 2.9–3.05 m. The connecting half-wavelength sections are twice these lengths. Note that the current which is injected into the center section must split at the top, and only one-half of the line current of the center radiator flows

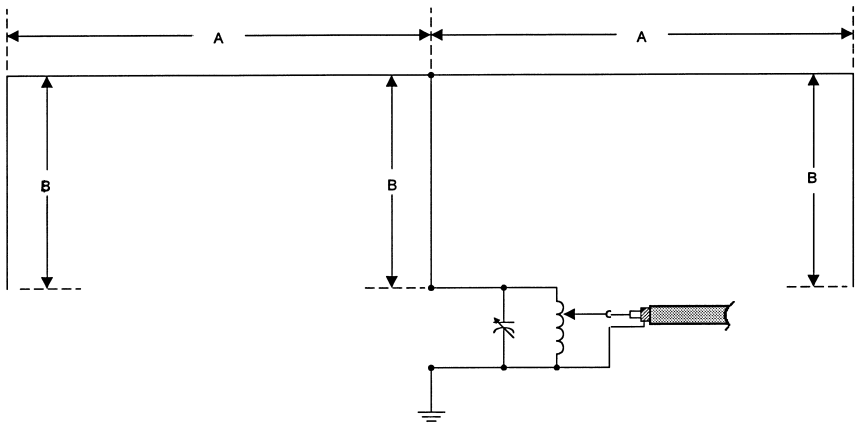


FIGURE 8.15

in each side radiator. This results in a **binomial current distribution** between the elements.

The gain of the bobtail curtain is 7–10 dB, with a figure '8' pattern broadside to the antenna. In trials some years ago, I witnessed a well-made bobtail curtain that only exhibited 5–6 dB (keeping in mind the difficulty of measuring antenna gain *in situ*), but even 5 dB is relatively decent compared to a dipole (nearly an *S*-unit on conservatively specified receivers). The directivity of the bobtail curtain is better than the dipole, but not quite as good as a set of three vertical radiators fed in-phase with each other (which will produce nearly the same pattern).

The bobtail curtain is fed at the base of the center element through a parallel tuned LC tank circuit used for impedance matching. The coaxial cable is connected to either a tap on the inductor (as shown) or to a link or primary winding (a couple of turns of wire) to the main inductor. The values of the inductor and capacitor are set such that the reactances are equal to 1100 ohms. For operation up to 20 MHz, a 50 pF variable capacitor will normally be satisfactory, although at higher frequencies the minimum capacitance of the typical 50 pF unit may be too high for the required capacitance (only a few picofarads). The inductor will vary from about 10 to 50 μH. The various inductances can be provided by either a variable inductor, or a fixed inductor with taps at the required inductance points.

THE THORNE ARRAY BOBTAIL CURTAIN ANTENNA

The Thorne Array Bobtail Curtain (TABC), shown in Figure 8.16, is basically a standard bobtail curtain array turned upside down, and fed

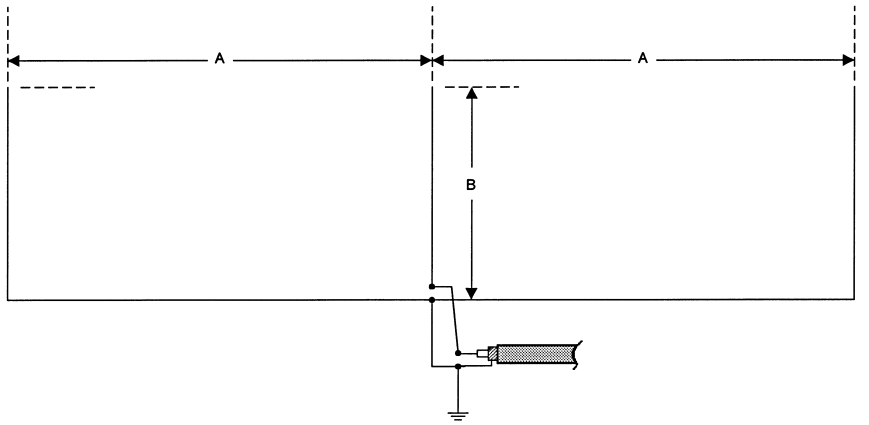

FIGURE 8.16

in a different manner. Bidirectional gains up to 5 dB have been measured on the 15 m band, although I suspect that the gain is due largely to compression of the elevation lobe of the antenna. This antenna has a very low angle of radiation, so works well for long-DX in the upper end of the short-wave spectrum. On the 15 m ham band, from a location in Texas, I have worked very loud Australian and New Zealand stations that were a lot less audible on the quarter-wavelength vertical and dipole antennas at the same location (and received much better signal reports of my own signal).

The TABC consists of three vertical quarter-wavelength ($\lambda/4$) radiators (B) separated by half-wavelength ($\lambda/2$) phasing elements (A). The two outer vertical elements are electrically connected to the corresponding phasing element, but insulated from the center vertical element. The two phasing elements are electrically connected to each other by a very short jumper wire. The center conductor of the 52 ohm coaxial cable to the receiver is connected to the base of the center vertical element, while the coaxial shield is connected to the jumper between phasing elements, and to ground.

The lengths of the two sections are $A = 91/F_{\mathrm{MHz}}$ meters and $B = 46/F_{\mathrm{MHz}}$ meters. For the 24 MHz band, the horizontal or phasing sections are 3.64 meters long while the vertical sections are 1.84 meters long.

Mechanically, the antenna is basically supported by dipole-like antenna end insulators and ropes to various masts or support structures (trees, buildings, etc.). If you prefer, the vertical sections can be replaced with 12–50 mm aluminum tubing, but you will have to provide some form of mounting for the tubing.

FOLDED DIPOLE 'X-ARRAY'

The array shown in Figure 8.17 uses four folded dipole antennas arranged in an 'X-array' pattern to provide about 6 dB gain. The antenna elements are made from 300 ohm twin-lead. The ends of the twin-lead conductors are shorted together in this type of antenna. The arrangement is two elements in each of two bays. In each bay, the inner ends of the folded dipole elements are spaced 0.2λ apart, while the two bays are spaced 1.25λ apart. The transmission line harnesses (P) are 0.45λ long. These transmission line harnesses are connected in phase with each other at the high impedance side of a 4:1 BALUN transformer; 75 ohm coaxial cable carries the signal to the receiver. All four elements in Figure 8.17 are in the same plane, and the direction of radiation/reception is perpendicular to that plane (i.e. in/out of the page).

PHASED VERTICALS

Figure 8.18 shows the basic two-element phased vertical array. This antenna uses two quarter-wavelength wire radiators erected in a vertical manner, spaced a half wavelength apart. Ropes or heavy twine can be used to support the antenna elements. The antenna element lengths are found from $L_{\text{meters}} = 75/F_{\text{MHz}}$, while the spacing between them is $D_{\text{meters}} = 150/F_{\text{MHz}}$.

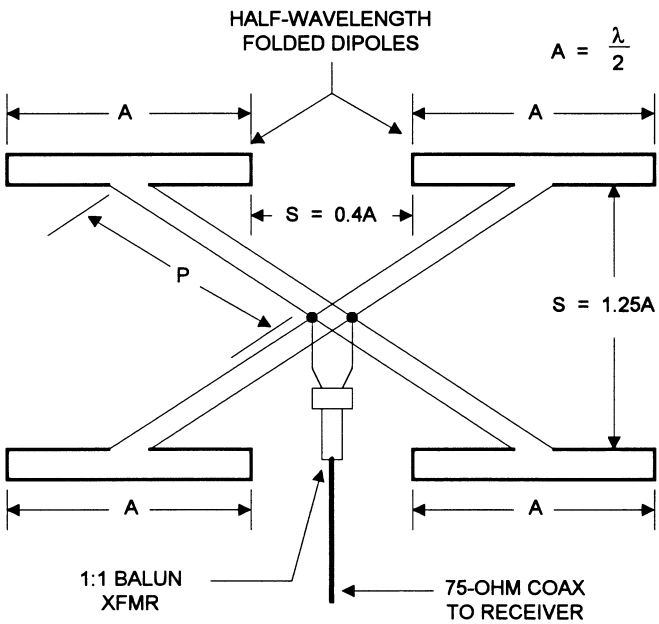

FIGURE 8.17

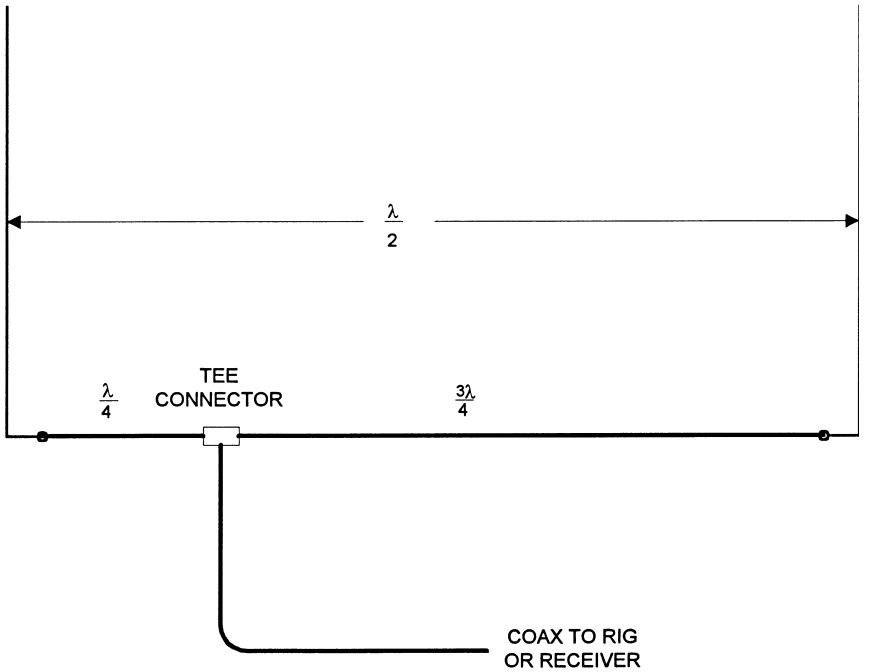

FIGURE 8.18

There are two ways to feed this antenna, and both use a coaxial cable 'tee' connector to split the signal from the rig between the two antennas. If you want to feed the antennas in phase, then the two segments of cable from the 'tee' to the antenna elements are equal lengths. But if you want to feed the elements 180° out of phase, then make one length $\lambda/4$ and the other $3\lambda/4$. In the case of in-phase feed, the directivity and gain are in and out of the page, while when the antennas are in phase the directivity and gain are bidirectional on a line between the two antennas (see again Figures 8.1E and 8.1F).

W8JK ARRAY

The W8JK array (Figure 8.19) is sometimes called the 'flat-top' beam. It is a bidirectional, end-fire array that consists of two half-wavelength in-phase collinear doublets, in parallel and fed 180° out of phase with each other, spaced between $\lambda/8$ and $\lambda/4$ apart. Each element in each collinear doublet is $\lambda/4$ long (dimension A). The view in Figure 8.20 is from above, so the plane of the dipoles is horizontal to the Earth's surface. The gain will be from 5.7 dBi at $\lambda/4$ spacing to 6.2 dBi at $\lambda/8$ spacing. Note that the spacing

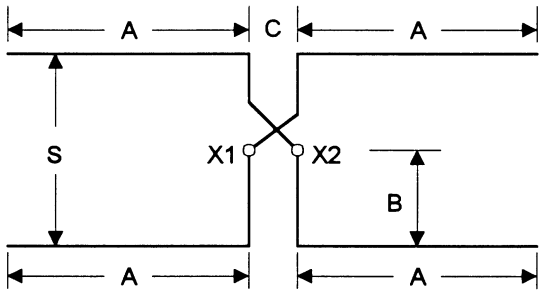

FIGURE 8.19

between the elements of the same dipole is of the order of

$$C = \frac{8.5}{F_{\text{MHz}}} \text{ meters}$$

The length of each wire element in the dipoles is found from:

$$A = \frac{71.5}{F_{\text{MHz}}} \text{ meters}$$

The feedline phasing harness between the center-feed points on the two dipoles is made of 450–600 ohm parallel transmission line (or 450 ohm twin-lead). The parallel feedline to the transmitter or receiver is attached to the phasing harness at points X1–X2, at a distance (B) of about $S/2$.

The impedance at the feedpoint (X1–X2) is several thousand ohms, so will necessarily create a rather high VSWR. An impedance matching stub can be provided at the feedpoint to improve the match to the transmission line. However, if tuned feeders are used then this antenna is capable of multiband (harmonically related) operation.

An end-fed version of the W8JK array is shown in Figure 8.20. In this case, the C-dimension is the same as calculated above, but the A-dimension

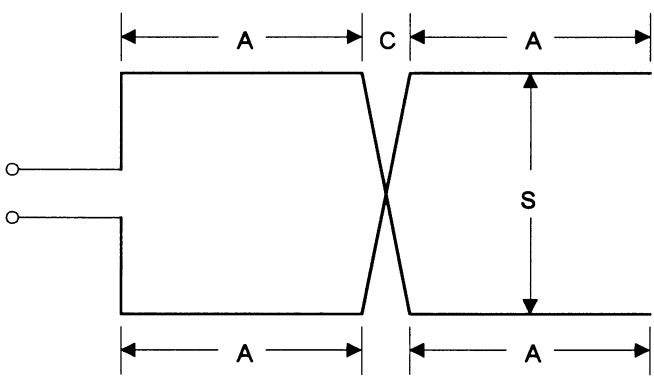

FIGURE 8.20

is not quite twice as long:

$$A = \frac{110}{F_{\text{MHz}}} \text{ meters}$$

As with the previous version, this antenna can be fed with a parallel tuned feeder, or with a matched line if an impedance matching stub is provided.

STACKED COLLINEAR ARRAYS

The collinear array antenna can be stacked as in Figure 8.21. This antenna consists of two collinear arrays (similar to Figure 8.5). The lengths of A, B and C are found from:

$$A = \frac{144}{F_{\text{MHz}}}$$

$$B = \frac{73}{F_{\text{MHz}}}$$

$$C = \frac{150}{F_{\text{MHz}}}$$

where A, B and C are in meters, and F_{MHz} is frequency in megahertz.

The two antennas are shown stacked vertically, although they can be stacked horizontally as well (although with a different pattern).

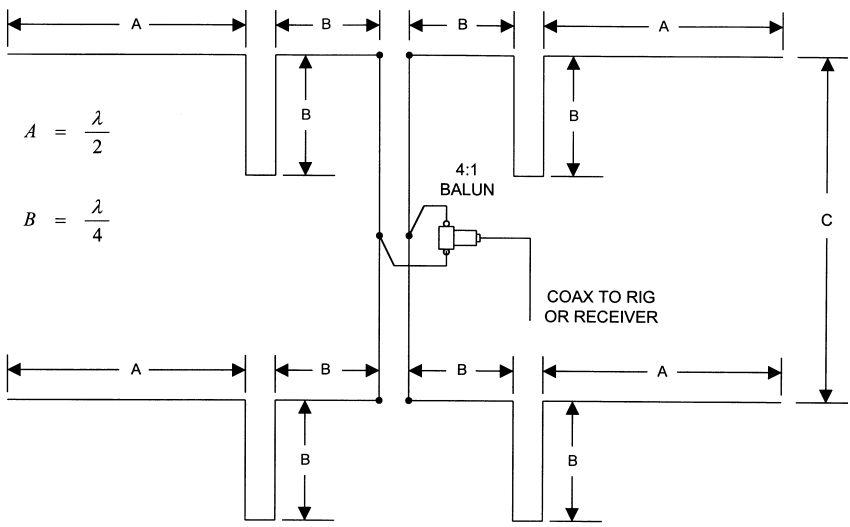

FIGURE 8.21

LARGE REFLECTOR ARRAY ANTENNA

Figure 8.22 shows a large-scale reflector array. It consists of a group of sixteen half-wavelength elements stacked vertically and horizontally. The elements are cross-connected with phasing harnesses. The spacing between elements is half wavelength, although the formula used to calculate this half wavelength is different from the half wavelength of the wire elements:

Wire elements:

$$\frac{\lambda}{2} = \frac{143}{F_{\text{MHz}}}$$

Spacing:

$$\frac{\lambda}{2} = \frac{150}{F_{\text{MHz}}}$$

The reflector screen can be made of chicken wire or any other screening material in which the holes are not more than about $\lambda/12$ in size. It is sized at least $\lambda/8$ larger than the outside dimensions of the array itself. The reflector screen is located a quarter wavelength behind the antenna array elements. The antenna array elements are made of either thin (#10 to #18) or thick wire (#000 to #10).

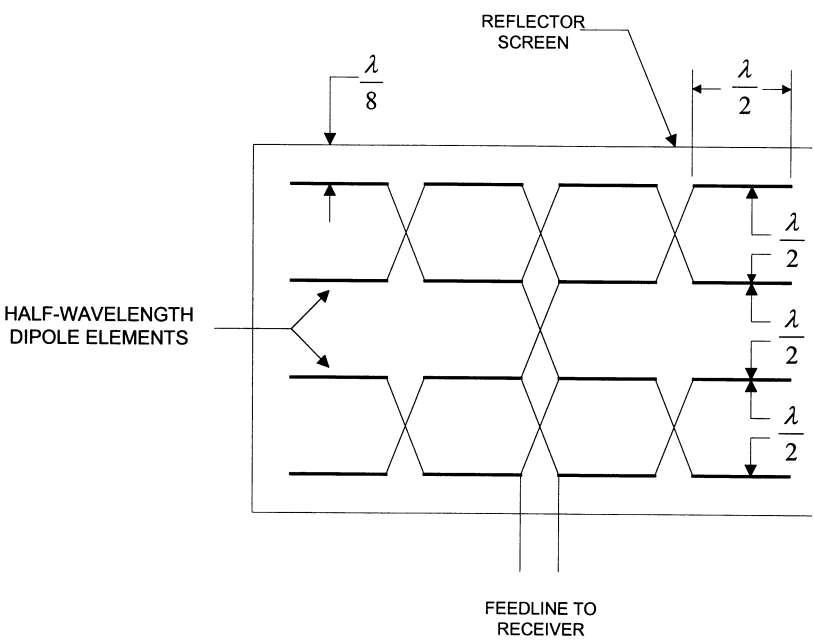

FIGURE 8.22

CHAPTER 9

Small loop antennas

In this chapter you will learn about small loop receiving antennas. The small loop antenna is almost ideal for DXing the crowded AM broadcast band and low frequency 'tropical' bands. These antennas are fundamentally different from the large loop types previously discussed and are very often the antenna of choice for low frequency work.

Large loop antennas are 0.5λ or larger and respond to the electrical field component of the electromagnetic wave. Small loop antennas, on the other hand, are $<0.1\lambda$ (some sources say 0.17λ and $<0.22\lambda$) and respond to the magnetic field component of the electromagnetic wave. One principal difference between the large loop and the small loop is found when examining the radio frequency current induced in the loop when a radio signal intersects it. In a large loop, the dimensions in each section are an appreciable portion of one wavelength, so the current will vary from one point in the conductor to another. But in a small loop, the current is the same throughout the entire loop.

The differences between small loops and large loops show up in some interesting ways, but perhaps the most striking are the directions of maximum response – the main lobes – and the directions of the nulls. Both types of loop produce figure-of-eight patterns, but in directions at right angles with respect to each other. The large loop antenna produces main lobes *orthogonal*, at right angles or 'broadside' to, the plane of the loop. Nulls are off the sides of the loop. The small loop, however, is exactly the opposite: the main lobes are off the sides of the loop (in the direction of the loop plane), and the nulls are broadside to the loop plane (see Figure 9.1A).

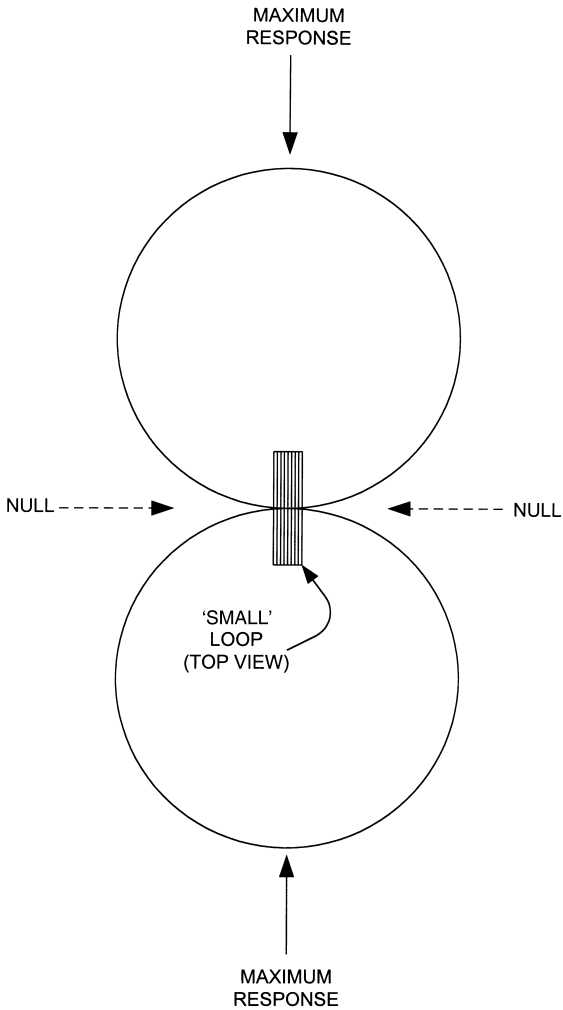

FIGURE 9.1A

Don't confuse small loop behavior with the behavior of the loopstick antenna. Loopstick antennas are made of coils of wire wound on a ferrite or powdered iron rod. The direction of maximum response for the loopstick antenna is broadside to the rod with deep nulls off the ends (Figure 9.1B). Both loopsticks and small wire loops are used for radio direction-finding and for shortwave, low frequency medium wave, AM broadcast band, and VLF DXing.

The nulls of a loop antenna are very sharp and very deep. Small changes of pointing direction can make a profound difference in the response of the antenna. If you point a loop antenna so that its null is aimed at a strong

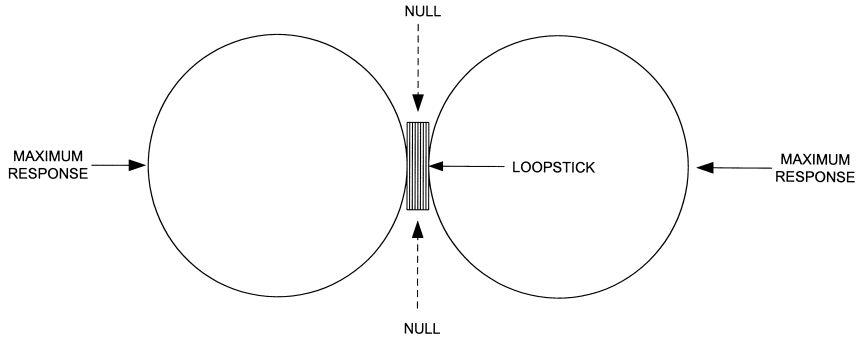

FIGURE 9.1B

station, the signal strength of the station appears to drop dramatically at the center of the notch. But turn the antenna only a few degrees one way or the other, and the signal strength increases sharply. The depth of the null can reach 10 to 15 dB on sloppy loops and 30 to 40 dB on well-built loops (20 dB is a very common value). I've seen claims of 60 dB nulls for some commercially available loop antennas. The construction and uniformity of the loop are primary factors in the sharpness and depth of the null.

One of the characteristics of the low frequency bands in which small loops are effective is the possibility of strong local interference smothering weaker ground wave and sky wave stations. As a result, you can't hear co-channel signals when one of them is very strong and the other is weak. Similarly, if a co-channel station has a signal strength that is an appreciable fraction of the desired signal, and is slightly different in frequency, then the two signals will heterodyne together and form a whistling sound in the receiver output. The frequency of the whistle is an audio tone equal to the difference in frequency between the two signals. This is often the case when trying to hear foreign broadcast band signals on frequencies (called *split frequencies*) between the standard 10 kHz spacing used in North and South America. The directional characteristics of the loop can help if the loop null is placed in the direction of the undesired signal.

Loops are used mainly in the low frequency bands even though such loops are either physically larger than high frequency loops or require more turns of wire. Loops have been used as high as VHF and are commonly used in the 10 meter ham band for such activities as hidden transmitter hunts.

Let's examine the basic theory of small loop antennas, and then take a look at some practical construction methods.

AIR CORE FRAME LOOPS ('BOX' LOOPS)

A wire loop antenna is made by winding a large coil of wire, consisting of one or more turns, on some sort of frame. The shape of the loop can be circular, square, triangular, hexagonal or octagonal. For practical reasons, the square loop seems to be most popular. With one exception, the loops considered in this section will be square so you can easily duplicate them.

The basic form of the simplest loop is shown in Figure 9.2. This loop is square, with sides the same length 'A' all around. The width of the loop ('B') is the distance from the first turn to the last turn in the loop, or the diameter of the wire if only one turn is used. The turns of the loop in Figure 9.2 are *depth wound,* meaning each turn of the loop is spaced in a slightly different parallel plane. The turns are spaced evenly across distance 'B'. Alternatively, the loop can be wound such that the turns are in the same plane (this is called *planar winding)*. In either case, the sides of the loop ('A') should be not less than five times the width ('B'). There seems to be little difference between depth and planar wound loops. The far-field patterns of the different shape loops are nearly the same if the respective cross sectional areas (πr^2 for circular loops and A^2 for square loops) are $<\lambda^2/100$.

The actual voltage across the output terminals of an untuned loop is a function of the angle of arrival of the signal *a*, as well as the strength of the signal and the design of the loop. The voltage V_o is given by:

$$V_o = \frac{2\pi ANE_f \cos(\alpha)}{\lambda}$$

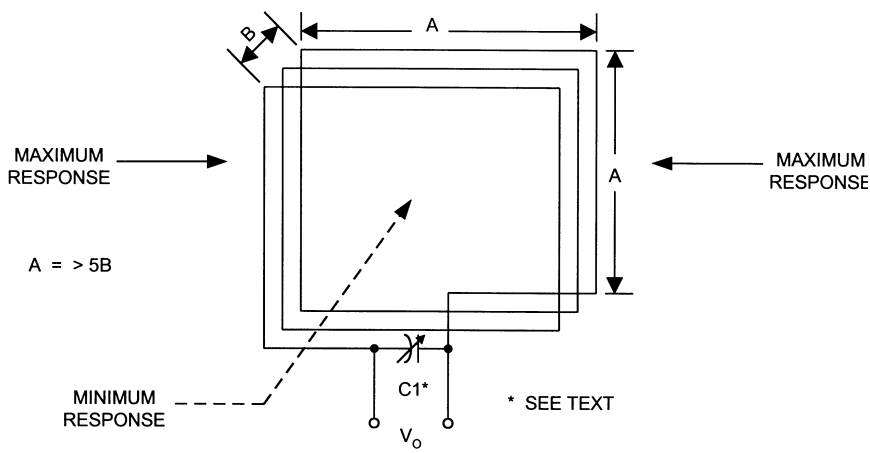

FIGURE 9.2

where:

V_o is the output voltage of the loop
A is the area of the loop in square meters (m^2)
N is the number of turns of wire in the loop
E_f is the strength of the signal in volts per meter (V/m)
a is the angle of arrival of the signal
λ is the wavelength of the arriving signal

Loops are sometimes specified in terms of the *effective height* of the antenna. This number is a theoretical construct that compares the output voltage of a small loop with a vertical piece of the same kind of wire that has a height of:

$$H_{\text{eff}} = \frac{2\pi NA}{\lambda}$$

If a capacitor (such as C1 in Figure 9.2) is used to tune the loop, then the output voltage V_o will rise substantially. The output voltage found using the first equation is multiplied by the loaded Q of the tuned circuit, which can be from 10 to 100 (if the antenna is well constructed):

$$V_o = \frac{2\pi ANE_f\, Q \cos(\alpha)}{\lambda}$$

Even though the output signal voltage of tuned loops is higher than that of untuned loops, it is nonetheless low compared with other forms of antenna. As a result, a loop preamplifier is usually needed for best performance.

TRANSFORMER LOOPS

It is common practice to make a small loop antenna with two loops rather than just one. Figure 9.3 shows such a transformer loop antenna. The main loop is built exactly as discussed above: several turns of wire on a large frame, with a tuning capacitor to resonate it to the frequency of choice. The other loop is a one or two turn coupling loop. This loop is installed in very close proximity to the main loop, usually (but not necessarily) on the inside edge not more than a couple of centimeters away. The purpose of this loop is to couple signal induced from the main loop to the receiver at a more reasonable impedance match.

The coupling loop is usually untuned, but in some designs a tuning capacitor (C2) is placed in series with the coupling loop. Because there are many fewer turns on the coupling loop than the main loop, its inductance is considerably smaller. As a result, the capacitance to resonate is usually much larger. In several loop antennas constructed for purposes of researching this chapter, I found that a 15-turn main loop resonated in the

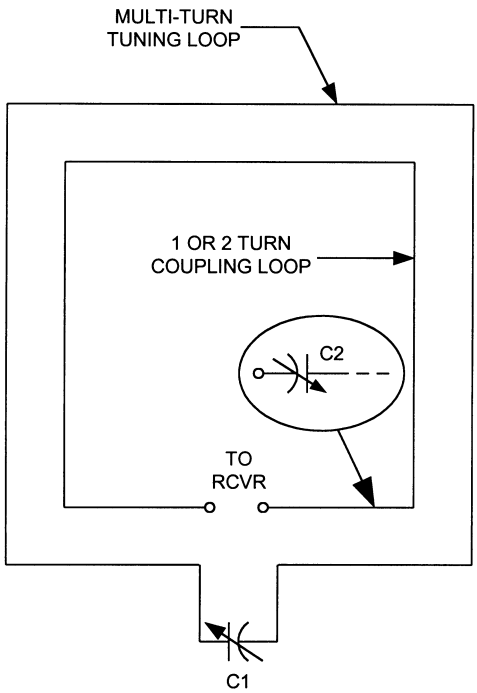

FIGURE 9.3

AM broadcast band with a standard 365 pF capacitor, but the two turn coupling loop required three sections of a ganged 3×365 pF capacitor connected in parallel to resonate at the same frequencies.

In several experiments, I used computer ribbon cable to make the loop turns. That type of cable consists of anywhere from eight to 64 parallel insulated conductors arranged in a flat ribbon shape. Properly interconnected (of which more later), the conductors of the ribbon cable form a continuous loop. It is no problem to take the outermost one or two conductors on one side of the wire array and use it for a coupling loop.

TUNING SCHEMES FOR LOOP ANTENNAS

Loop performance is greatly enhanced by tuning the inductance of the loop to the desired frequency. The bandwidth of the loop is reduced, which reduces front-end overload. Tuning also increases the signal level available to the receiver by a factor of 10 to 100 times. Although tuning can be a bother if the loop is installed remotely from the receiver, the benefits are well worth it in most cases.

There are several different schemes available for tuning, and these are detailed in Figure 9.4. The parallel tuning scheme, which is by far the most popular, is shown in Figure 9.4A. In this type of circuit, the capacitor (C1) is connected in parallel with the inductor, which in this case is the loop. Parallel resonant circuits have a very high impedance to signals on their

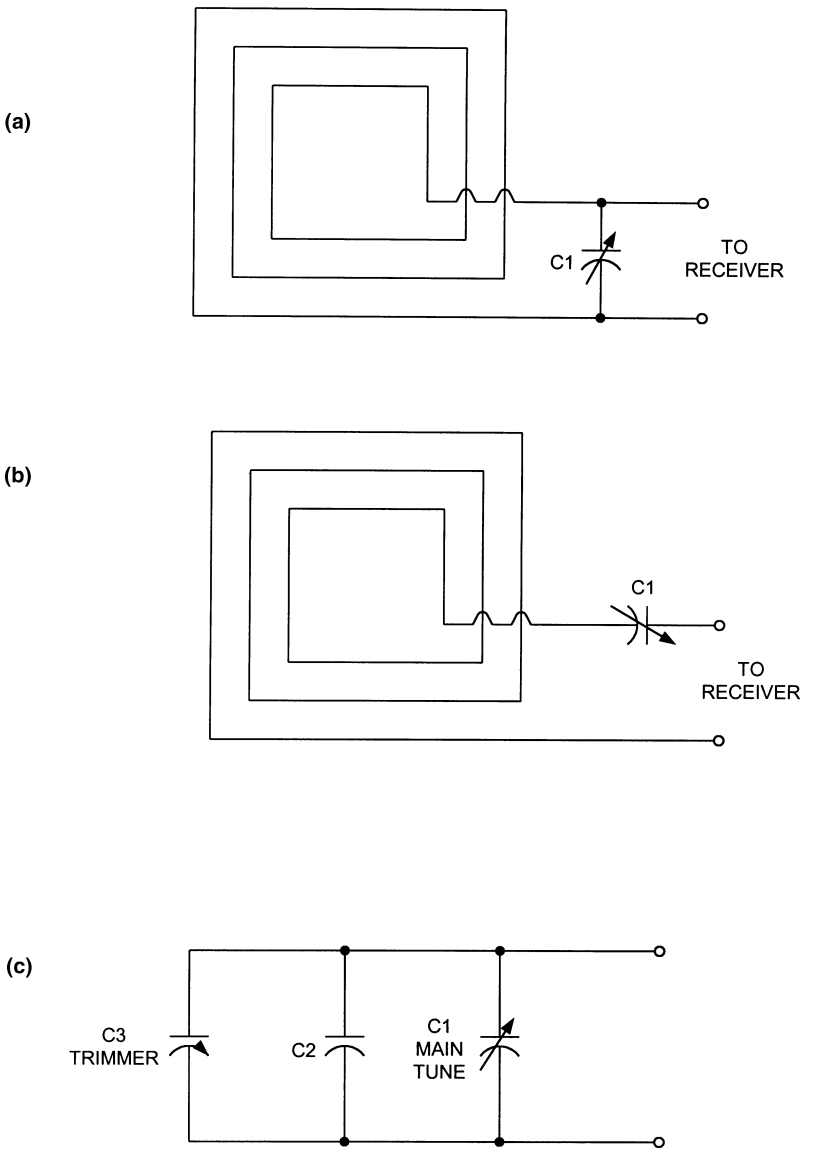

FIGURE 9.4

resonant frequency, and a very low impedance to other frequencies. As a result, the voltage level of resonant signals is very much larger than the voltage level of off-frequency signals.

The series resonant scheme is shown in Figure 9.4B. In this circuit, the loop is connected in series with the capacitor. A property of series resonant circuits is that it offers a high impedance to all frequencies except the resonant frequency (exactly the opposite of the case of parallel resonant circuits). As a result, current from the signal will pass through the series resonant circuit at the resonant frequency, but off-frequency signals are blocked by the high impedance.

There is a wide margin for error in the inductance of loop antennas, and even the precise-looking equations to determine the required values of capacitance and inductance for proper tuning are actually only estimations. The exact geometry of the loop 'as built' determines the actual inductance in each particular case. As a result, it is often the case that the tuning provided by the capacitor is not as exact as desired, so some form of compensation is needed. In some cases, the capacitance required for resonance is not easily available in a standard variable capacitor and some means must be provided for changing the capacitance. Figure 9.4C shows how this is done. The main tuning capacitor can be connected in either series or parallel with other capacitors to change the value. If the capacitors are connected in parallel, then the total capacitance is increased (all capacitances are added together). But if the extra capacitor is connected in series then the total capacitance is reduced. The extra capacitors can be switched in and out of a circuit to change frequency bands.

Tuning of a remote loop can be a bother if done by hand, so some means must be found to do it from the receiver location (unless you enjoy climbing into the attic or onto the roof). Traditional means of tuning called for using a low speed DC motor, or stepper motor, to turn the tuning capacitor. A very popular combination was the little 1 to 12 RPM motors used to drive rotating displays in retail store show windows. But that approach is not really needed today. We can use varactor voltage variable capacitance diodes to tune the circuit.

A varactor works because the junction capacitance of the diode is a function of the applied reverse bias voltage. A high voltage (such as 30 volts) drops the capacitance while a low voltage increases it. Varactors are available with maximum capacitances of 22, 33, 60, 100, and 400 pF. The latter are of most interest to us because they have the same range as the tuning capacitors normally used with loops. Look for service shop replacement diodes intended for use in AM broadcast band radios. A good selection, which I have used, is the NTE-618 device. It produces a high capacitance >400 pF, and a low of only a few picofarads over a range of 0 to 15 volts.

Figure 9.5 shows how a remote tuning scheme can work with loop antennas. The tuning capacitor is a combination of a varactor diode and two optional capacitors: a fixed capacitor (C1) and a trimmer (C2). The DC tuning voltage (V_t is provided from the receiver end from a fixed DC power supply ($V+$). A potentiometer (R1) is used to set the voltage to the varactor, hence also to tune the loop. A DC blocking capacitor (C3) keeps the DC tuning voltage from being shorted out by the receiver input circuitry.

THE SQUARE HOBBY BOARD LOOP

A very common way to build a square loop antenna is to take two pieces of thin lumber, place them in a cross shape, and then wind the wire around the ends of the wooden arms. This type of antenna is shown in Figure 9.6. The

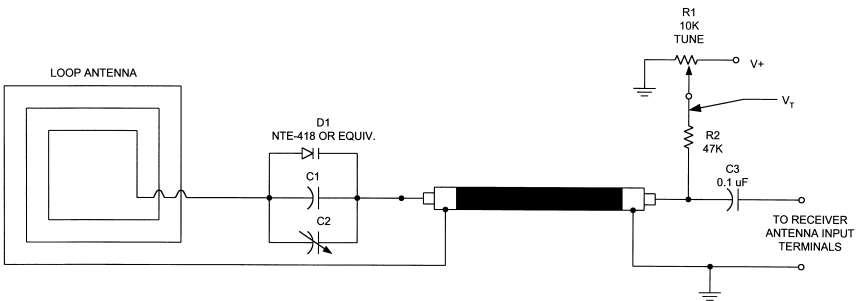

FIGURE 9.5

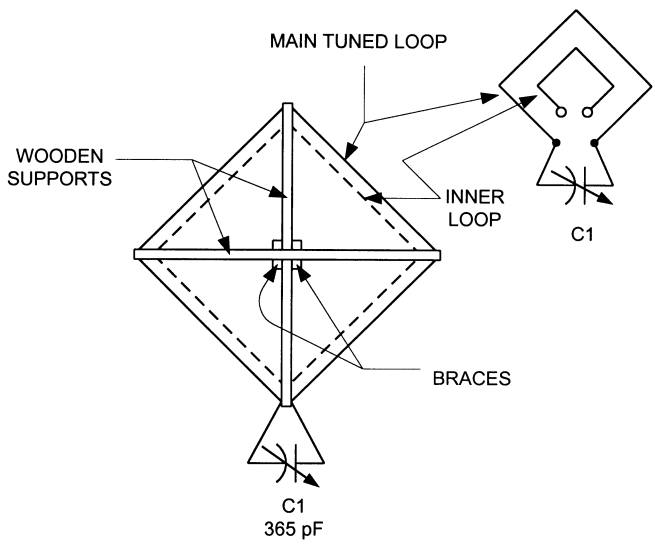

FIGURE 9.6

wooden supports can be made of $1'' \times 2''$ lumber, or some other stock. A test loop made while researching this book was made with two $3/16'' \times 3'' \times 24''$ Bass wood 'hobby board' stock acquired from a local hobby shop. Model builders use this wood as a stronger alternative to balsa wood.

The electrical circuit of the hobby board loop shown in Figure 9.6 is a transformer loop design. The main tuned loop is on the outside and consists of ten turns of #26 enameled wire. It is tuned by a 365 pF capacitor. The inner loop is used for coupling to the receiver and consists of a single turn of #22 insulated solid hook-up wire.

Details for the boards are shown in Figure 9.7. Each board is 24 inches (61 cm) long. At the mid-point (12″ or 30.5 cm), there is a $\frac{1}{4}$ inch (0.635 cm) wide, 1.5 inch (3.8 cm) long slot cut. These slots are used to mate the two boards together.

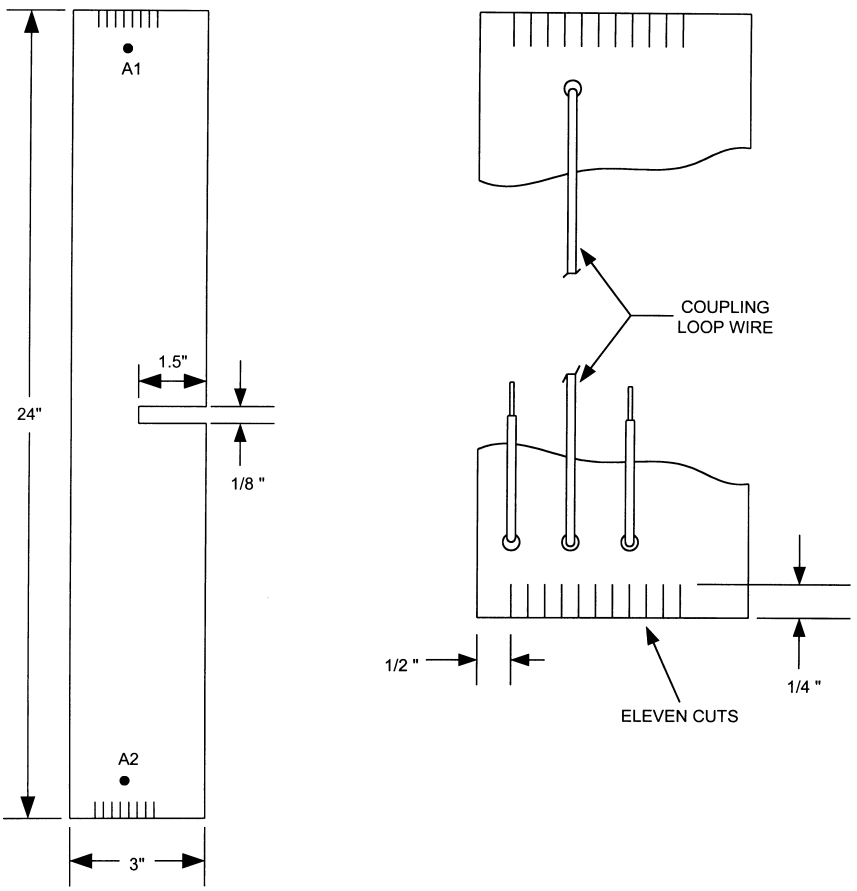

FIGURE 9.7

At each end there are ten tiny slits made by a jeweler's saw (also called a 'jig saw' in hobbyist circles) with a thin blade. These slits are just wide enough to allow a single #26 wire to be inserted without slipping. The slits are about $\frac{1}{4}$ inch (0.635 cm) long, and are $\frac{1}{4}$ inch (0.635 cm) apart. There are ten slits on both ends of the horizontal piece while the vertical piece has ten slits on the top end and 11 slits on the bottom end. The reason for offsetting the wire slits is to allow room on the other side of the 3 inch width of the vertical member for a mounting stick.

When assembling the antenna, use wood glue on the mating surfaces, square them to be at right angles to each other, and clamp the two pieces in a vice or with C-clamps for 30 minutes (or longer if the glue maker specifies). Next, glue the support blocks into place and clamp them for a similar period.

THE SPORTS FAN'S LOOP

OK, sports fans, what do you do when the best game of the week is broadcast only on a low-powered AM station – and you live at the outer edge of their service area where the signal strength leaves much to be desired? You use the sports fan's loop antenna, that's what! I first learned of this antenna from a friend of mine, a professional broadcast engineer, who worked at a religious radio station that had a pipsqueak signal but lots of fans. It really works – *one might say it's a miracle*.

The basic idea is to build a 16-turn, 24 inch (61 cm) square tuned loop (Figure 9.8) and then place the AM portable radio at the center (Figure 9.9) so that its loopstick is aimed so that its null end is broadside of the loop. When you do so, the nulls of both the loop and the loopstick are in the same direction. The signal will be picked up by the loop and then coupled to the radio's loopstick antenna. Sixteen-conductor ribbon cable can be used for making the loop. For an extra touch of class, place the antenna and radio assembly on a dining room table 'Lazy Susan' to make rotation easier. A 365 pF tuning capacitor is used to resonate the loop. If you listen to only one station, then this capacitor can be a trimmer type.

SHIELDED LOOP ANTENNAS

The loop antennas discussed thus far in this chapter have all been unshielded types. Unshielded loops work well under most circumstances, but in some cases their pattern is distorted by interaction with the ground and nearby structures (trees, buildings, etc.). In my own tests, trips to a nearby field proved necessary to measure the depth of the null because of

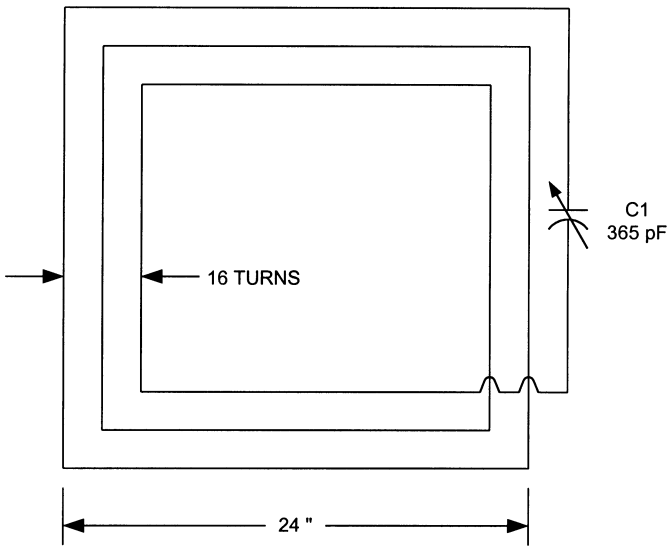

FIGURE 9.8

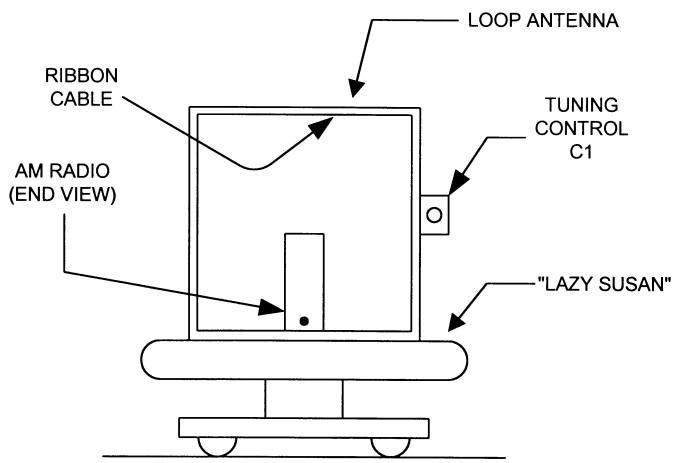

FIGURE 9.9

interaction with the aluminum siding on my house. Figure 9.10 shows two situations. In Figure 9.10A, we see the pattern of the normal 'free-space' loop, i.e., a perfect figure-of-eight pattern. But when the loop interacts with the nearby environment, the pattern distorts. In Figure 9.10B we see some filling of the notch for a moderately distorted pattern. Some interactions are so severe that the pattern is distorted beyond all recognition.

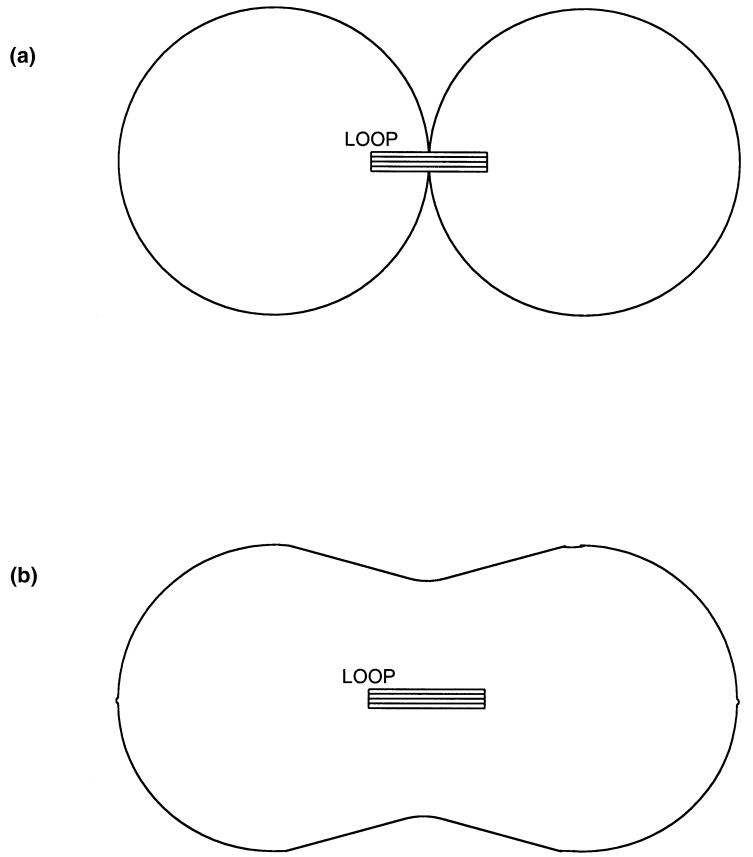

FIGURE 9.10

The solution to the problem is to reduce interaction by shielding the loop, as in Figure 9.11. Loop antennas operate on the magnetic component of the electromagnetic wave, so the loop can be shielded against voltage signals and electrostatic interactions. In order to prevent harming the ability to pick up the magnetic field, a gap is left in the shield at one point.

There are several ways to shield a loop. You can, for example, wrap the loop in adhesive-backed copper foil tape. Alternatively, you can wrap the loop in aluminum foil and hold it together with tape. Another method is to insert the loop inside a copper or aluminum tubing frame. The list seems endless. Perhaps one of the most popular methods is to use coaxial cable to make a large single turn loop. Figure 9.12 shows this type of loop made with RG-8/U or RG-11/U coaxial cable. The cable is normally supported by wooden cross arms, as in the other forms of loop, but they are not shown

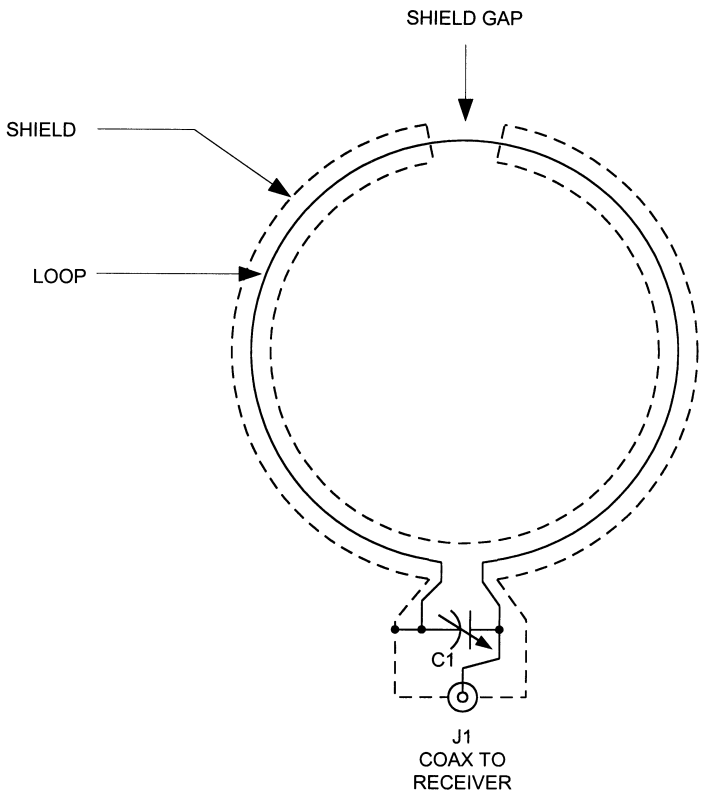

FIGURE 9.11

here for sake of simplicity. Note that, at the upper end, the coaxial cable shields are not connected.

Another example is the antenna shown in Figure 9.13. This antenna is made of wide metal conductors. Examples include the same type of hobbyist's brass stock as used above. It can also be copper foil or some other stock that can be soldered. Some electronic parts stores sell adhesive backed foil stock used for making printed circuit boards. The foil can be glued to some flat insulating surface. Although K-inch plywood springs to mind immediately, another alternative is found in artists' supplies stores. Ordinary poster board is too floppy to stand up, but poster board glued to a Styrofoam backing can be used. It is extremely easy to work with using X-acto knives and other common household tools.

Two controls are used on this antenna. Capacitor C1 tunes the loop to the resonant frequency of the desired station. Potentiometer R1 is used as a phasing control. The dimensions of the antenna are not terribly critical,

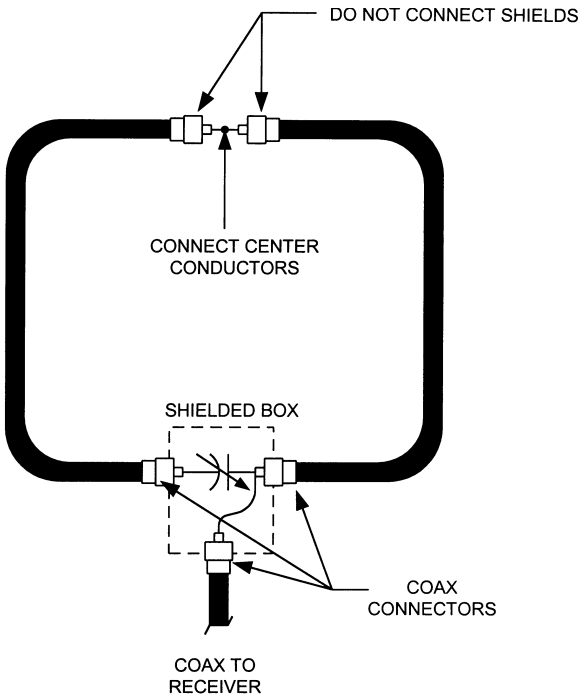

FIGURE 9.12

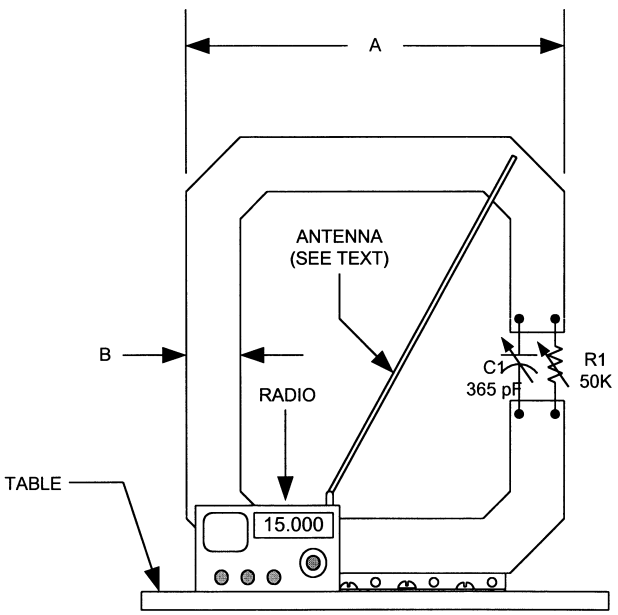

FIGURE 9.13

although some guidelines are in order. In the Villard article, he recommended a 40 cm (15.75-inch) square loop ('A'). If the loop is 7.62 cm (three inches) wide, the antenna will resonate at 15 MHz with around 33 pF of capacitance. If the dimensions are increased to A = 91 cm (36 inches) and B = 10.16 cm (four inches), then the inductance increases and only 28 pF are needed at 15 MHz. The larger size loop can be used at lower frequencies as well. For example, the 91 cm loop will resonate at 6 MHz with 177 pF.

To use this antenna, position the radio's telescopic antenna close and adjacent to the loop *but not touching it*. The loop antenna can be rotated to find the best position to either null or enhance a particular station. The 'Lazy Susan' idea will work well in this case.

TESTING YOUR LOOP ANTENNA

When each loop prototype was completed, I tested it on the AM broadcast band over several evenings. The same procedure can be used with any loop. A strong local signal at 1310 kHz served to check the pattern. The station and my home were located on US Geological Survey 7.5 minute quadrangle maps of my area (or the equivalent Ordnance Survey maps in the UK). The maps had adjacent coverage, so the compass bearing from my location to the station could be determined. Checking the antenna showed an S7/S8 signal when the loop was endwise to the station – that is, the station was in one of its lobes. Rotating the loop so that its broadside faced the direction of the station dropped the signal strength to less than S1, and frequently bottomed out the meter. Because my receiver has a 3 dB/S-unit calibration on the S-meter, I figured the null to be more than 20 dB, although it will take a bit more experimentation to find the actual depth. This test is best done during daylight hours, I found out, because there is always a residual sky wave cacophony on the AM band that raises the S-meter 'floor' in the null.

USING A LOOP ANTENNA

Most readers will use a loop for DXing rather than hidden transmitter hunting, navigation, or other RDF purposes. For the DXer, there are actually two uses for the loop. One is when you are a renter or live in a community that has routine covenants against outdoor antennas. In this situation, the loop will serve as an active antenna for receiving AM broadcast band and other low frequency signals without the neighbors or landlord becoming annoyed.

The other use is illustrated by the case of a friend of mine. He regularly tunes in clear channel WSM (650 kHz, Nashville) in the wee hours between

Saturday evening ('Grand Ole Opry' time) and dawn. However, that 'clear' channel of WSM isn't really so clear, especially without a narrow filter in the receiver. He uses a loop antenna to null out a nearby 630 kHz signal that made listening a bit dicey, and can now tape his 1940s/1950s vintage country music.

It isn't necessary to place the desired station directly in the main lobes off the ends of the antenna, but rather place the nulls (broadside) in the direction of the offending station that you want to eliminate. So what happens if the offending station and the desired station are in a direct line with each other with your receiving location in the middle between them? Both nulls and lobes on a loop antenna are bidirectional, so a null on the offending station will also null the desired station in the opposite direction.

One method is to use a sense antenna to spoil the pattern of the loop to a cardioid shape. Another method is to use a spoiler loop to null the undesired signal. The spoiler loop is a large box loop placed one to three feet (found experimentally) behind the reception loop in the direction of the offending signal. This method is detailed in Figure 9.14. The small loopstick may be the antenna inside the receiver, while the large loop is a box loop such as the sports fan's loop. The large box loop is placed about one to three feet behind the loopstick and in the direction of the offending station. The angle with respect to the line of centers should be 60° to 90°, which is also found experimentally. It's also possible to use two air core loops to produce an asymmetrical receiving pattern.

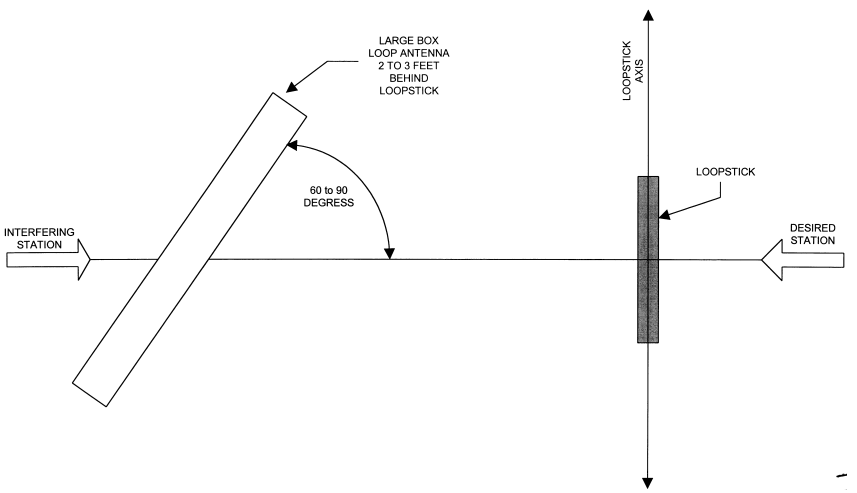

FIGURE 9.14

LOOP PREAMPLIFIERS

All small loop antennas produce a weak output signal, so a loop preamplifier is indicated for all but the most sensitive receivers. The preamplifier can be mounted either at the receiver or the antenna, but it is most effective when mounted at the antenna (unless the coax to the receiver is short).

SHARPENING THE LOOP

Many years ago the *Q-multiplier* was a popular add-on accessory for a communications receiver. These devices were sold as Heathkits and many construction projects were seen in magazines and amateur radio books. The Q-multiplier has the effect of seeming to greatly increase the sensitivity of a receiver, as well as greatly reducing the bandwidth of the front end. Thus, it allows better reception of some stations because of increased sensitivity and narrowed bandwidth.

A Q-multiplier is an active electronic circuit placed at the antenna input of a receiver. It is essentially an Armstrong oscillator, as shown in Figure 9.15, that doesn't quite oscillate. These circuits have a tuned circuit (L1/C1) at the input of an amplifier stage, and a feedback coupling loop (L3). The

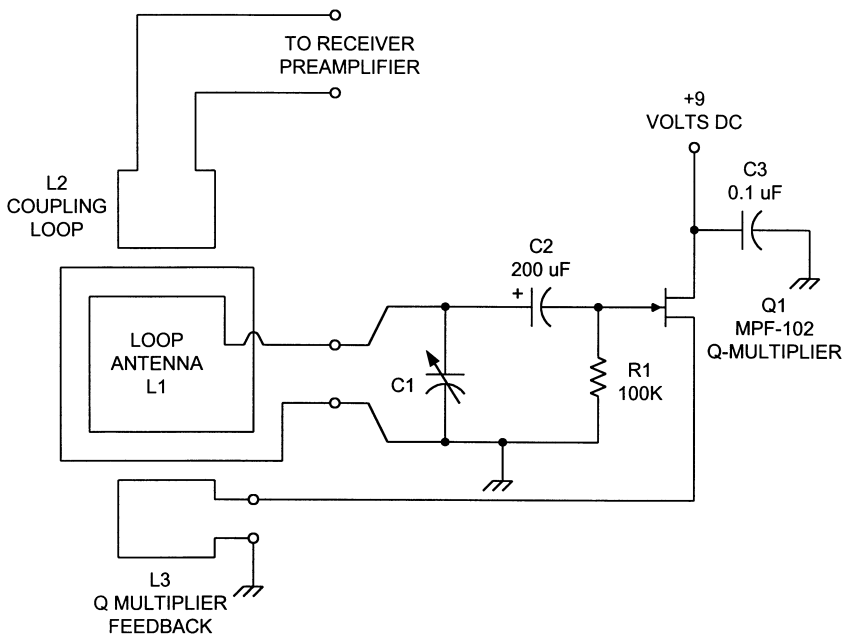

FIGURE 9.15

degree of feedback is controlled by the coupling between L1 and L3. The coupling is varied both by varying how close the two coils are, and their relative orientation with respect to each other. Certain other circuits use a series potentiometer in the L3 side that controls the amount of feedback.

The Q-multiplier is adjusted to the point that the circuit is just on the verge of oscillating, but not quite. As the feedback is backed away from the threshold of oscillation, but not too far, the narrowing of bandwidth occurs as does the increase in sensitivity. It takes some skill to operate a Q-multiplier, but it is easy to use once you get the hang of it and is a terrific accessory for any loop antenna.

CHAPTER 10

Yagi beam antennas

The Yagi beam antenna (more correctly, the Yagi–Uda antenna, after both of the designers of Tohoku University in Japan 1926) is *unidirectional*. It can be vertically polarized or horizontally polarized with little difference in performance (other than the polarization!). The Yagi antenna can be rotated into position with little effort. Yet the Yagi antenna shows power gain (so it puts out and receives a stronger signal), reduces the interfering signals from other directions, and is relatively compact.

COMPOSITION OF A BEAM ANTENNA

The Yagi antenna is characterized by a single driven element which takes power from the transmitter (or is connected to the receiver), plus one or more *parasitic elements*. The parasitic elements are not connected to the driven element, but rather receive their power from the driven element by indirect means. The indirect means is that they intercept the signal, and then re-radiate them.

The minimalist two element beam antenna may be composed of either a driven element and a reflector, or a driven element and a director. The reflector and directors are known as parasitic elements.

The *parasitic reflector* is three to five per cent *longer* than the half wavelength driven element. It provides power gain in the direction away from itself. It is inductive in reactance and lagging in phase.

The *parasitic director* is three to five per cent *shorter* than the half wavelength driven element. It provides power gain in its own direction. It is capacitive in reactance and leading in phase.

The factors that affect the phase difference between the direct and re-radiated signals is determined principally by the *element length* and the *spacing* between the elements. Proper adjustment of these factors determines the gain and the front-to-back ratio that is available.

The presence of a parasitic element in conjunction with a driven element tends to reduce the feedpoint impedance of the driven element for close spacings ($<\lambda/2$) and increase it for greater than $\lambda/2$ spacing. In general, beam antennas have element spacing of 0.1λ to 0.25λ (with 0.15λ to 0.19λ being common), so the impedance will be lower than the nominal impedance for a half wavelength dipole.

TWO-ELEMENT YAGI ARRAY

Figure 10.1 shows the two-element Yagi array antenna. This particular one uses a driven element and a director, so the direction of maximum signal is in the direction of the director. The gain of a two-element Yagi is about 5.5 dBd (gain above a dipole) for spacing less than 0.1λ and the parasitic element is a director. For the case where a reflector is used, the gain peak is 4.7 dBd at about 0.2λ spacing.

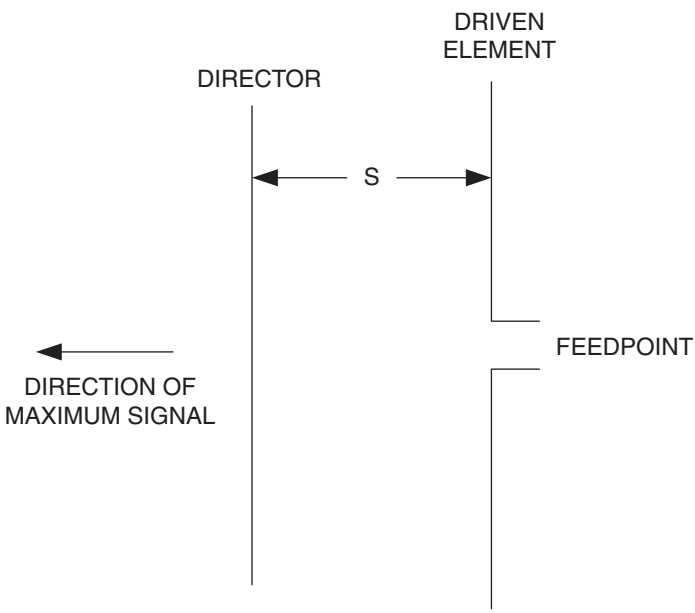

FIGURE 10.1

The difference between reflector and director usage is quite profound. The usual curve shows the director with higher gain, but it is more responsive to element spacing. The reflector has less gain, but is more tolerant of spacing errors.

The front-to-back ratio of the beam antenna is poor for two-element antennas. A compromise spacing of 0.15λ provides front-to-back ratios of 5 to 12 dB.

The feedpoint resistance of the antenna is clearly not 73 ohms as would be implied by the use of a half wavelength dipole for a driven element. The feedpoint impedance will vary roughly linearly from about 5 ohms at a spacing of 0.05λ to about 30 ohms for spacings of about 0.15λ. Above 0.15λ the differences between director and reflector implementations takes place. A reflector two-element beam feedpoint impedance will increase roughly linearly from 30 ohms at 0.15λ to about 45 ohms at 0.25λ spacing. The director implementation is a little less linearly related to spacing, but varies from about 30 ohms at 0.15λ to about 37 ohms at 0.25λ spacing.

Element lengths

The element lengths for a two-element Yagi beam are given below:

Director: $$\text{Director} = \frac{138.6}{F_{\text{MHz}}}$$

Driven element: $$\text{D.E.} = \frac{146}{F_{\text{MHz}}}$$

Spacing: $$\text{Spacing} = \frac{44.98}{F_{\text{MHz}}}$$

Where:

Director is the length of the director
D.E. is the length of the driven element in meters (m)
Spacing is the spacing between the elements in meters (m)
F_{MHz} is the frequency in megahertz.

These element lengths will result in 0.15λ spacing, which is considered about ideal.

THREE-ELEMENT YAGI BEAM

Figure 10.2 shows a Yagi antenna made up of a half wavelength driven element, a reflector and a director. The gain of the array and the front-to-back ratio peaks at a particular boom length (boom not shown), which is indicative of the spacing between the elements. Maximum gain occurs at a boom length of 0.45λ. An example of a three-element Yagi antenna built on a 0.3λ boom will provide 7 to 8 dBd forward gain, and a front-to-back ratio of 15 to 28 dB depending on the element tuning.

The feedpoint impedance of the three-element beam is about 18 to 25 ohms, so some means must be provided for adjusting the impedance to the 52 ohm coaxial cable.

Element lengths

Director: $$\text{Director} = \frac{140.7}{F_{\text{MHz}}}$$

Driven element: $$\text{D.E.} = \frac{145.7}{F_{\text{MHz}}}$$

Reflector: $$\text{Reflector} = \frac{150}{F_{\text{MHz}}}$$

Spacing: $$\text{Spacing} = \frac{43.29}{F_{\text{MHz}}}$$

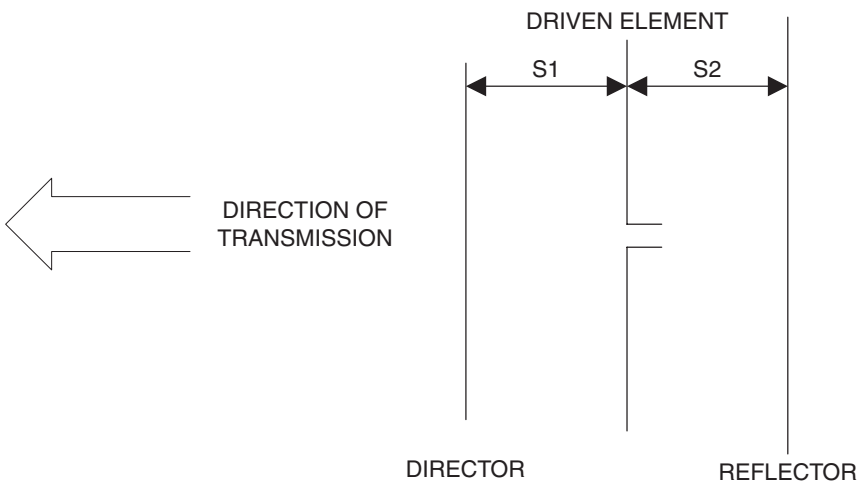

FIGURE 10.2

Where:

Director is the length of the director in meters (m)
D.E. is the length of the driven element in meters (m)
Reflector is the length of the reflector element in meters (m)
Spacing is the spacing of the elements in meters (m).

FOUR-ELEMENT YAGI ANTENNA

Figure 10.3 shows a four-element Yagi antenna. There is a tremendous increase in forward gain by adding a second director to the three-element case, but the front-to-back ratio is poorer unless the spacing is increased from 0.15λ to about 0.25λ. When all elements are spaced 0.15λ apart, the front-to-back ratio is only about 10 dB, but at 0.25λ the front-to-back ratio increases to 27 dB.

Element lengths

The dimensions calculated from the equations below will yield a forward gain of about 9.1 dBd, with a front-to-back ratio of about 27 dB.

Director: $$\text{Director} = \frac{138.93}{F_{\text{MHz}}}$$

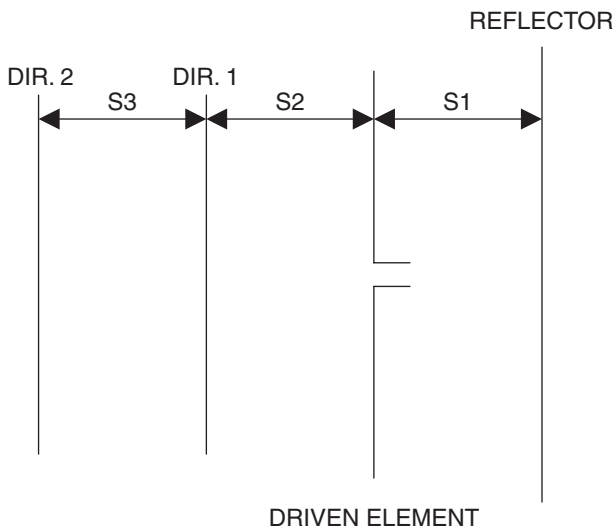

FIGURE 10.3

Driven element: $$\text{D.E.} = \frac{143.65}{F_{\text{MHz}}}$$

Spacing S1: $$\text{S1} = \frac{60.95}{F_{\text{MHz}}}$$

Spacings S2 and S3: $$\text{S2} = \text{S3} = \frac{75}{F_{\text{MHz}}}$$

Where:

Director is the length of the director element in meters (m)
D.E. is the length of the driven element in meters (m)
Reflector is the length of the reflector element in meters (m)
S1, *S2* and *S3* are in meters (m).

SIX-ELEMENT YAGI ANTENNA

Computer studies of Yagi antenna arrays demonstrate that five-element antennas are little more than four-element antennas, despite the extra director. But the addition of two additional directors adds significantly to the gain. The six-element antenna (Figure 10.4) shows a gain of nearly 10.5 dBd, and a front-to-back ratio of nearly 35 dB. Unfortunately, a six-element antenna is quite large, even with 0.15λ element spacing. At 14 MHz the antenna soars to about 16 meters boom length.

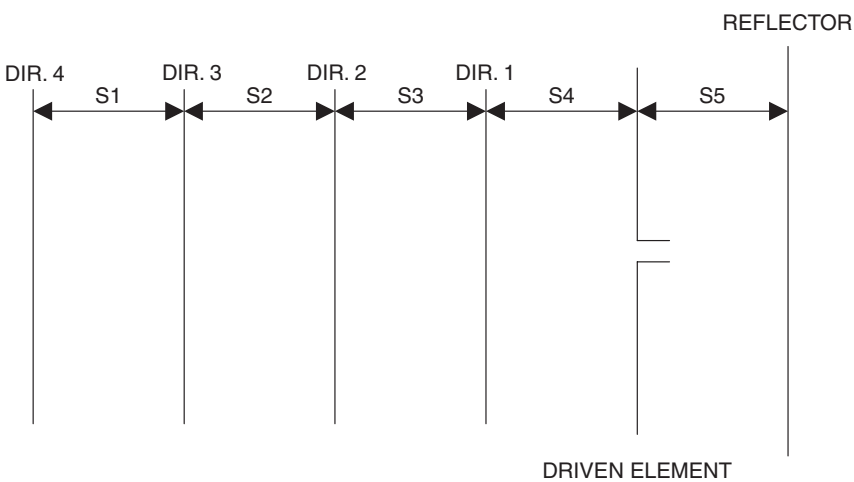

FIGURE 10.4

Element lengths

Director: $$\text{Director} = \frac{134.39}{F_{\text{MHz}}}$$

Driven element: $$\text{D.E.} = \frac{144.05}{F_{\text{MHz}}}$$

Reflector: $$\text{Reflector} = \frac{148.56}{F_{\text{MHz}}}$$

Element spacing: $$\text{Spacing} = \frac{44.8}{F_{\text{MHz}}}$$

Where:
Director is the length of the director elements in meters (m)
D.E. is the length of the driven element in meters (m)
Reflector is the length of the reflector element in meters (m)
Spacing is the spacing between the elements in meters (m).

IMPEDANCE MATCHING THE BEAM ANTENNA

The feedpoint impedance of most beam antennas is lower than the feedpoint impedance of a half wavelength dipole (72 ohms), despite the fact that the half wavelength dipole is a driven element. The feedpoint impedance may be as low as 18 to 20 ohms, and as high as 37 ohms. At 37 ohms there is a reasonable match to 52 ohm coaxial cable (1.41:1), but at 25 ohms the VSWR is more than 2:1. The typical solid-state transmitter will shut down and produce little RF power at this VSWR. What is needed is a means of matching the impedance of the beam to 52 or 75 ohm coaxial cable.

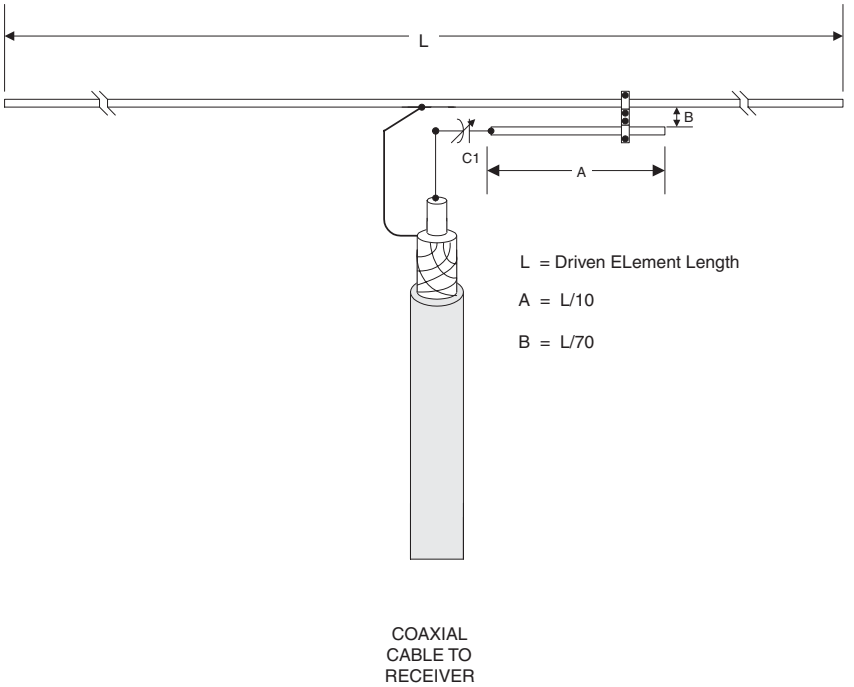
The *gamma match* is shown in Figure 10.5. It consists of a piece of coaxial cable connector such that its shield is to the center point on the radiating element (L), and its center conductor goes to the matching device. The dimensions of the gamma match of Figure 10.5 are as follows:

(L is the driven element length)

$$A = \frac{L}{10}$$

$$B = \frac{L}{70}$$

Where:
L, A and B are in meters (m).



L
B
C1
A
L = Driven ELement Length
A = L/10
B = L/70

RECEIVER

FIGURE 10.5

CHAPTER 11

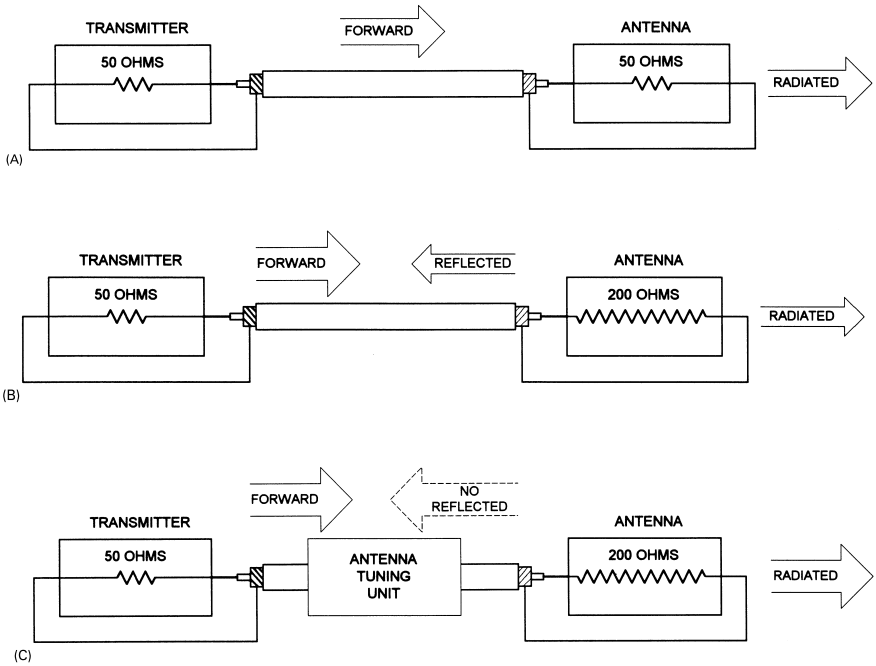
Impedance matching

It is common practice to match the impedances of the antenna, transmission line, and either the receiver or the transmitter. The reason can be seen in Figure 11.1. Although the example selected is for a transmitting antenna, because of reciprocity the same notions also apply to the receive antenna, although power flows are reversed (and considerably smaller).

The case shown in Figure 11.1A is for the matched case, i.e. the transmitter output impedance, the transmission line impedance, and the antenna feedpoint impedance (which is the 'load') are all the same (e.g. 50 ohms). The thickness of the arrow is intended to represent the relative power level.

In this situation, forward power from the transmitter is sent toward the load end of the transmission line. When the radio frequency (RF) signal reaches the load it is *completely absorbed*. Some of it will go towards heating the load, and part of it will be radiated. The loss to heating in a well-designed, properly installed antenna is negligible, so it is not unreasonable to show the arrow representing the radiated portion as the same size as the forward power. The implication of the system being matched is that all of the power from the transmitter is radiated and can become a useful signal.

When the load and source are mismatched, as in Figure 11.1B, not all of the foward power is absorbed by the load. Some of it is reflected back down the transmission line toward the transmitter. When this reflected wave interferes with the forward waves still propagating up the line, the result is **standing waves** (see Chapter 2). The measure of the standing waves is the **standing wave ratio** (SWR, or VSWR if voltage is measured).



The existence of the reflected power wave has some implications in practical systems. First, it represents a loss. The reflected power is not available to contribute to the radiated signal. If no other losses occur, then this loss might prove tolerably low, but that is rarely the case. At some frequencies and in some situations, the goal is to squeeze out as much signal as possible.

Second, some transmitters, mostly modern designs with solid-state final RF power amplifiers, are intolerant of high VSWR loads. In the early days of solid-state transmitters, the first of which were CB rigs, the expensive output transistors would often blow out when even a transient high VSWR situation occurred. Older vacuum tube ('valve' to UK readers) designs were more tolerant of a high VSWR. Although those systems experienced the VSWR loss problem, the transmitter was not harmed. Modern transmitters, on the other hand, now include **automatic load control** (ALC) or other circuitry to begin reducing RF output power as the VSWR climbs. The shut down 'knee' usually starts somewhere around a VSWR of 1.5:1, and the rig will be completely shut down at some VSWR between 2.5:1 and 3:1. One rig produced 100 W of power at a VSWR of 1:1, but only 100 mW at a VSWR of 2.5:1.

A third reason is that losses in coaxial cable can be quite severe, especially at higher frequencies. Those losses increase markedly with increasing

VSWR, especially in the lower grades of coaxial cable normally used for radio antennas.

If the antenna feedpoint impedance does not match the feedline impedance, then a VSWR proportional to their ratio is created. Unfortunately, it is not always possible to create an antenna with a feedpoint impedance equal to the characteristic impedance of the feedline. Unless some means is found to effect the match, then all of the gremlins associated with a high VSWR occur.

The solution to the problem is to provide an intermediate impedance matching device (Figure 11.1C) between the transmitter (or receiver) and the antenna. The matching device might be an inductor–capacitor (LC) network, a transformer (e.g. a BALUN), or a transmission line matching section. The impedance matching device can be considered as a 'black box' between two resistances (R1 and R2, as in Figure 11.2). The property of the box is to provide the transformation that makes each resistor think it is looking at another resistor of the same value as itself. Although these devices are bilateral, i.e. the transformation occurs in both directions, it is common practice to use R1 to represent the transmitter output impedance or the receiver antenna input impedance, and R2 to represent the load impedance (e.g. antenna feedpoint impedance). In most cases, the value of R1 in transmitters is 50 ohms, and in receivers it will be either 50 ohms or 300 ohms.

LC MATCHING NETWORKS

LC matching networks are combinations of inductance and capacitance that will allow an input impedance (R1) to be transformed to an output impedance (R2). The common name for these circuits is **antenna tuner** or **antenna tuning unit** (ATU). Several common forms of ATU circuit are shown in Figures 11.3–11.5.

The circuits in Figure 11.3 are for the case where R1 > R2. This situation might occur in vertical antennas, for example, where the feedpoint impedance varies from a few ohms to about 37 ohms, both of which are less than the standard 50 ohms used by the rest of the system. The circuit in Figure 11.3A is one variant of the L-section coupler (two other variants are shown

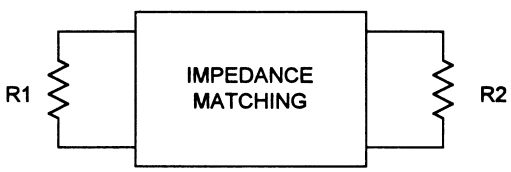


FIGURE 11.2

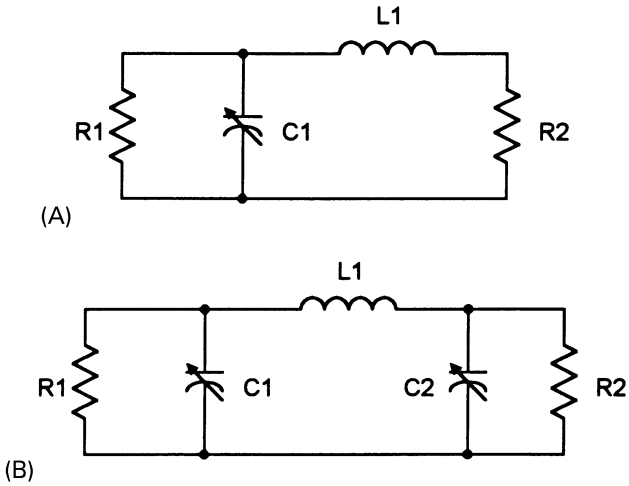

FIGURE 11.3

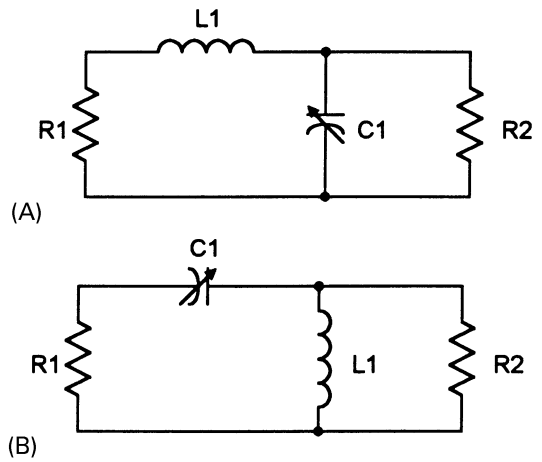

FIGURE 11.4

in Figure 11.4). In this version, the capacitor shunts the line at the input of the network, and the inductor is in series with the line.

Many homebrewed and commercial L-section couplers are designed so that changing jumpers or switch settings allows you to configure the inductor and capacitor in any of the three variants (Figures 11.3A, 11.4A, and 11.4B).

The circuit in Figure 11.4B is the π-network. This type of circuit is often used for impedance transformation when R1 is very much larger than R2 ($R1 \gg R2$). It was once very common as a transmitter output network

FIGURE 11.5

because vacuum tube RF power amplifiers needed to match 3000–6000 ohm anode impedances to 50 ohms for the antenna output. The network consists of two shunt capacitors on either side of a series inductor.

A series of four transmatch-style antenna tuning unit circuits is shown in Figure 11.5. These circuits are used in a wide variety of commercially available high-frequency (HF) ATUs. Some of them use dual capacitors, i.e. two-section capacitors in which two separate capacitors share the same shaft. All of the capacitors in these should be wide-spaced 'transmitting' capacitors if the ATU is used as part of a transmitting antenna. For receive-only cases, however, ordinary receiver-style variable capacitors can be used. Although the invidual component values can be calculated, it is common to use 140 or 250 pF for the capacitors, and either 18 μH or 28 μH for the inductor.

The inductor is either a variable or switchable type. Variable inductors are built with a roller mechanism that selects the turns required for any specified value of inductance. However, these inductors can be quite pricey, so many builders opt instead for an air core inductor with several taps at various points along the coil. By selecting the tap one can change the inductance.

The calculation of values for the various style of LC impedance matching network is not terribly difficult if you are trained in mathematics. But if you either prefer the convenience of computer calculations, or are a person who found a first course in algebra and trigonometry a daunting and fearsome experience, then you might wish to take advantage of the software supplement to this book.

QUARTER-WAVELENGTH MATCHING SECTIONS

The quarter-wavelength matching section, also called the Q-section, is made of transmission line (segment 'A' in Figure 11.6). The characteristic impedance of the Q-section line (Z_A) is selected to provide impedance transformation of the load impedance (Z_L) to the characteristic impedance of the line ('B') to the transmitter (Z_B). In some cases, the Q-section is connected directly to the transmitter output (or receiver input), in which case Z_L is transformed to Z_S.

There are two things that you must calculate when making a quarter-wave matching section: the **physical length of the transmission line** and the **characteristic impedance** required to match the load impedance to the source impedance. The physical length to make an electrical quarter wavelength is foreshortened from the physical quarter wavelength due to the velocity factor of the cable. The calculation is

$$L_{\text{meters}} = \frac{75V}{F_{\text{MHz}}} \text{ meters}$$

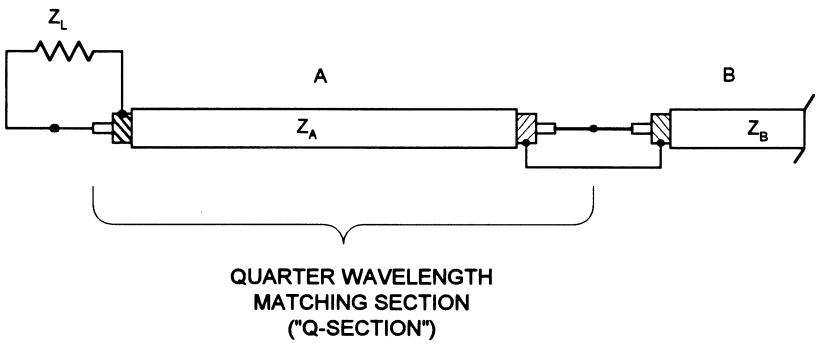

FIGURE 11.6

where L is the length in meters, F_{MHz} is the center operating frequency in megahertz, and V is the velocity factor of the transmission line (either 0.66 or 0.80 for coaxial cable – see Chapter 3).

Calculating the required characteristic impedance requires knowledge of the value of the load impedance and the characteristic impedance of the transmission line to the receiver or transmitter. The calculation is:

$$Z_{\mathrm{A}} = \sqrt{Z_{\mathrm{L}} Z_{\mathrm{B}}}$$

For example, suppose we wish to make a Q-section for matching a 100 ohm impedance (such as found at the feedpoint of a quad loop) to 52 ohm coaxial cable. If the match is not made, then the VSWR will be about 2:1, which for many uses is clearly too high. The calculation is

$$Z_{\mathrm{A}} = \sqrt{(100\,\mathrm{ohms}) \times (52\,\mathrm{ohms})}$$
$$Z_{\mathrm{A}} = \sqrt{5200} = 72\,\mathrm{ohms}$$

The required characteristic impedance is 72 ohms, which is a very good match to 75 ohm coaxial cable. Lest you think this is an example contrived to make the arithmetic work out to a standard impedance found in coaxial cable catalogs (which it is), it is also a very real example that is used for a number of practical antennas. Clearly, though, if the result of this equation is not near enough to some standard coaxial cable to reduce the VSWR to an acceptable level, then some other means of matching the impedance must be found.

The method of Figure 11.6 suffers from the limitations discussed above, namely the possible lack of a readily available characteristic impedance value. However, a much more general case is shown in Figure 11.7. This is the **series matching section** method. Sections L1 and L3 are made of the same type of cable, with the same characteristic impedance. The center section, L2, is made of a cable with a different characteristic impedance,

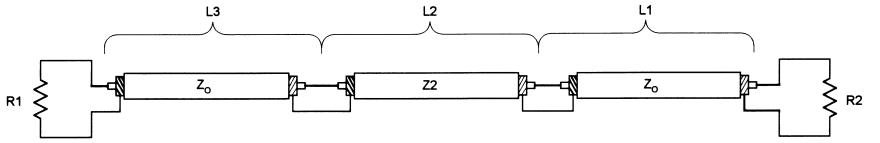

FIGURE 11.7

e.g. 75 ohm coaxial cable or 300 ohm twin-lead. The calculation of the different lengths is a bit daunting, so you are referred to the software supplement to this book in order to make the calculations.

In both the series matching section and the Q-section (which is actually a limited special case of the series section), coaxial cable, twin-lead, or parallel line can be used for the transmission lines, even though only coaxial cable is shown here.

MATCHING STUBS

Another means for effecting the impedance match is to use either a quarter-wavelength or half-wavelength **matching stub** (Figure 11.8). The stub is sometimes mounted at the feedpoint of the antenna, and the transmission line is tapped on the stub at a point (L1) that matches the impedance. In the case shown in Figure 11.8A, a shorting bar is provided at the bottom of the stub. In some cases, the stub is open and the shorting bar is not used.

Another case is shown in Figure 11.8B. In this circuit, the transmission line is connected directly to the antenna, and the stub is used to remove complex impedances by being positioned somewhere between the antenna feedpoint and a point (L1) that is a quarter wavelength down the transmission line from the feedpoint.

The final case is shown in Figure 11.8C. In this scheme, the transmission line is coaxial cable, otherwise this scheme is like Figure 11.8B. The three sections of coaxial cable are connected together using a coaxial 'tee' connector. Typically of the PL-259/SO-239 family, these connectors have three ports that are internally all connected together.

The lengths L1 and L2 depend on the VSWR experienced on the particular antenna, as well as the relationship of Z_L and Z_0. Two cases are seen:

(1) $Z_L > Z_0$:

$$\text{L1} = \arctan\sqrt{\text{VSWR}}\ \text{degrees}$$

$$\text{L2} = \arctan\left(\frac{\sqrt{\text{VSWR}}}{\text{VSWR} - 1}\right)\ \text{degrees}$$

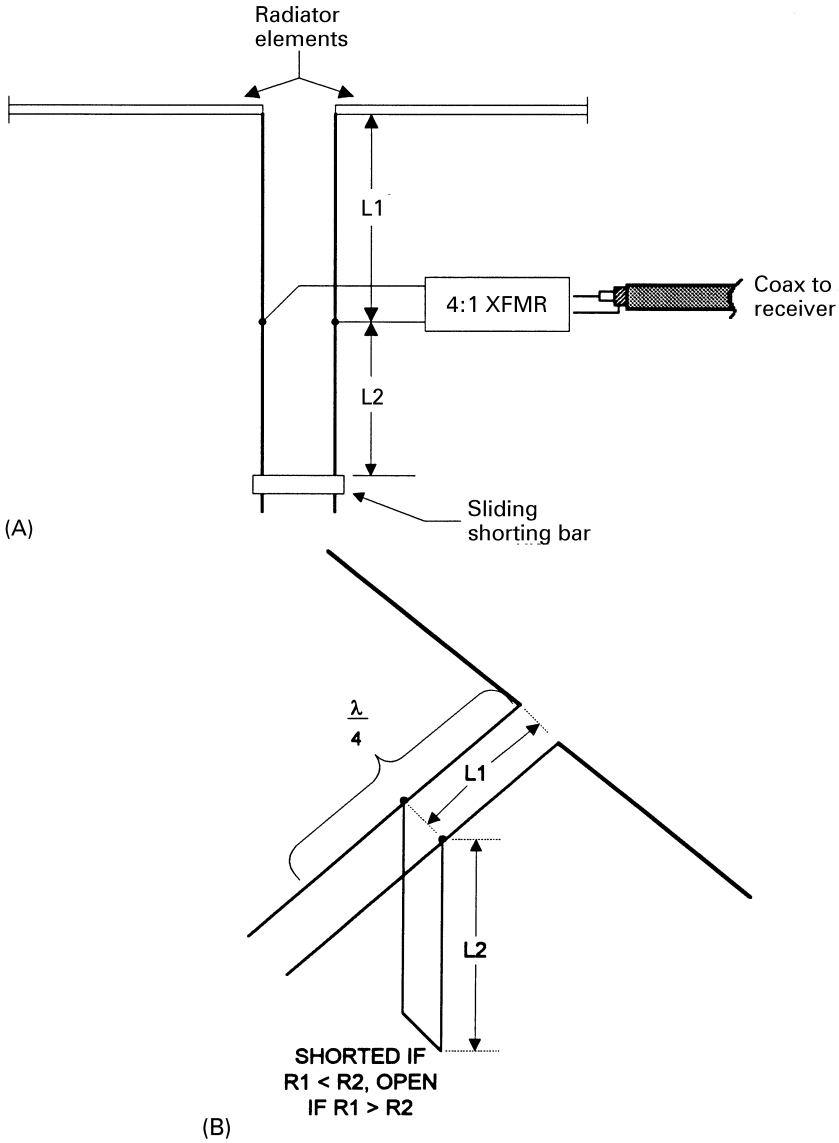

FIGURE 11.8

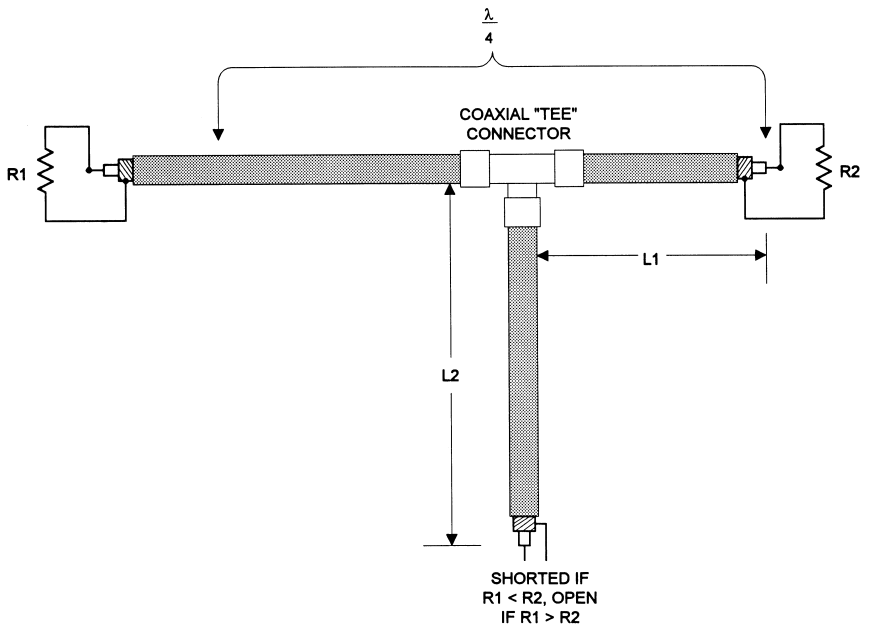
(2) $Z_L < Z_0$:

$$L1 = \arctan \frac{1}{\sqrt{VSWR}} \text{ degrees}$$

$$L2 = \frac{VSWR - 1}{\sqrt{VSWR}} \text{ degrees}$$



(C)

FIGURE 11.8 (*continued*)

Note that the results of these equations are in degrees. In a transmission line, one wavelength equals 360°, a half wavelength is 180°, and a quarter wavelength is 90°. You can scale the actual length against these values, keeping in mind the velocity factor of the transmission line. Consider an example. Suppose we need to match an antenna that has a 3:1 VSWR on its resonant frequency of 9.75 Mhz using 300 ohm twin-lead ($V = 0.82$). Further, the impedance of the load is 900 ohms (note: VSWR $= 900/300 = 3{:}1$). Because $Z_L > Z_0$, we use the first pair of equations:

$$\begin{aligned} \text{L1} &= \arctan \sqrt{3} \\ \text{L1} &= \arctan\,(1.73) \\ &= 60^\circ \\ \text{L2} &= \arctan\left(\frac{\sqrt{3}}{3-1}\right) \\ \text{L2} &= \arctan \frac{1.73}{2} \\ &= \arctan\,(0.865) \\ &= 40.9^\circ \end{aligned}$$

For a VSWR of 3:1, then we need L1 = 60° and L2 = 40.9°. We can calculate these as a fraction of a quarter wavelength (90°), using

$$\text{Length} = \frac{L \times 75V}{90F_{\text{MHz}}} \text{ meters}$$

where 'Length' is the physical length of the transmission line segment L1 or L2, L is either L1 or L2 expressed in degrees as calculated above, V is the velocity factor of the transmission line, and F_{MHz} is the operating frequency in megahertz.

For the 9.75 MHz cable, using 300 ohm twin-lead ($V = 0.82$), the physical lengths are

$$\text{L1} = \frac{(60)(75)(0.82)}{(90)(9.75)} \text{ meters}$$

$$\text{L1} = \frac{3690}{877.5}$$

$$= 4.2 \text{ meters}$$

$$\text{L2} = \frac{(41)(75)(0.82)}{(90)(9.75)}$$

$$= 2.87 \text{ meters}$$

The matching stub is used on a large number of antennas. Once you get away from the simple half-wavelength dipole fed with 75 ohm coaxial cable, the number of antennas that require some form of impedance matching increases considerably, and the matching stub is used for a lot of different designs.

BALUN AND OTHER BROAD-BAND TRANSFORMERS

There are a number of different transformers used in impedance matching in antenna systems. The term 'BALUN' is used extensively, and it comes from **BALanced-UNbalanced**. Correctly used, then, the term 'BALUN' refers to a transformer that matches a balanced load (e.g. a dipole antenna feedpoint) to an unbalanced load (e.g. coaxial cable). However, it has become common (if erroneous) practice to use 'BALUN' in a generic sense to refer to any of the **broad-band transmission line transformers**. More correctly, some of those are balanced–balanced, so should be called BAL–BAL, and others are of an unbalanced–unbalanced configuration so are called UN–UN. I suppose BALUN sounds more like a word than BAL–BAL or UN–UN (note: some antenna and accessories catalogs do use these terms correctly, but the erroneous usage is also seen).

One of the earliest forms of BALUN transformer is the coaxial cable BALUN shown in Figure 11.9. Both pieces of coaxial cable used in this BALUN transformer are of the same type (e.g. 75 ohm coaxial cable). When

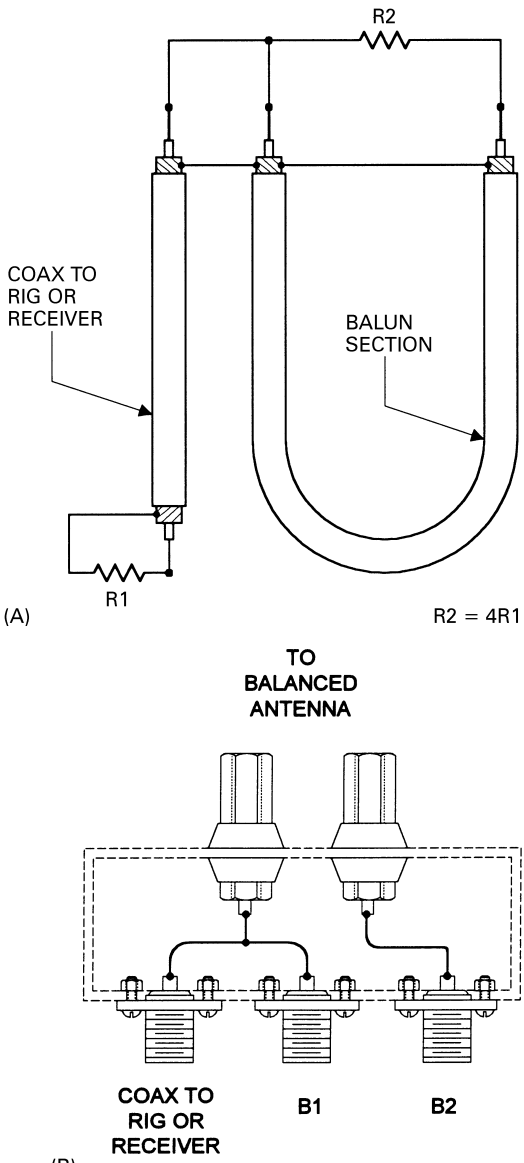


FIGURE 11.9

connected in this configuration, the BALUN transformer produces a 4:1 impedance transformation, which means that a 300 ohm balanced antenna (e.g. folded dipole) will look like a 75 ohm unbalanced load. The coaxial cable to the ham rig or receiver can be of any convenient length. The BALUN section, however, must be a half wavelength long (keeping in mind the velocity factor). The length of the BALUN section is found from:

$$L_{\text{meters}} = \frac{150V}{F_{\text{MHz}}} \text{ meters}$$

where F_{MHz} is the frequency in megahertz and V is the velocity factor (0.66 for polythene coaxial cable, and 0.80 for polyfoam coaxial cable).

A connection box for making the coaxial BALUN is shown in Figure 11.9B. This box is intended for mounting on the antenna center insulator, and should not be used for supporting the antenna unless eye bolts or other more rugged fixtures are provided at the left and right ends. The balanced antenna feedpoint is connected to a pair of five-way binding posts, while the coaxial cable for the run to the rig or receiver and the BALUN sections (B1 and B2) are connected to SO-239 coaxial connectors.

The coaxial BALUN is designed for a specific frequency, but will work over a small margin either side of the design frequency (e.g. typically one HF ham band can be accommodated). But for wide-band operation, you might want to build a broad-band transformer such as those shown in Figure 11.10. Note that some of these transformers only show one core symbol (e.g. Figure 11.10A). Those transformers have all the windings on the same core. The dots show the phase sense of the windings and indicate the same end of the winding).

The two most common forms of BALUN transformer are those in Figures 11.10A and 11.10B. The version in Figure 11.10A has no impedance transformation, and is usually referred to as a 1:1 BALUN. The transformer in Figure 11.10B, on the other hand, offers a 4:1 impedance transformation, so is equivalent to the coaxial BALUN shown in Figure 11.9A. The transformers in Figures 11.10C and 11.10D are both UN–UNs. The configuration in Figure 11.10 produces a 9:1 impedance transformation, while that in Figure 11.10D produces a 16:1 transformation.

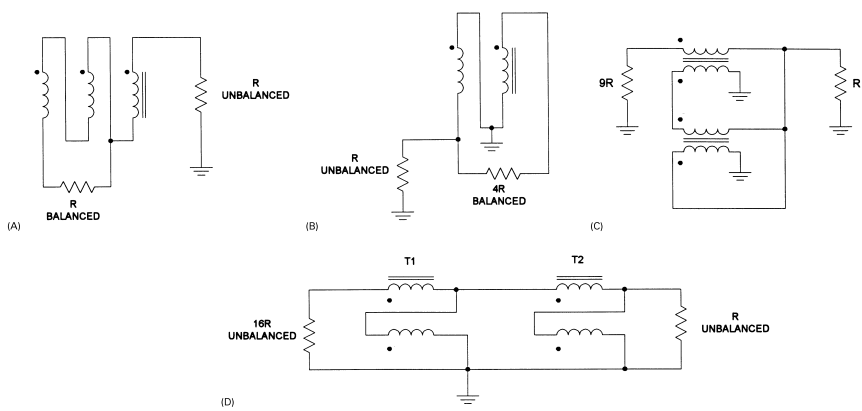

FIGURE 11.10

The construction of coil BALUNs and broad-band transformers is shown in Figure 11.11. The transformer shown in Figure 11.11A is wound on a toroid core made of either powdered iron or ferrite material. The toroid is doughnut shaped. It has the interesting attribute of containing the magnetic field to its own geometry, so has little interaction with its environment. This fact means that it will work like the book says more often than certain other transformer core configurations.

Note how the wires are wound on the toroid core. They are kept paired and lay next to each other. In this manner they are wound together as if they were only one piece. When two wires are used, this form of winding is called **bifilar winding**. When three wires are wound together in this manner, a **trifilar**

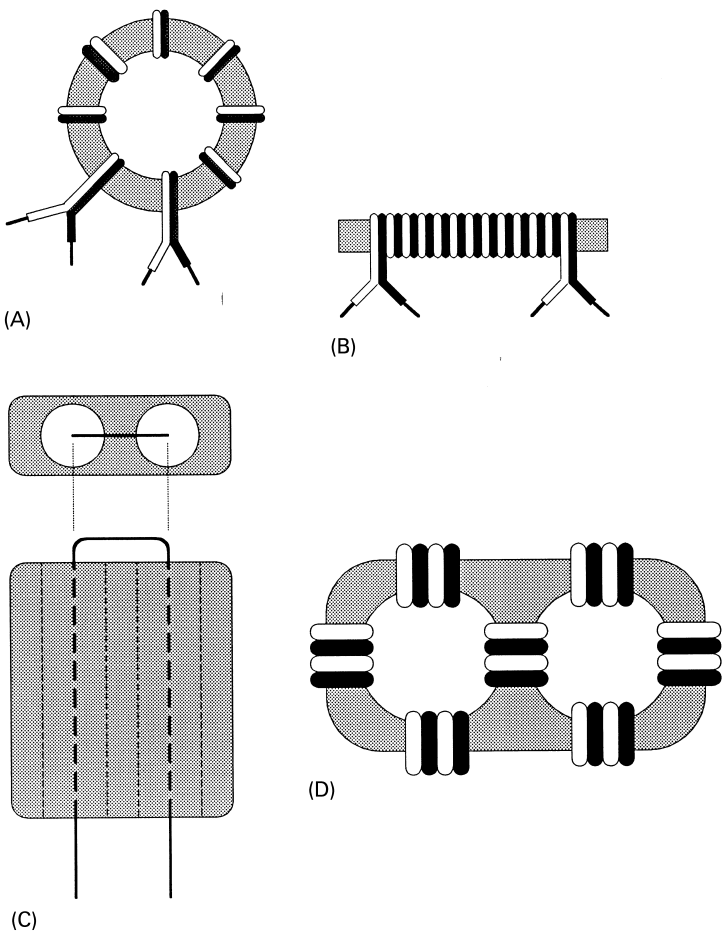

FIGURE 11.11

winding is produced. The bifilar method is used to wind the transformer in Figure 11.10B, while trifilar winding is used for that in Figure 11.10A.

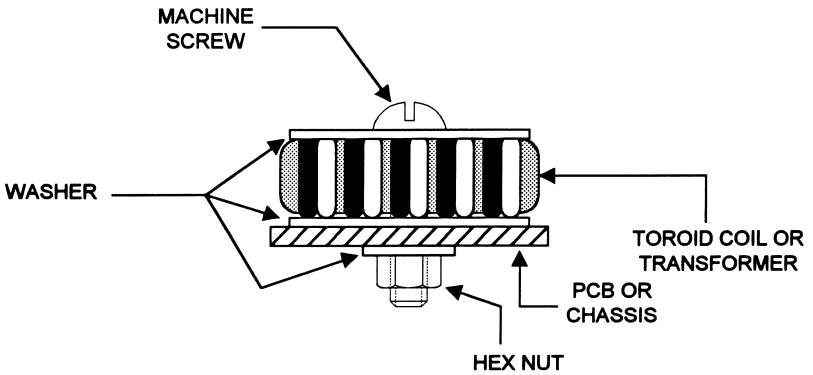
The solenoid winding method is shown in Figure 11.11B. The core can be either air (in which case a coil form is needed), or a ferrite rod (as shown). Again we see the use of either bifilar or trifilar winding, depending on the nature of the transformer being made.

The so-called bazooka BALUN core is shown in Figures 11.11C and 11.11D, using two different winding styles. In the style of Figure 11.11C, the wire is passed through both holes to form a loop ('internal winding'). Counting the number of turns is a little different than one might suppose. The case shown in Figure 11.11C is one turn, even though many people erroneously assume that it is half a turn. If one end of the wire is passed through both holes one more time, then there are two turns present. Both the primary and secondary windings can be wound in this same manner, laying one over the top of the other (the primary is usually laid down first). The case shown in Figure 11.11D shows an end view of the bazooka BALUN core. In this case, several turns are wound in both the internal and external winding styles. These two styles can be intermixed on the same form, but wherever possible you are advised to use the internal winding mode preferentially.

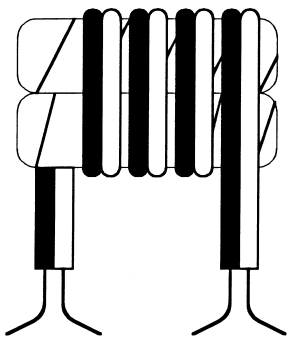
Figure 11.12A shows how a toroid core inductor or transformer is mounted on either a printed circuit board (PCB) or metal chassis. Fiber or nylon washers are used to secure and protect the toroidal core, and nylon or other non-metallic fasteners (machine screw and hex nut) are used to keep it in place. It is important to use non-metallic fasteners to keep from interfering with the operation of the transformer. Only in the case of the largest toroids (>5 or 6 cm in diameter) are metal fasteners usable, and even then there is some bad effect.

The scheme in Figure 11.12B is used for transmitter ATUs and similar applications where the power is higher. Two or more 5 cm or larger toroids are stacked one on top of the other. Each toroid core is first wound with fiberglass tape to insulate it from the other core. After the cores are wrapped with tape and stacked on top of each other, a final layer of tape can be added to keep the whole assembly stable. The bifilar or trifilar windings are then laid down on the stacked cores.

A number of manufacturers offer BALUNs, BAL–BALs, and UN–UNs, in both voltage and current configurations. Some are designed to replace the center insulator of an antenna such as the dipole. Others are intended for mounting elsewhere. The transformer in Figure 11.13 is intended for use on vertical antennas. The feedpoint impedance of the quarter-wavelength vertical will vary from something less than 5 ohms to about 37 ohms, depending on the installation. The transformer of Figure 11.13 is an UN–UN that has a single attachment point for 52 ohm coaxial cable to the rig or receiver.



(A)



(B)

FIGURE 11.12

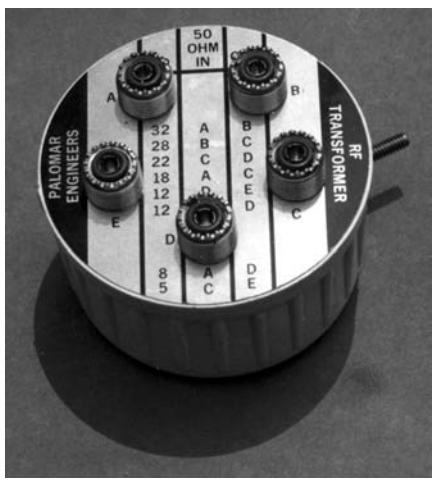


FIGURE 11.13

The other four coaxial connectors are various load impedances that will be transformed to 52 ohms if that port is used.

COMMERCIAL ANTENNA TUNERS

An 'antenna tuner' located at the transmitter end of the transmission line will not effect a good impedance match to the antenna, but it can mitigate the effects of a high VSWR on the transmitter. Even a single-band resonant antenna will exhibit a high enough VSWR at the ends of the band to upset the operation of the transmitter that is equipped with automatic load control (that is, all modern solid-state rigs). Although antenna tuner construction is well within the abilities of most do-it-yourself 'homebrewers,' it is also likely that most will opt instead for a ready-built ATU. A number of reasonably priced models are available on the market.

Figure 11.14 shows the MFJ-956 receiver S/M/L wave preselector/tuner. This device places a series resonant circuit in series with the antenna downlead before it goes to the receiver. A single variable capacitor (365 pF maximum) is in series with an inductance. Four different switch-selected inductance values are provided (2.5 mH, 330 μH, 22 μH, and 1 μH) to cover the range 150 kHz to 30 MHz. When the inductor switch is in the BYP ('bypass') position, the preselector/tuner is effectively out of the circuit, and the antenna–receiver combination works as normal. In the GND ('ground') position, the antenna input of the receiver (but not the antenna) is grounded.

Tuners for transmitting use are shown in Figures 11.15 and 11.16. The tuner in Figure 11.15 is the MFJ-949E Deluxe Versa Tuner II, while that in Figure 11.16 is the MFJ-986 Differential Tee tuner. These tuners are a bit larger than the standard receiver-only tuner, but are nonetheless just as

FIGURE 11.14

FIGURE 11.15

FIGURE 11.16

useful to the receiver owner as well. The only thing that will not work for receiver owners is the VSWR metering system. These are based on the same technology as RF wattmeters, so require the output of a radio transmitter for excitation. Both models allow more than one antenna (although only one at a time!) to be switch selected.

CHAPTER 12

Simple antenna instrumentation and measurements

It is very difficult to get an antenna working properly without making some simple measurements. Although it would be nice to make pattern measurements, those are beyond the reach of almost all of us. On the other hand, the 'I worked [or heard] a guy on the other side of the world' type of measurement tells us little or nothing. During the peak of the sunspot cycle a breath of hot air on the antenna can be picked up on all continents.

There are some things that can be measured, however. For example, the voltage standing wave ratio (VSWR) and the resonant frequency of the antenna are readily accessible. It is also possible to measure the impedance of the antenna feedpoint. Hams can measure the VSWR either with a special VSWR meter (often built into transmitters or antenna tuning units), or by using a radio frequency (RF) wattmeter.

By stepping through the band and testing the VSWR at various frequencies, one can draw a VSWR curve (Figure 12.1) that shows how the antenna performs across the band. The resonant frequency is the point where the VSWR dips to a minimum. You can use the resonant frequency to figure out whether the antenna is too long (resonant frequency lower than the hoped-for design frequency), or too short (resonant frequency above the design frequency).

But resonant frequency and VSWR curves are not the entire story because they do not tell us anything about the impedance presented by the antenna. One cannot get the VSWR to be 1:1 unless the antenna impedance and transmission line impedance are the same. For example, a dipole has a nominal textbook impedance of 73 ohms, so makes a very good match

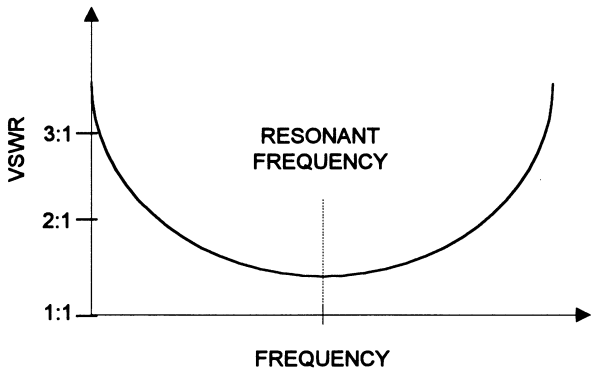

FIGURE 12.1

to 75 ohm coaxial cable. But the actual impedance of a real dipole may vary from a few ohms to more than 100 ohms. For example, if your antenna exhibits a feedpoint impedance of (say) 25 ohms, using 75 ohm coaxial cable to feed it produces a VSWR = 75/25 = 3:1. Not too great. Measuring the feedpoint impedance is therefore quite important to making the antenna work properly.

There are any number of instruments on the market that will aid in making antenna measurements. Some of them are quite reasonably priced (or can be built), while others are beyond the reach of all but the most ardent and well-endowed enthusiasts. In this chapter we will look at RF power meters, VSWR meters, dip meters, noise bridges, impedance bridges, and a newer breed of more universal instrument called the SWR analyzer. We will also look at a few accessories that are useful in the measurement or adjustment of radio antennas (e.g. coaxial switches, attenuators, and dummy loads).

RF POWER METERS AND VSWR METERS

The RF power meter is designed to indicate the actual value of RF power (in watts). VSWR meters are similar, but are either calibrated in VSWR units or have a selectable scale that is so calibrated. Some RF wattmeters measure the voltage on the transmission line, while others measure the current flowing in the line. If things are done right, then these approaches work nicely. But sometimes those methods can be fooled. A better system is to measure both the current and the voltage and to display their product. Although this task sounds like a formidible instrumentation job, it is actually the way one of the most popular RF power meters works. The Bird Electronics Model 43 (Figure 12.2) is one of the oldest and most popular professional-grade instruments. It uses a specially designed internal transmission line segment

FIGURE 12.2

with sampling loops inserted in the form of plug-in 'elements' (the round object with an arrow in Figure 12.2). The elements are customized for the RF power level and frequency range. The arrow on the element indicates the direction of the power flow. When the arrow points to the antenna feedline, the instrument is measuring the forward RF power, and if pointed toward the transmitter it is measuring the reflected RF power.

Although the Model 43 type of meter will provide the RF power measurements more accurately under a wider range of conditions, a ham radio style VSWR meter/RF power meter will work well (and measure accurately) under most ham conditions. In addition, these instruments will provide a measure of the VSWR (with an RF wattmeter you need to calculate the VSWR). Figure 12.3 shows two typical ham-style VSWR/RF power meters. The instrument in Figure 12.3A is small and simple, but quite effective. It will measure forward and reflected power over the entire high-frequency (HF) band, as well as the VSWR. To measure the VSWR, set the full-scale/SWR switch (marked 'FS' and 'SWR') to the FS position, key the transmitter, and adjust the knob to achieve a full-scale deflection of the meter pointer. When the FS/SWR switch is set to the SWR position, it will read the VSWR. These instructions, by the way, fit a large number of different instruments, by many manufacturers, in this same class.

The instrument in Figure 12.3B is for the very high/ultrahigh frequency (VHF/UHF) bands. It does not have to be set as does the meter above. The

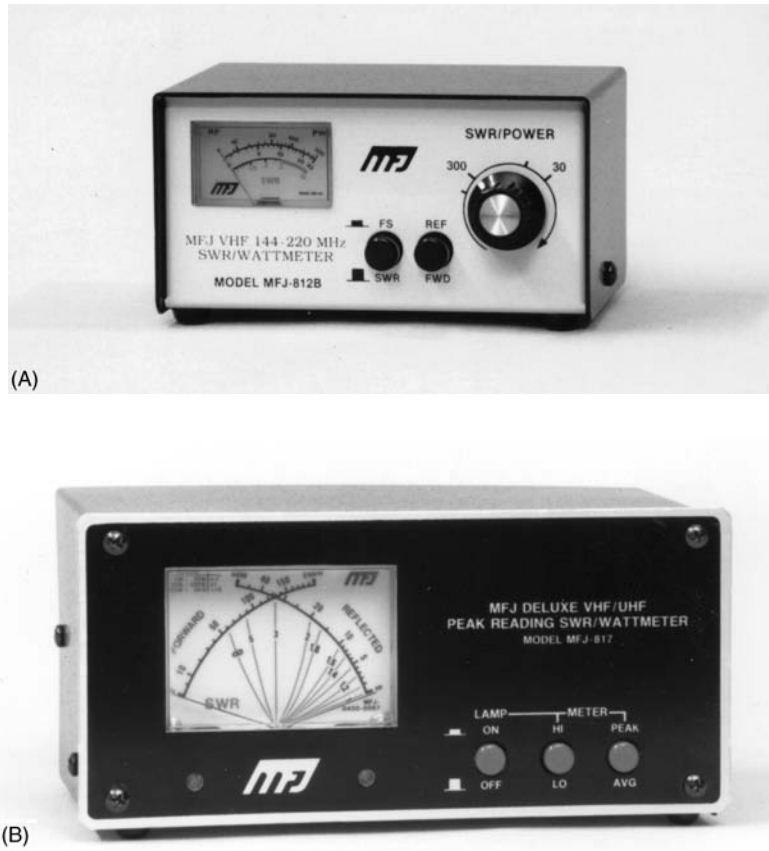

FIGURE 12.3

reason is that it uses the 'crossed-needles' method of displaying forward and reverse power. Lines of intersection with the two scales form a species of nomograph that reads out the VSWR from observation of the point where the needles cross. This instrument also includes a **peak reading** function. Most passive RF power meters inherently measure the average RF power because of the inertia of the meter movement. But with active circuitry, i.e. circuits that require direct-current power to operate, it is possible to sample and hold the peaks of the RF waveform. This meter then becomes more useful for measuring continuous-wave and amplitude-modulated waveforms (including SSB). Some authorities claim that the peak reading meter is preferred for SSB operation – and I concur.

DIP METERS

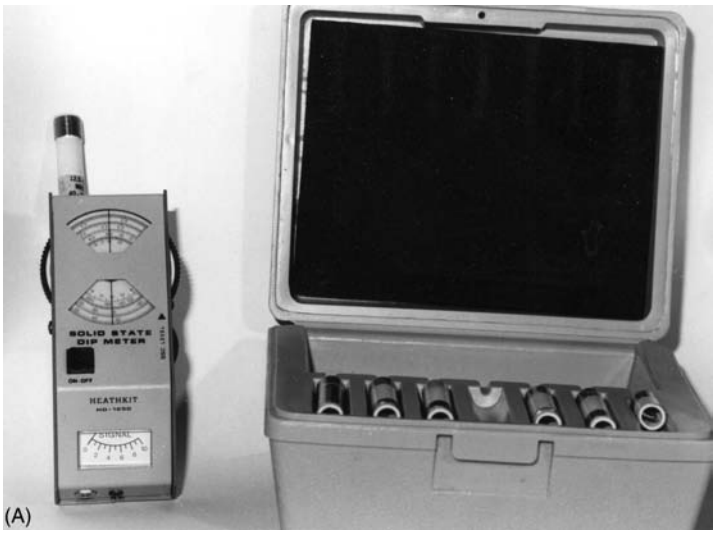
The **dip meter** works because a resonant circuit will draw power from any nearby field oscillating at its resonant frequency. An antenna that is cut to a specific frequency is resonant, so acts like an LC resonant circuit. At one time, these instruments were called **grid dip meters** because they were vacuum tube ('valve') operated. The metering monitored the grid current to detect the sudden decrease when the instrument was coupled to an external resonant circuit. Today, some people still use the archaic term 'grid dipper' even though dip meters have not had grids for nearly 30 years.

Figure 12.4A shows a typical dip meter. It consists of an LC oscillator in which the inductor is protruding outside the box so that it can be coupled to the circuit under test. A large dial is calibrated for frequency, and a meter monitors the signal level. Coils for additional bands are stored in the carrying case.

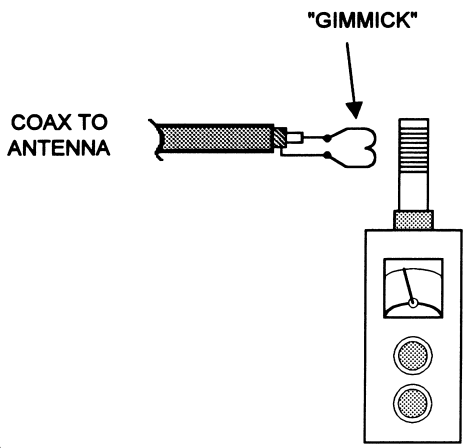
The frequency dial of the dip meter bears some additional comment. It typically covers a very wide range of frequencies, yet the dip we need is very sharp. The calibration is none too accurate. As a result, it is wise to find the dip, and then use a receiver to measure the operating frequency while the dip meter coil is still coupled to the circuit being tested. This operation is a neat trick unless you are possessed with good manual dexterity. It is necessary to measure the frequency while the instrument is coupled because this type of LC oscillator changes frequency markedly when the loading of the coil changes.

The proper method for coupling the dip meter to an antenna transmission line is shown in Figure 12.4B. Construct a 'gimmick', i.e. a small coil of one to three turns, of sufficient diameter to slip over the coil protruding from the dip meter. Either slip the dipper coil inside the gimmick, or bring it into close proximity. Energy is transferred from the dipper to the gimmick and thus to the antenna. When the dipper is tuned to the resonant frequency of the antenna, a sudden drain is put on the dipper, and the signal level drops sharply. The frequency of this dip tells you the resonant frequency of the antenna.

The dipper must be tuned very slowly – very, very slowly – or you will miss the dipping action of the meter. Tuning too fast is the principal reason why many newcomers fail to make the dipper work. To make matters more confusing, the meter needle will drift all over the scale as the instrument is tuned. This occurs because it is natural for LC-tuned oscillators to produce different signal level at different frequencies (generally, but not always, decreasing as frequency increases). The effect to watch for is a very sharp drop in the meter reading.



(A)



(B)

FIGURE 12.4

ANTENNA IMPEDANCE (OR 'RESISTANCE') BRIDGES

While it is necessary to measure the VSWR of an antenna to see how well it is working, the VSWR alone is insufficient to optimize performance. If you do not know the feedpoint impedance at resonance (minimum VSWR), then you cannot do much to correct a problem. Several instruments are available that will measure the feedpoint resistance of the antenna (it is called 'impedance' in some user manuals, but it is really only the resistive component of

impedance). The instruments in Figure 12.5 are examples of antenna resistance meters. The instrument in Figure 12.5A is based on the Wheatstone bridge circuit. It uses a variable resistor (connected to the thumbwheel resistance dial) as one leg of the bridge, and the antenna

(A)

(B)

FIGURE 12.5

resistance another leg (fixed resistors form the remaining two legs of the classic Wheatstone bridge). This model is passive, and requires an external signal source. There is an internal amplifier that allows you to use a signal generator, or the amplifier can be bypassed if you wish to drive it with a transmitter signal.

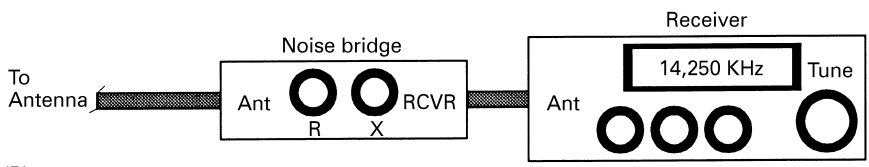
The instrument in Figure 12.5B is a little different. It is basically a sensitive VSWR meter with a built-in signal generator. Knowing the system impedance it can thereby calculate the resistance from knowledge of the VSWR.

RF NOISE BRIDGES

The **noise bridge** (Figure 12.6A) is an interesting antenna instrument that is used in conjunction with a radio receiver to measure the antenna feedpoint resistance, approximate the reactance component of the impedance, and find the resonant frequency. These instruments use white noise ('hiss' is what it sounds like on the receiver speaker) to generate a wide spectrum of radio frequencies. When the receiver is used to monitor the noise, a null is noted at the resonant frequency.

Figure 12.6B shows how the noise bridge is connected between the antenna transmission line and the antenna input connector of the receiver. The line between the bridge and the receiver can be any length, but it is wise

(A)



(B)

FIGURE 12.6

to keep it short. One reader of my columns wrote in to take exception to the 'short as possible' requirement because it is not strictly necessary in a *perfect world*. My own experience says differently, especially at higher frequencies where the line is a significant fraction of a wavelength. A meter or so should not affect any HF measurement, however.

The line to the antenna should either be as short as possible (preferably zero length), but in the real world, where one has to be more practical than theoretically pure, it is sufficient to make the transmission line an integer multiple of an electrical half wavelength long (the physical length is shorter than the free space half wavelength because of the velocity factor). The impedance hanging on the far end of the half wavelength $\times N$ line is repeated every half wavelength. A consequence of this effect is that the impedance measured at the transmitter or receiver end is the same as at the antenna end.

To use the noise bridge, set the resistance (R) and reactance (X) controls to mid-scale (X = 0). Adjust the receiver frequency to the expected resonant frequency. At this point you can do either of two different measurement schemes.

Method 1

First, you can set the R-control of the noise bridge to the desired antenna impedance, and then tune the receiver until a dip in the noise occurs (as heard in the output or noted on the S-meter). For example, suppose you have a dipole cut for 11.75 MHz, and installed such that the expected feedpoint impedance should be around 70 ohms. It is fed with a half wavelength of polyfoam dielectric 75 ohm coaxial cable ($V = 0.80$). The cable length is $(150)(0.8)/11.75 = 10.2$ m. The noise bridge X-control is set to 0, and the resistance control is set to the letter that represents 70 ohms (given in the calibration manual). This resistance setting can also be determined experimentally by connecting a 70 ohm resistor across the antenna terminal and adjusting the R-control for the minimum noise. When the noise bridge is set, then adjust the receiver for minimum noise. The frequency at which the dip occurs is the actual resonant frequency. I used this method to investigate a vertical cut for 21.25 MHz, only to find the actual resonance was 19.2 MHz, which explained the high VSWR.

Method 2

The other method is to set the receiver to the design resonant frequency of the antenna. You then adjust the R-control for a dip in the noise level. The value of the resistance is the feedpoint impedance of the antenna. You can either match that impedance, or adjust the antenna to bring the actual resonant frequency closer to the design frequency.

VSWR ANALYZERS

The basic premise in this section is that the instruments used must be accessible to people who do not have a ham radio or professional radio operator's license. Some of the instruments discussed above meet that requirement, but a relatively new breed of instrument called the SWR analyzer provides a lot of capability to the short-wave listener, scanner operator, and ham radio operator alike. It uses a low-power RF signal generator and some clever circuitry to measure the VSWR of the antenna. One model also measures the feedpoint resistance.

The simple version shown in Figure 12.7 is for the low VHF band (up to and including the 6 m ham band). It is a hand-held, battery-powered instrument. The meter reads the VSWR of the antenna at the frequency set by the TUNE dial.

A somewhat more sophisticated instrument, the MFJ Enterprises Model MFJ-259, is shown in Figure 12.8. The front panel has two meters, SWR and RESISTANCE. The SWR meter is calibrated up to 3:1, with a little uncalibrated scale to indicate higher SWRs. The RESISTANCE meter is calibrated from 0 to 500 ohms, which is consistent with the SWR range. Two controls on the front panel are TUNE and FREQUENCY (MHz) (a

FIGURE 12.7

FIGURE 12.8

bandswitch). The MFJ-259 has a digital frequency meter to measure the operating frequency of the internal oscillator. This frequency counter can also be used to measure the frequency of external signal sources (DO NOT connect the counter to the output of a transmitter – the instrument will be destroyed). The top end of the MFJ-259 has a number of controls and connectors. An SO-239 'UHF' style coaxial connector is provided for the antenna connection. A BNC coaxial connector is provided to apply an external signal to the frequency counter, while a pushbutton INPUT switch is available to switch the counter from internal to external signal sources. Another pushbutton switch is used to set the gate timing of the counter (a red LED on the front panel blinks every time the gate is triggered). The tuning is from 1.8 to 174 MHz, while the counter will measure up to 200 MHz.

The MFJ-259 will work from an external 12 V DC source, or from an internal battery pack consisting of eight size-AA standard cells. MFJ recommends that either alkaline or rechargeable batteries, rather than ordinary zinc–carbon cells, be used in order to reduce the possibility of leakage that could damage the instrument (this is good practice in all battery-powered instruments). I have a homebrewed battery pack that uses eight size-D nickel cadmium batteries (4 A-h rating) that can be recharged from a 12 V DC power supply, and it works well with the MFJ-259.

Unlike many lesser SWR meters, this instrument is not fooled by antennas that have impedances consisting of both resistance and reactance elements. An example in the manual demonstrates an impedance of 25 + j25 ohms (i.e. R is 25 ohms and reactance, X, is also 25 ohms). When connected to a 50 ohm load one might be tempted to think the VSWR is 1:1, and some cheaper meters will so indicate. But the actual SWR is 2.6:1, which is what the MFJ-259 will read.

The resistance measurement assumes a resistive load (i.e. the measurement is made at the resonant frequency of the antenna), and is referenced to 50 ohms. The VSWR and resistance measurements should be consistent with each other. If the VSWR is 2:1, then the resistance should be either 100 ohms (100/50 = 2:1) or 25 ohms (50/25 = 2:1). If the resistance is not consistent with the VSWR reading, then you should assume that the impedance has a significant reactive component, and take steps to tune it out.

In addition to antenna measurements, the MFJ-259 is equipped to measure a wide variety of other things as well. It will measure the velocity factor of transmission line, help in tuning or adjusting matching stubs or matching networks, measure capacitance or inductance, and measure the resonant frequency of LC networks.

Figure 12.9 shows an MFJ-249 meter (similar to the MFJ-259, but without the resistance measurement) equipped with the MFJ-66 dip meter adapter. It can be used to make the MFJ-249 or MFJ-259 work in the same manner as a dip meter. Using this adapter allows you to measure the resonant frequency of tank circuits using the dipper approach, as well as to measure things such as the coefficient of coupling between two LC circuits, transformers, and other radio circuits.

DUMMY LOADS (ARTIFICIAL AERIAL)

The **dummy load**, or **artificial aerial** as it is also called, is a resistor used to simulate an antenna when adjusting a transmitter or other radio apparatus. These devices consist of a non-inductive, 50 ohm resistor inside a shielded enclosure.

The dummy load offers several benefits over regular antennas. First, it is a constant resistance over the entire frequency range, and, second, it does not present any appreciable reactance. Third, and perhaps most important, the dummy load provides the ability to conduct tests off the air where you will not cause television interference, broadcast interference, or interference to other users of the test frequency that you select. Besides, it is illegal and just plain rude to radiate when you do not have to!

One use for dummy loads is to adjust antenna tuners. You can connect the dummy load to the antenna output of the tuner, and then adjust the

FIGURE 12.9

controls for best VSWR at a number of frequencies. By recording the knob settings, you can 'rough in' the antenna tuner when changing frequency.

Several types of dummy load are shown in Figures 12.10 and 12.11. The version in Figure 12.10 is a small 5 W HF model intended for measuring the output of CB transmitters. I have used this particular dummy load for adjusting a wide range of RF projects and instruments over the years. To make accurate power measurements, the dummy load is placed at the ANT connector of the RF power meter, and the transmitter connected to the other end. The power reading is not obscured by transmission line effects or the reactance that a real antenna might present.

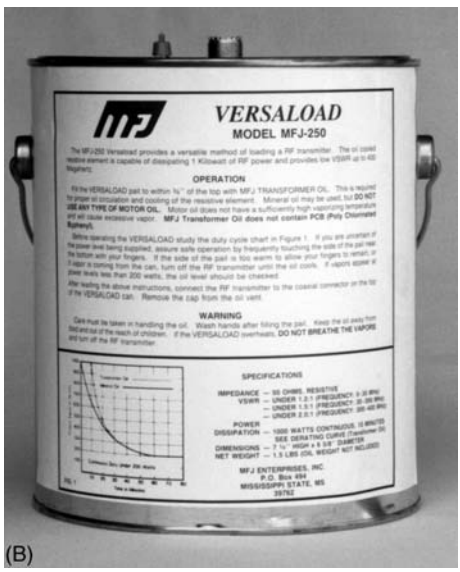
The dummy loads shown in Figure 12.11 are intended for ham radio power levels. The model in Figure 12.11A is air cooled, and operates at RF power levels up to 1500 W, over a range of 1–650 MHz. The version in Figure 12.11B is oil cooled, and will handle up to 1000 W of RF power.

COAXIAL SWITCHES

A coaxial switch (Figure 12.12) is used to allow a receiver or ham radio set to use any of several antennas (models with up to 16 ports are available, but this one is a two-port model). The common connector is for the receiver or transmitter, while the two antennas are connector to the 'A' and 'B' ports,

FIGURE 12.10

(A)



(B)

FIGURE 12.11

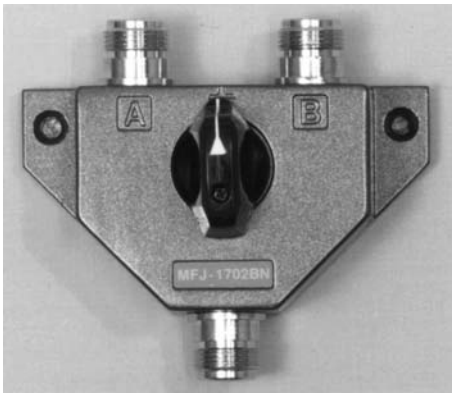


FIGURE 12.12

respectively. Alternatively, one can turn the switch around backwards (it is bidirectional, after all), and use the same antenna on two different receivers or transmitters.

The use of the coaxial switch in antenna measurement is in comparing the antenna being tested with either another antenna or a dummy load. The kind of off-the-air checks that amateurs and short-wave listeners can make are notoriously inaccurate, but can be made a lot more useful by making comparisons with known antennas. For example, a friend of mine, the late Johnnie H. Thorne (K4NFU/5) had an antenna farm in Texas (and it did seem that he grew antennas, judging from the number he had). He kept a standard dipole, optimally installed and cut for 20 m, and made all of his test designs for the same frequency. He would compare new designs to the dipole by switching back and forth while monitoring the signal strength on the receiver S-meter. He could also compare two different antennas by comparing them against each other or against the dipole.

STEP ATTENUATORS

The **step attenuator** (Figure 12.13) is a precision instrument that provides highly accurate levels of attenuation in steps of 1 dB, 2 dB, 3 dB, 5 dB, 10 dBV, and one or more 20 dB settings. You can use these to calibrate instruments, or measure signal levels. One use is to make comparison measurements of two signal sources, two antennas, etc.

For example, suppose you want to measure the gain of a new antenna relative to a dipole (assuming that both are cut for the same frequency). You would pick or provide a distant signal on the resonant frequency of the antenna. The attenuator is inserted into the feedline path of the test antenna (Figure 12.14). The signal strength is then measured with the dipole in the

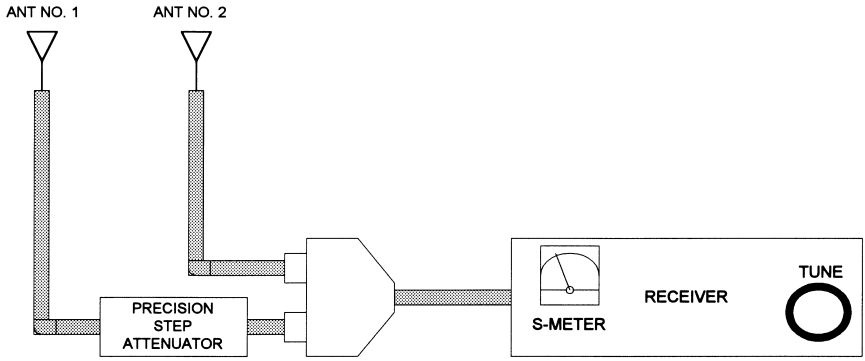

FIGURE 12.13

FIGURE 12.14

circuit (see the coaxial switch discussion above), and the reading of the S-meter noted. If you have an RF sensitivity control, then adjust it to a convenient point on the meter dial, like S-9 or some other marked spot. Next, cut to the new antenna and note the signal strength. If it increased, then select the various levels of attenuation until the new signal level is the same as the initial signal level. The set level of attenuation is equivalent to the gain difference between the antennas. If the new signal level is lower than the initial signal level, then the new antenna has less gain than the old antenna. Put the attenuator in line with the comparison antenna, rather than the test antenna.

CHAPTER 13

Getting a 'good ground'

Because this book is about radio antennas it is necessary to also spend some time on the topic of antenna grounds. The effectiveness and safety of a radio antenna often hangs on whether or not it has a good radio frequency (RF) ground. Poor grounds cause most forms of antenna to operate at less than best efficiency (sometimes a whole lot less). In fact, when transmitting it is possible to burn up between 50 and 90% of your RF power heating the ground losses under the antenna, instead of propagating into the air. Ground resistances can vary from very low values of 5 ohms, up to more than 100 ohms (5–30 ohms is a frequently quoted range). RF power is dissipated in the ground resistance, so is not available for radiation. The factors that affect the ground resistance include the **conductivity of the ground**, its chemical **composition**, and its **water content**.

The ideal ground depth is rarely right on the surface, and, depending on the local water table level, might be a couple of meters or so below the surface. It is common practice among some amateur radio operators to use the building electrical ground wiring for the RF antenna ground of their station. Neglecting to install an outdoor ground that will properly do the job, they opt instead for a single connection to the grounded 'third wire' in a nearby electrical outlet. Besides being dangerous to work with, unless you know what you are doing, it is also a very poor RF ground. It is too long for even the low RF bands, and radiates RF around the house in large quantity. Stations that use the household electrical wiring as the radio ground tend to cause television interference, and other electromagnetic interference both in their own building and in nearby buildings.

Other people use the plumbing piping in the house, but this is also a problem. While the cold water pipe entering older houses is metal, and is buried for quite a distance underground, it is also a single conductor, and is often made of a metal that is not optimal for radio work. Also, in modern buildings, the main water service and the distribution pipes in the plumbing system of the building may well not be metal at all, but rather PVC or some other insulating synthetic material. Even if you get a metal water pipe, if it is the hot water pipe then no effective ground exists. There is also a very severe danger of hooking your ground to the gas service line, which could *cause a fire or explosion*. In the USA, gas pipes are usually painted black, or are unpainted, but enough water pipes also fit this description that it is good practice to avoid the pipes in a building when searching for a radio grounding solution.

TRADITIONAL RADIO GROUNDING SOLUTIONS

The goal in making a radio ground is to provide a low resistance path to the earth for radio signals. An additional goal is to make a path to the earth for lightning that strikes the antenna, or even nearby (see Chapter 2 for the use of lightning arrestors in antenna lines).

We can reduce the ground resistance by either altering the composition of the earth surrounding the ground point, or by using a large surface area conductor as the ground point. Figure 13.1 shows the traditional ground rod used by small radio stations, including amateur and receive-only stations. Use either a copper (or copper-clad steel) rod at least 2–3 m long. Electrical supply houses, as well as amateur radio and communications equipment suppliers, also sell these ground rods. Do not use the non-clad steel types sold by some electrical supply houses. They are usable by electricians when making a service entrance ground in your home or workplace, but RF applications require the low skin resistance of the copper-clad variety. The rod need not be all copper, because of the skin effect forcing the RF current to flow only on the outer surface of the rod. Try to use a 2.5 m or longer rod if at all possible, because it will work better than the shorter kind. Do not bother with the small television antenna 100–150 cm ground rods; they are next to useless for high-frequency (HF) radio stations. Drive the ground rod into the earth until only a few centimeters remain above the surface. Connect a heavy gage ground wire from your station to the ground rod (some people use heavy braid or the sort once used for the return connection from the battery to the body of an automobile; an additional source is salvaged braid from the heavier gages of coaxial cable). The ground wire should be as short as possible. Furthermore, it should be a low-inductance conductor. Use either heavy braid (or the outer conductor stripped from RG-8 or RG-11 coaxial cable), or sheet copper. You can buy

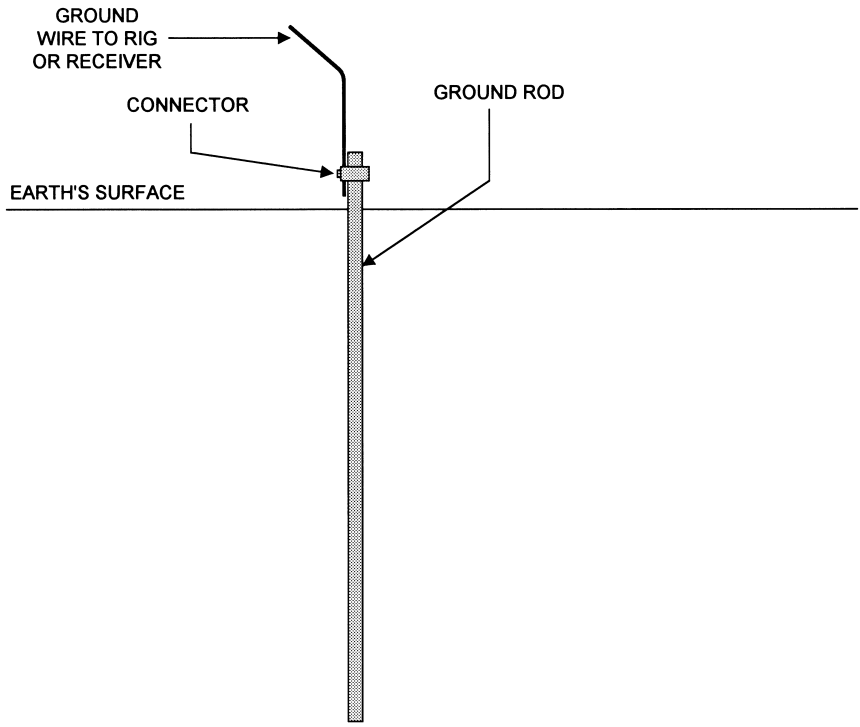

FIGURE 13.1

rolls of sheet copper from metal distributors in widths from 10 cm up to about 50 cm. Some amateurs prefer to use 17.5 cm-wide roofing foil that is rated at a weight of 1.5 kg/m. Sweat solder the ground wire to the rod. You can get away with using mechanical connections like the electricians use, but will eventually have to service the installation when corrosion takes its toll. I prefer to use soldered connections, and then cover the joint with either petroleum jelly or acrylic spray lacquer.

Another alternative is to use a copper plumbing pipe as the ground rod. The pipe can be purchased in 2–5 m lengths from plumbing supply shops or hardware stores. The pipe selected should be 19 mm in diameter or larger. Some people report using up to 50 mm diameter pipe for this application. The surface area of the hollow pipe is greater than that of a solid rod of the same diameter. Because of certain current flow geometries in the system, however, the ground resistance is not half the resistance of a rod the same diameter, but is nonetheless lower.

Unlike the copper-clad steel rod, the copper pipe has no compression strength and will deform when hit with a hammer or other driving tool.

To overcome this problem (see Figure 13.2) you can use a garden hose as a 'water drill' to sink the ground rod.

Sweat solder a 'tee'-joint on the top end of the pipe, and then sweat solder a faucet or spigot fitting that matches the garden hose end on one end of the 'tee'-joint. Cap off the other port of the 'tee'-joint. Use the 'tee'-joint as a handle to drive the pipe into the ground. When water pressure is applied, the pipe will sink slowly into the ground as you apply a downward pressure on the tee-handle. In some cases, the pipe will slip into the ground easily, requiring only a few minutes. In other cases, where the soil is hard or has a heavy clay content, it will take considerably greater effort and more time. When you finish the task, turn off the water and remove the garden hose. Some people also recommend unsoldering and removing the 'tee'-joint.

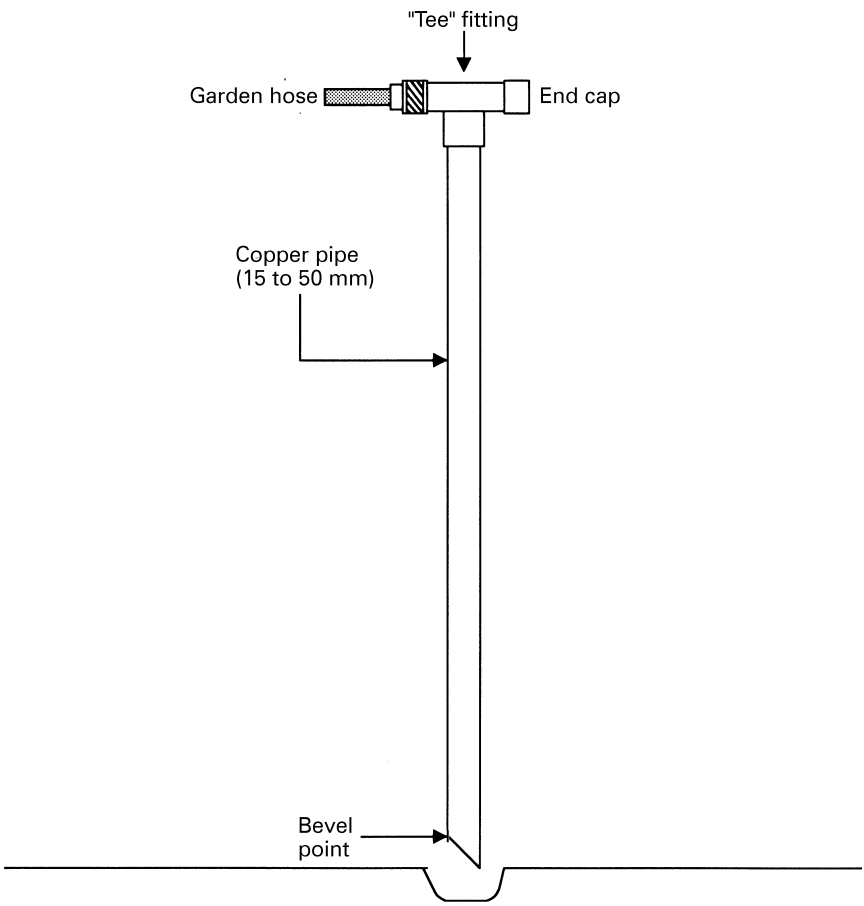

FIGURE 13.2

ALTERING SOIL CONDUCTIVITY

The conductivity of the soil determines how well, or how poorly, it conducts electrical current (Table 13.1). Moist soil over a brackish water dome conducts best. In the USA, the southern swamps make better radio station locations than most of the rest of the country; and the sand of the western deserts make the worst.

In Arizona, for example, one finds that few buildings have cellers or basements. The reason is that there is a thick calcium-based layer (called 'caleche') a meter or two down that resists even mechanized diggers. To build homes in that sand they have to drill holes in the caleche and then sink pylons down to bedrock.

The same caleche also prevents water from sinking into the sand, so it flows off the land in natural channels in the desert. The area is rather dangerous for out-of-state campers who do not understand that those nice flat, areas at the bottom of gulleys have a habit of filling in seconds if there is a distant thunder storm in the mountains. They look up, and to their horror see a 3–5 m high wall of water rushing toward them at 50 km/h! During the late summer months, Arizona has a 'monsoon' season when it rains hard and floods every day (90% of the state's annual rainfall comes in a 6-week period from sometime in July to mid-September). Evaporation is so rapid that an hour after the rain stops, there is little evidence of the rainfall except in the gulleys. If you have never felt hot rain, then visit southern Arizona in August – but be prepared for temperatures around 43°C in the shade and 80°C on the front seat of an automobile if you are so unwise as to leave all the windows rolled up.

Figure 13.3 shows a method for reducing the soil electrical resistance by treating with one of three chemicals: copper sulfate, magnesium sulfate or common rock salt. Rock salt is one of several salt materials used for snow and ice melting in snow-prone areas. If you cannot locate rock salt in a hardware store, then look for a store that sells ice cream making supplies. Rock salt is a principal ingredient in the process (but not the product).

TABLE 13.1

Type of soil	Dielectric constant	Conductivity (siemans/m)	Relative quality
Salt water	81	5	Best
Fresh water	80	0.001	Very poor
Pastoral hills	14–20	0.03–0.01	Very good
Marshy, wooded	12	0.0075	Average/poor
Rocky hills	12–14	10	Poor
Sandy	10	0.002	Poor
Cities	3–5	0.001	Very poor

Figure 13.3A shows a side sectioned view of a circular slit trench method of applying the chemical treatment to reduce ground resistance. **WARNING**: before using this method, you need to determine whether or not you really want to do it. The method involves putting conductive chemicals into the ground. *Make sure that local, state or national environmental regulations do not prohibit the practice*. Also, if you ever want to use the spot to grow vegetables or flowers – or even grass – it will prove difficult because the chemicals essentially poison the soil for several years. Fortunately, they are water-soluble, so the effect will not last forever.

Dig a 15–30 cm deep circular trench, about 30–60 cm from the ground rod. Fill that trench with a 10–12 cm layer of rock salt, magnesium sulfate, or copper sulfate (use only one). Water the trench well for about 15 minutes. Cover the remaining depth with soil removed when you have dug the trench. If you use about 100 kg of material, the treatment will need to be repeated every 24–36 months, depending upon the local rainfall and soil composition.

Figure 13.3B shows an alternative method: the saltpipe. Use either copper or PVC plumbing pipe, up to 10 cm in diameter (although 4–8 cm is easier to work). The overall length of the pipe should be at least 50–150 cm. Although longer pipes are useful, they are also difficult to install. Drill a large number of small holes in the pipe (no hole over 10 mm), sparing only the end that will be above the surface. Cap off both ends.

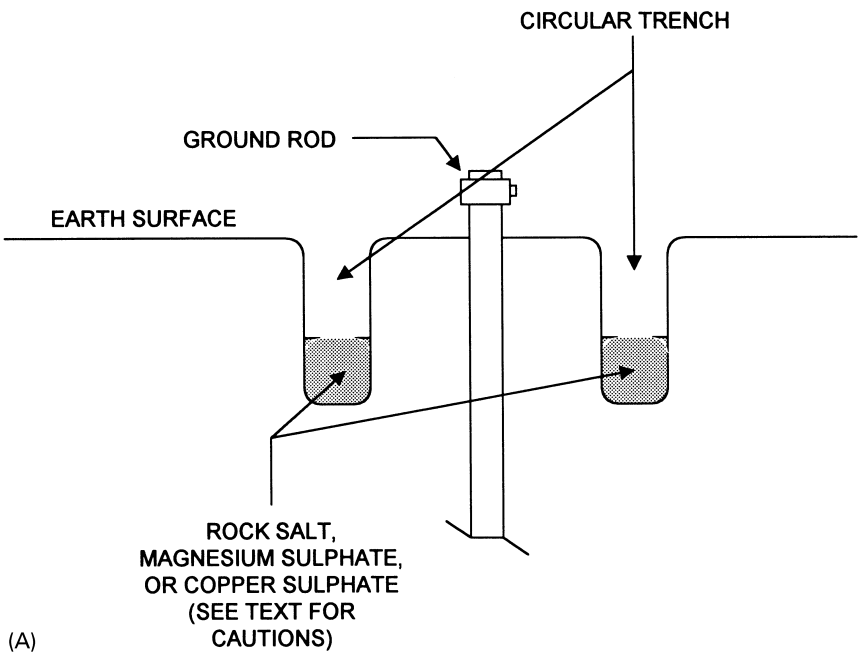

FIGURE 13.3

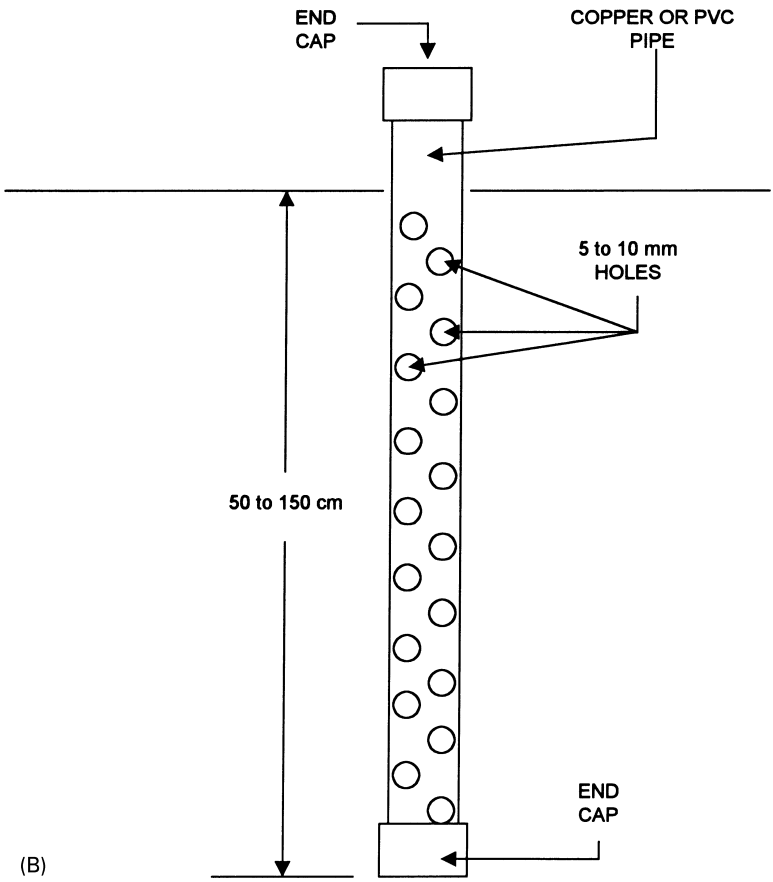

FIGURE 13.3 (*continued*)

Install several saltpipes in a pattern around the ground rod. Installation is best accomplished using a fencepost hole digger. Drop the saltpipe into the hole and backfill with water. Remove the top endcap and hose down for about 15 minutes, or until all the material is gone. Refill the pipe occasionally to account for the salt leaching out. When the chemical is completely leeched out of the pipe, refill the pipe and recap the top end. Leave the pipe in place.

Be certain of local environmental laws before using the above methods.

MULTIPLE GROUND RODS

The key to a low-resistance ground is the surface area in contact with the soil. One means for gaining surface area, and thereby reducing ground

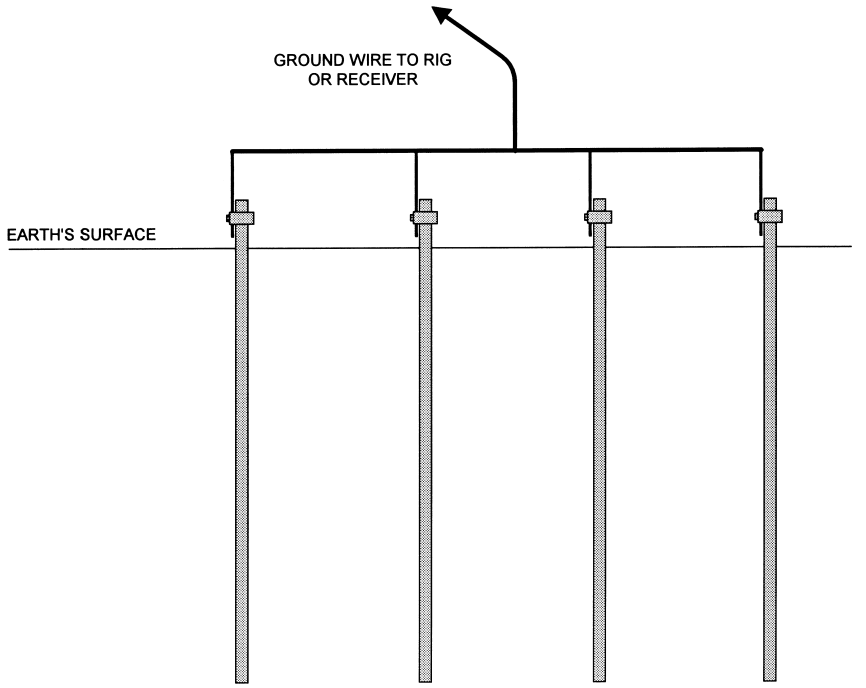

FIGURE 13.4

resistance, is to use multiple ground rods. Figure 13.4 shows the use of four ground rods in the same system. The rods are placed 30–100 cm apart for low- and medium-power levels, and perhaps more than 100 cm for higher amateur radio power levels. An electrical connection is made between the rods on the surface using either copper stripping or copper braid. The connections are sweat soldered in the manner described above, with the feedpoint at the center rod.

RADIALS AND COUNTERPOISE GROUNDS

The effectiveness of the ground system is enhanced substantially by the use of radials either above ground, on the surface, or buried under the surface. Figure 13.5 shows a vertical antenna with a set of ground radials. It is not unreasonable to use both radials and a ground rod. Vertical antennas are relatively ineffective unless provided with a good ground system, and for most installations that requirement is best met through a system of ground radials.

An effective system of radials requires a large number of radials. Although as few as two quarter-wavelength resonant radials will provide

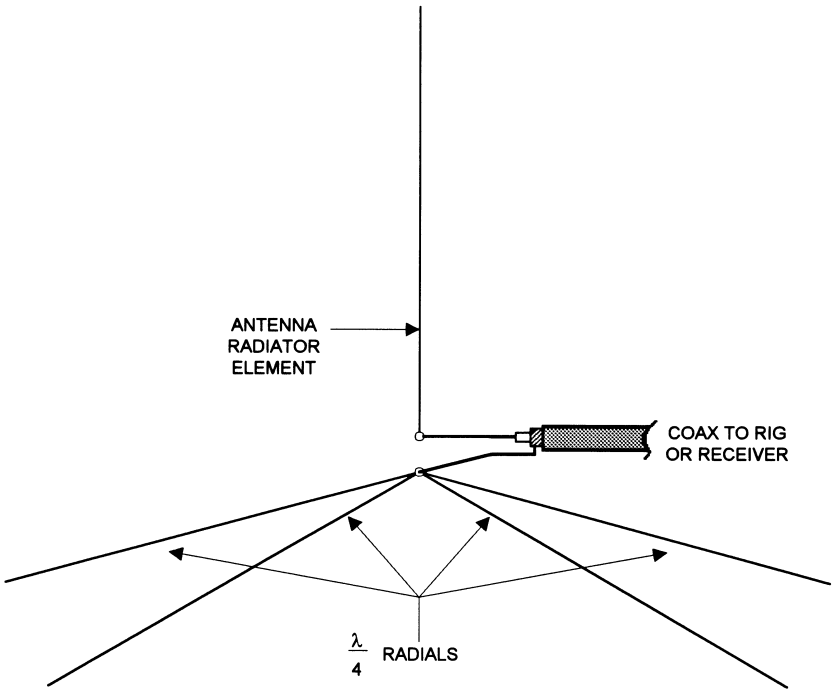

FIGURE 13.5

a significant improvement, the best performance is to use more. Broadcasters in the AM band (550–1640 kHz) are advised to use 120 half-wavelength radials. Installing more than 120 radials is both expensive and time-consuming, but does not provide any substantial improvement. For amateur and small commercial stations, a minimum of 16 quarter-wavelength radials should be used. Above ground, the use of insulated wire is recommended to reduce the possibility of anyone receiving RF burn if it is accidentally touched while transmitting. Although some sources claim that any size wire from AWG 26 up to AWG 10 (SWG 0–12) can be used, it is best to use larger sizes in that range (i.e. AWG 14 through AWG 10 (SWG 16–12)). Either solid or stranded wire can be used.

When viewed from above, the radials should be laid out in a symmetrical pattern around the antenna. This coverage provides both the lowest resistance and the best radiation pattern for the antenna. Solder all radials together at a common point, which might be the ground or mounting rod used to support the vertical antenna.

If your antenna is ground mounted, or if the radials are used with the station ground, then use a system such as that in Figure 13.6 to make the connections. A clamp on the ground rod is used to bind together the rod, the radials and the ground wire from the receiver or transmitter. The radials

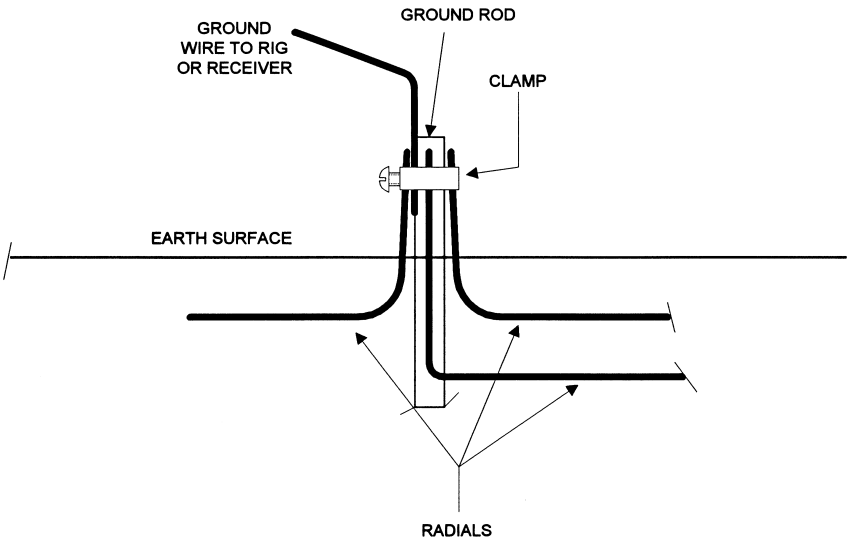

FIGURE 13.6

should be buried a few centimeters below the surface. Some people report using the tip of a spade or shovel to dig a very thin trench into which the wire can be pushed. Be careful to get the radial wire deep enough. Ordinary soil dynamics can make the wire rise to the surface within a year or so.

TUNING THE GROUND WIRE

An alternative that some operators use is the **ground wire tuner**. These instruments insert a series-tuned inductor–capacitor (LC network) in series with the ground line. These devices are usually called **artificial ground tuners**, and are inserted into the ground line of the station (Figure 13.7). Ground line tuners are especially recommended for cases where the wire to the ground is too long, in the case of single-wire antennas (e.g. Windom antennas or random-length wires), or anytime the tuning seems peculiar, but the antenna tuning unit works well into a dummy load. The purpose of the unit is to tune out any inductive or capacitive reactance on the line. Transmitter operators adjust the ground line tuner for maximum ground current at the operating frequency, although receiver operators will have to experiment a bit to find the correct settings. MFJ Enterprizes, Inc. (PO Box 494, Mississippi State, MS 39762, USA) makes several such devices. The version shown in Figure 13.8 is a stand-alone unit that contains only the ground current meter, inductor, and capacitor. The instrument in Figure 13.9 is a combination unit that includes both the ground line tuner and antenna tuner in one box.

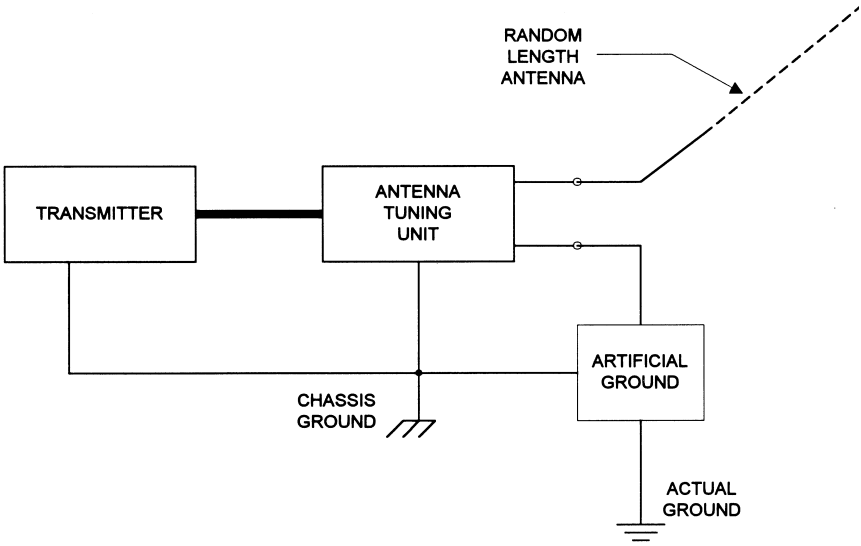

FIGURE 13.7

FIGURE 13.8

FIGURE 13.9

WARNING

Grounds for radio installations are intended for two purposes: making the radio antenna work better and lightning protection. Be absolutely sure to check with local authorities over the minimum requirements for grounding antenna structures – and then doing more than is minimally required. Not only is it possible to get into trouble with the authorities with a poor ground, you may also find that your homeowners and liability insurance is not valid if an uninspected installation is made. My own homeowners policy states that the insurance coverage is not in effect if an antenna is erected that meets the minimum requirements for a mechanical and electrical inspection by the county government but does not have a valid inspection certificate. Check with your local government and insurer before building any antenna or ground system.

CONCLUSION

Now that you have learned how to build safe and efficient antennas and grounds, in the words of Captain Piccard '*make it so*.'

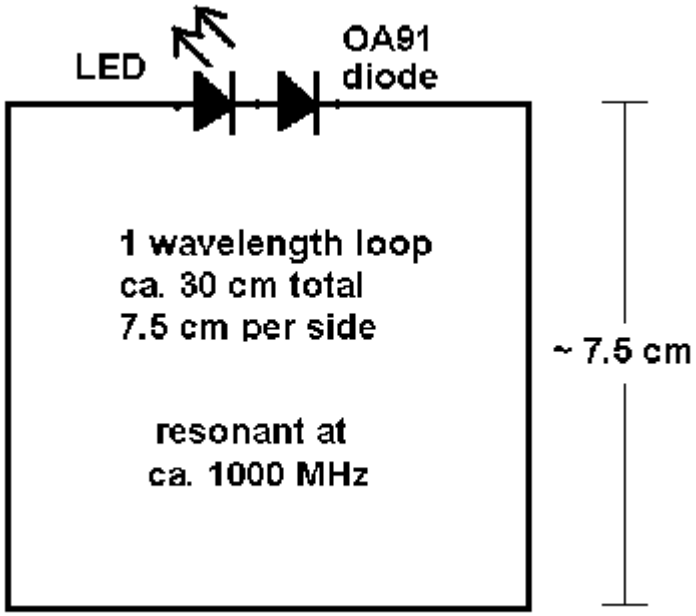
Simple demonstration to show mobile phones emit radio waves

Dr Jonathan Hare, Sussex University, Department of Physics, Falmer, Brighton. BN1 9QH
Note: this article is in press: Elektor Magazine, July-August 2010, p. 56-57

For other experiments with this device please see my full article at: mobile phone detector



left: mobile phone radio wave detector and right: the simple schematic. Below: detail of the LED and germanium diode.

IMPORTANT NOTE: this device works very well on the old style mobile phones (as shown in the photo above). However, it does not always work well with modern smart phones. This may be because modern phones use higher frequencies, less power and use the power in a slightly different way (e.g. spread

spectrum). Some smart phones do work and success may be due to the signal strength of the local mobile phone mast nearby. If you are in a low signal area the phone will create more power to ensure reliable communications. If you are in a very strong signal area (very near the local network) your phone will drop its output power and consiquently there will be less power to pick-up and to convert to a voltage to light the LED.

This is a very simple and cheap device that demonstrates mobile phones ('cell phones' or 'handies') generate radio waves. We have a 30 cm (7.5 cm per side) full-wavelength loop antenna (a 'Quad' to radio amateurs) connected to a germanium diode and a hyper-bright LED. The loop can be made of copper wire, thin sheet metal or a track on a pcb. The diodes need to be wired correctly. I think the germanium diode is needed as the LED probably has too great a self-capacitance to perform at the very high AC frequencies generated by the phone (ca. 900 or 1800 Hz) but will work well with the DC pulses from the germanium diode (which has a very small capacitance).

To show the mobile generates radio waves put the mobile near to the loop and dial a number (use a free phone number, e.g. your voice mail) or text. The radio waves will induce a voltage into the loop, large enough to light the LED. The LED will flash indicating the digital data being sent by the mobile phone transmitter. You may need to set your phone to 'GSM 900/1800' rather than the '3G' network in the settings menu.

NONRESIDENT TRAINING COURSE

October 1995

Electronics Technician

Volume 7—Antennas and Wave Propagation

NAVEDTRA 14092

DISTRIBUTION STATEMENT A: Approved for public release; distribution is unlimited.

Although the words "he," "him," and "his" are used sparingly in this course to enhance communication, they are not intended to be gender driven or to affront or discriminate against anyone.

DISTRIBUTION STATEMENT A: Approved for public release; distribution is unlimited.

PREFACE

By enrolling in this self-study course, you have demonstrated a desire to improve yourself and the Navy. Remember, however, this self-study course is only one part of the total Navy training program. Practical experience, schools, selected reading, and your desire to succeed are also necessary to successfully round out a fully meaningful training program.

COURSE OVERVIEW: In completing this nonresident training course, you should be able to: discuss wave propagation in terms of the effects the earth's atmosphere has on it and the options available to receive optimum performance from equipment; identify communications and radar antennas using physical characteristics and installation location, radiation patterns, and power and frequency-handling capabilities. Be familiar with safety precautions for technicians working aloft; and discuss the different types of transmission lines in terms of physical structure, frequency limitations, electronic fields, and radiation losses.

THE COURSE: This self-study course is organized into subject matter areas, each containing learning objectives to help you determine what you should learn along with text and illustrations to help you understand the information. The subject matter reflects day-to-day requirements and experiences of personnel in the rating or skill area. It also reflects guidance provided by Enlisted Community Managers (ECMs) and other senior personnel, technical references, instructions, etc., and either the occupational or naval standards, which are listed in the *Manual of Navy Enlisted Manpower Personnel Classifications and Occupational Standards*, NAVPERS 18068.

THE QUESTIONS: The questions that appear in this course are designed to help you understand the material in the text.

VALUE: In completing this course, you will improve your military and professional knowledge. Importantly, it can also help you study for the Navy-wide advancement in rate examination. If you are studying and discover a reference in the text to another publication for further information, look it up.

Sailor's Creed

"I am a United States Sailor.

I will support and defend the Constitution of the United States of America and I will obey the orders of those appointed over me.

I represent the fighting spirit of the Navy and those who have gone before me to defend freedom and democracy around the world.

I proudly serve my country's Navy combat team with honor, courage and commitment.

I am committed to excellence and the fair treatment of all."

SUMMARY OF THE ELECTRONICS TECHNICIAN TRAINING SERIES

This series of training manuals was developed to replace the *Electronics Technician 3 & 2* TRAMAN. The content is directed to personnel working toward advancement to Electronics Technician Second Class.

The nine volumes in the series are based on major topic areas with which the ET2 should be familiar. Volume 1, *Safety,* provides an introduction to general safety as it relates to the ET rating. It also provides both general and specific information on electronic tag-out procedures, man-aloft procedures, hazardous materials (i.e., solvents, batteries, and vacuum tubes), and radiation hazards. Volume 2, *Administration,* discusses COSAL updates, 3-M documentation, supply paperwork, and other associated administrative topics. Volume 3, *Communication Systems,* provides a basic introduction to shipboard and shore-based communication systems. Systems covered include man-pat radios (i.e., PRC-104, PSC-3) in the hf, vhf, uhf, SATCOM, and shf ranges. Also provided is an introduction to the Communications Link Interoperability System (CLIPS). Volume 4, *Radar Systems,* is a basic introduction to air search, surface search, ground controlled approach, and carrier controlled approach radar systems. Volume 5, *Navigation Systems, is* a basic introduction to navigation systems, such as OMEGA, SATNAV, TACAN, and man-pat systems. Volume 6, *Digital Data Systems, is* a basic introduction to digital data systems and includes discussions about SNAP II, laptop computers, and desktop computers. Volume 7, *Antennas and Wave Propagation,* is an introduction to wave propagation, as it pertains to Electronics Technicians, and shipboard and shore-based antennas. Volume 8, *Support Systems,* discusses system interfaces, troubleshooting, sub-systems, dry air, cooling, and power systems. Volume 9, *Electro-Optics, is* an introduction to night vision equipment, lasers, thermal imaging, and fiber optics.

INSTRUCTIONS FOR TAKING THE COURSE

ASSIGNMENTS

The text pages that you are to study are listed at the beginning of each assignment. Study these pages carefully before attempting to answer the questions. Pay close attention to tables and illustrations and read the learning objectives. The learning objectives state what you should be able to do after studying the material. Answering the questions correctly helps you accomplish the objectives.

SELECTING YOUR ANSWERS

Read each question carefully, then select the BEST answer. You may refer freely to the text. The answers must be the result of your own work and decisions. You are prohibited from referring to or copying the answers of others and from giving answers to anyone else taking the course.

SUBMITTING YOUR ASSIGNMENTS

To have your assignments graded, you must be enrolled in the course with the Nonresident Training Course Administration Branch at the Naval Education and Training Professional Development and Technology Center (NETPDTC). Following enrollment, there are two ways of having your assignments graded: (1) use the Internet to submit your assignments as you complete them, or (2) send all the assignments at one time by mail to NETPDTC.

Grading on the Internet: Advantages to Internet grading are:

- you may submit your answers as soon as you complete an assignment, and
- you get your results faster; usually by the next working day (approximately 24 hours).

In addition to receiving grade results for each assignment, you will receive course completion confirmation once you have completed all the assignments. To submit your assignment answers via the Internet, go to:

http://courses.cnet.navy.mil

Grading by Mail: When you submit answer sheets by mail, send all of your assignments at one time. Do NOT submit individual answer sheets for grading. Mail all of your assignments in an envelope, which you either provide yourself or obtain from your nearest Educational Services Officer (ESO). Submit answer sheets to:

COMMANDING OFFICER
NETPDTC N331
6490 SAUFLEY FIELD ROAD
PENSACOLA FL 32559-5000

Answer Sheets: All courses include one "scannable" answer sheet for each assignment. These answer sheets are preprinted with your SSN, name, assignment number, and course number. Explanations for completing the answer sheets are on the answer sheet.

Do not use answer sheet reproductions: Use only the original answer sheets that we provide—reproductions will not work with our scanning equipment and cannot be processed.

Follow the instructions for marking your answers on the answer sheet. Be sure that blocks 1, 2, and 3 are filled in correctly. This information is necessary for your course to be properly processed and for you to receive credit for your work.

COMPLETION TIME

Courses must be completed within 12 months from the date of enrollment. This includes time required to resubmit failed assignments.

PASS/FAIL ASSIGNMENT PROCEDURES

If your overall course score is 3.2 or higher, you will pass the course and will not be required to resubmit assignments. Once your assignments have been graded you will receive course completion confirmation.

If you receive less than a 3.2 on any assignment and your overall course score is below 3.2, you will be given the opportunity to resubmit failed assignments. **You may resubmit failed assignments only once.** Internet students will receive notification when they have failed an assignment--they may then resubmit failed assignments on the web site. Internet students may view and print results for failed assignments from the web site. Students who submit by mail will receive a failing result letter and a new answer sheet for resubmission of each failed assignment.

COMPLETION CONFIRMATION

After successfully completing this course, you will receive a letter of completion.

ERRATA

Errata are used to correct minor errors or delete obsolete information in a course. Errata may also be used to provide instructions to the student. If a course has an errata, it will be included as the first page(s) after the front cover. Errata for all courses can be accessed and viewed/downloaded at:

http://www.advancement.cnet.navy.mil

STUDENT FEEDBACK QUESTIONS

We value your suggestions, questions, and criticisms on our courses. If you would like to communicate with us regarding this course, we encourage you, if possible, to use e-mail. If you write or fax, please use a copy of the Student Comment form that follows this page.

For subject matter questions:

E-mail: n315.products@cnet.navy.mil
Phone: Comm: (850) 452-1001, Ext. 1713
DSN: 922-1001, Ext. 1713
FAX: (850) 452-1370
(Do not fax answer sheets.)
Address: COMMANDING OFFICER
NETPDTC N315
6490 SAUFLEY FIELD ROAD
PENSACOLA FL 32509-5237

For enrollment, shipping, grading, or completion letter questions

E-mail: fleetservices@cnet.navy.mil
Phone: Toll Free: 877-264-8583
Comm: (850) 452-1511/1181/1859
DSN: 922-1511/1181/1859
FAX: (850) 452-1370
(Do not fax answer sheets.)
Address: COMMANDING OFFICER
NETPDTC N331
6490 SAUFLEY FIELD ROAD
PENSACOLA FL 32559-5000

NAVAL RESERVE RETIREMENT CREDIT

If you are a member of the Naval Reserve, you may earn retirement points for successfully completing this course, if authorized under current directives governing retirement of Naval Reserve personnel. For Naval Reserve retirement, this course is evaluated at 5 points. (Refer to *Administrative Procedures for Naval Reservists on Inactive Duty,* BUPERSINST 1001.39, for more information about retirement points.)

Student Comments

Course Title: *Electronics Technician, Volume 7—Antennas and Wave Propagation*

NAVEDTRA: 14092 **Date**: _____

We need some information about you:

CHAPTER 1

WAVE PROPAGATION

The eyes and ears of a ship or shore station depend on sophisticated, highly computerized electronic systems. The one thing all of these systems have in common is that they lead to and from *antennas.* Ship's operators who must communicate, navigate, and be ready to fight the ship 24 hours a day depend on you to keep these emitters and sensors operational.

In this volume, we will review wave propagation, antenna characteristics, shore-based and shipboard communications antennas, matching networks, antenna tuning, radar antennas, antenna safety, transmission lines, connector installation and weatherproofing, waveguides, and waveguide couplings. When you have completed this chapter, you should be able to discuss the basic principles of wave propagation and the atmosphere's effects on wave propagation.

THE EARTH'S ATMOSPHERE

While radio waves traveling in free space have little outside influence to affect them, radio waves traveling in the earth's atmosphere have many influences that affect them. We have all experienced problems with radio waves, caused by certain atmospheric conditions complicating what at first seemed to be a relatively simple electronic problem. These problem-causing conditions result from a lack of uniformity in the earth's atmosphere.

Many factors can affect atmospheric conditions, either positively or negatively. Three of these are variations in geographic height, differences in geographic location, and changes in time (day, night, season, year).

To understand wave propagation, you must have at least a basic understanding of the earth's atmosphere. The earth's atmosphere is divided into three separate regions, or layers. They are the *troposphere,* the *stratosphere,* and the *ionosphere.* These layers are illustrated in figure 1-1.

TROPOSPHERE

Almost all weather phenomena take place in the troposphere. The temperature in this region decreases rapidly with altitude. Clouds form, and there may be a lot of turbulence because of variations in the temperature, pressure, and density. These conditions have a profound effect on the propagation of radio waves, as we will explain later in this chapter.

STRATOSPHERE

The stratosphere is located between the troposphere and the ionosphere. The temperature throughout this region is almost constant and there is little water vapor present. Because it is a relatively calm region with little or no temperature change, the stratosphere has almost no effect on radio waves.

IONOSPHERE

This is the most important region of the earth's atmosphere for long distance, point-to-point communications. Because the existence of the ionosphere is directly related to radiation emitted from the sun, the movement of the earth about the sun or changes in the sun's activity will result in variations in the ionosphere. These variations are of two general types: (1) those that more or less occur in cycles and, therefore, can be predicted with reasonable accuracy; and (2) those that are irregular as a result of abnormal behavior of the sun and, therefore, cannot be predicted. Both regular and irregular variations have important effects on radio-wave propagation. Since irregular variations cannot be predicted, we will concentrate on regular variations.

Regular Variations

The regular variations can be divided into four main classes: daily, 27-day, seasonal, and 11-year. We will concentrate our discussion on daily variations,

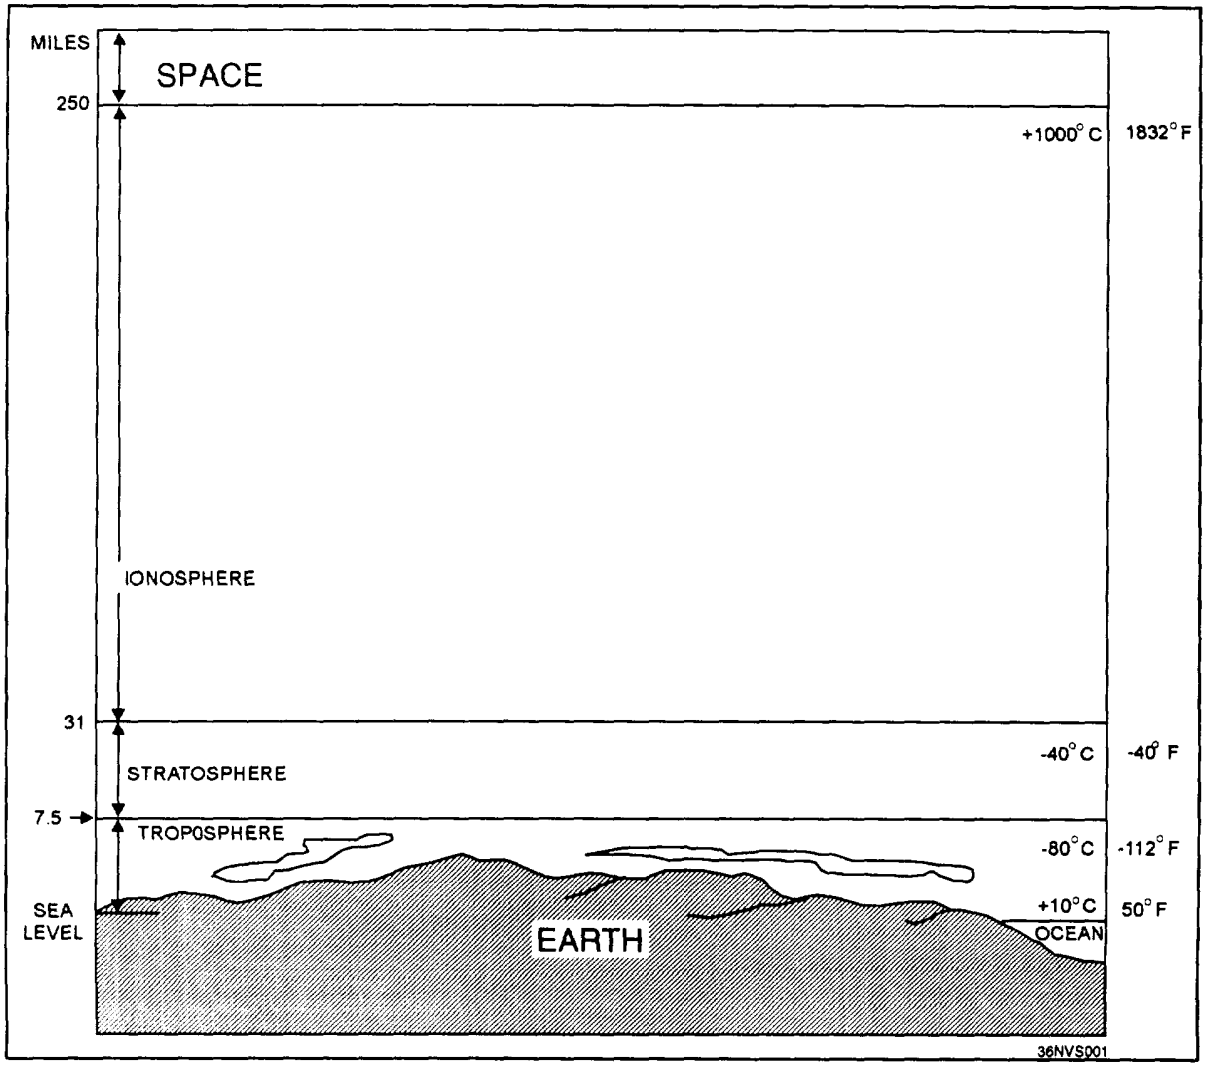

Figure 1.1—Atmospheric layers.

since they have the greatest effect on your job. Daily variations in the ionosphere produce four cloud-like layers of electrically-charged gas atoms called *ions*, which enable radio waves to be propagated great distances around the earth. Ions are formed by a process called *ionization*.

Ionization

In ionization, high-energy ultraviolet light waves from the sun periodically enter the ionosphere, strike neutral gas atoms, and knock one or more electrons free from each atom. When the electrons are knocked free, the atoms become positively charged **(positive ions)** and remain in space, along with the negatively-charged free electrons. The free electrons absorb some of the ultraviolet energy that initially set them free and form an ionized layer.

Since the atmosphere is bombarded by ultraviolet waves of differing frequencies, several ionized layers are formed at different altitudes. Ultraviolet waves of higher frequencies penetrate the most, so they produce ionized layers in the lower portion of the ionosphere. Conversely, ultraviolet waves of lower frequencies penetrate the least, so they form layers in the upper regions of the ionosphere.

An important factor in determining the density of these ionized layers is the elevation angle of the sun. Since this angle changes frequently, the height and thickness of the ionized layers vary, depending

on the time of day and the season of the year. Another important factor in determining layer density is known as *recombination*.

Recombination

Recombination is the reverse process of ionization. It occurs when free electrons and positive ions collide, combine, and return the positive ions to their original neutral state.

Like ionization, the recombination process depends on the time of day. Between early morning and late afternoon, the rate of ionization exceeds the rate of recombination. During this period the ionized layers reach their greatest density and exert maximum influence on radio waves. However, during the late afternoon and early evening, the rate of recombination exceeds the rate of ionization, causing the densities of the ionized layers to decrease. Throughout the night, density continues to decrease, reaching its lowest point just before sunrise. It is important to understand that this ionization and recombination process varies, depending on the ionospheric layer and the time of day. The following paragraphs provide an explanation of the four ionospheric layers.

Ionospheric Layers

The ionosphere is composed of three distinct layers, designated from lowest level to highest level **(D, E,** and **F)** as shown in figure 1-2. In addition, the **F** layer is divided into two layers, designated **F1** (the lower level) and **F2** (the higher level).

The presence or absence of these layers in the ionosphere and their height above the earth vary with the position of the sun. At high noon, radiation in the ionosphere above a given point is greatest, while at night it is minimum. When the radiation is removed, many of the particles that were ionized recombine. During the time between these two conditions, the position and number of ionized layers within the ionosphere change.

Since the position of the sun varies daily, monthly, and yearly with respect to a specific point on earth, the exact number of layers present is extremely difficult to determine. However, the following general statements about these layers can be made.

D LAYER.— The **D** layer ranges from about 30 to 55 miles above the earth. Ionization in the **D** layer is low because less ultraviolet light penetrates to this level. At very low frequencies, the **D** layer and the ground act as a huge waveguide, making communication possible only with large antennas and high-power transmitters. At low and medium frequencies, the **D** layer becomes highly absorptive, which limits the effective daytime communication range to about 200 miles. At frequencies above about 3 MHz, the **D** layer begins to lose its absorptive qualities.

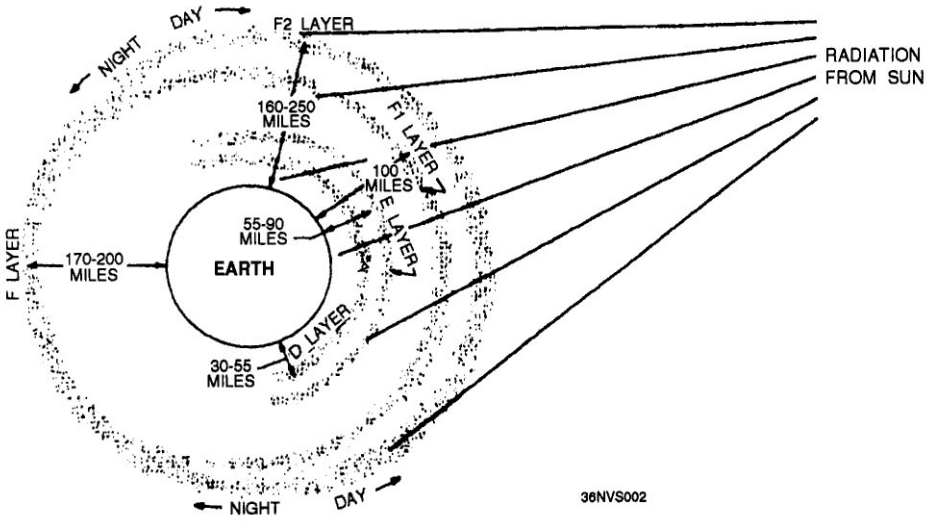

Figure 1-2.—Layers of the ionosphere.

Long-distance communication is possible at frequencies as high as 30 MHz. Waves at frequencies above this range pass through the **D** layer but are attenuated. After sunset. the **D** layer disappears because of the rapid recombination of ions. Low-frequency and medium-frequency long-distance communication becomes possible. This is why **AM** behaves so differently at night. Signals passing through the **D** layer normally are not absorbed but are propagated by the **E** and **F** layers.

E LAYER.— The **E** layer ranges from approximately 55 to 90 miles above the earth. The rate of ionospheric recombination in this layer is rather rapid after sunset, causing it to nearly disappear by midnight. The **E** layer permits medium-range communications on the low-frequency through very-high-frequency bands. At frequencies above about 150 MHz, radio waves pass through the **E** layer.

Sometimes a solar flare will cause this layer to ionize at night over specific areas. Propagation in this layer during this time is called SPORADIC-E. The range of communication in sporadic-E often exceeds 1000 miles, but the range is not as great as with F layer propagation.

F LAYER.— The **F** layer exists from about 90 to 240 miles above the earth. During daylight hours, the **F** layer separates into two layers, **F1** and **F2.** During the night, the **F1** layer usually disappears, The **F** layer produces maximum ionization during the afternoon hours, but the effects of the daily cycle are not as pronounced as in the **D** and **E** layers. Atoms in the **F** layer stay ionized for a longer time after sunset, and during maximum sunspot activity, they can stay ionized all night long.

Since the **F** layer is the highest of the ionospheric layers, it also has the longest propagation capability. For horizontal waves, the single-hop **F2** distance can reach 3000 miles. For signals to propagate over greater distances, multiple hops are required.

The **F** layer is responsible for most high-frequency, long-distance communications. The maximum frequency that the **F** layer will return depends on the degree of sunspot activity. During maximum sunspot activity, the **F** layer can return signals at frequencies as high as 100 MHz. During minimum sunspot activity, the maximum usable frequency can drop to as low as 10 MHz.

ATMOSPHERIC PROPAGATION

Within the atmosphere, radio waves can be refracted, reflected, and diffracted. In the following paragraphs, we will discuss these propagation characteristics.

REFRACTION

A radio wave transmitted into ionized layers is always refracted, or bent. This bending of radio waves is called *refraction*. Notice the radio wave shown in figure 1-3, traveling through the earth's atmosphere at a constant speed. As the wave enters the denser layer of charged ions, its upper portion moves faster than its lower portion. The abrupt speed increase of the upper part of the wave causes it to bend back toward the earth. This bending is always toward the propagation medium where the radio wave's velocity is the least.

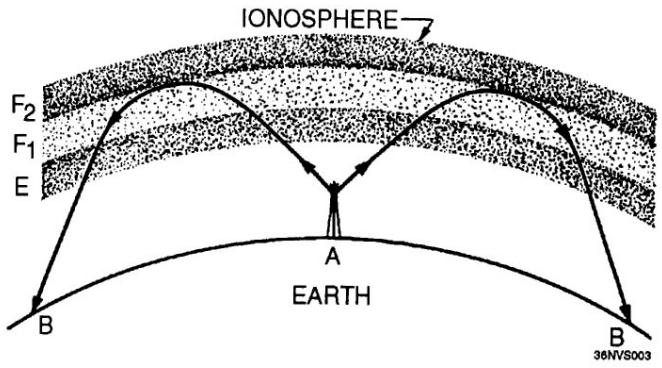

Figure 1-3.—Radio-wave refraction.

The amount of refraction a radio wave undergoes depends on three main factors.

1. The ionization density of the layer

2. The frequency of the radio wave

3. The angle at which the radio wave enters the layer

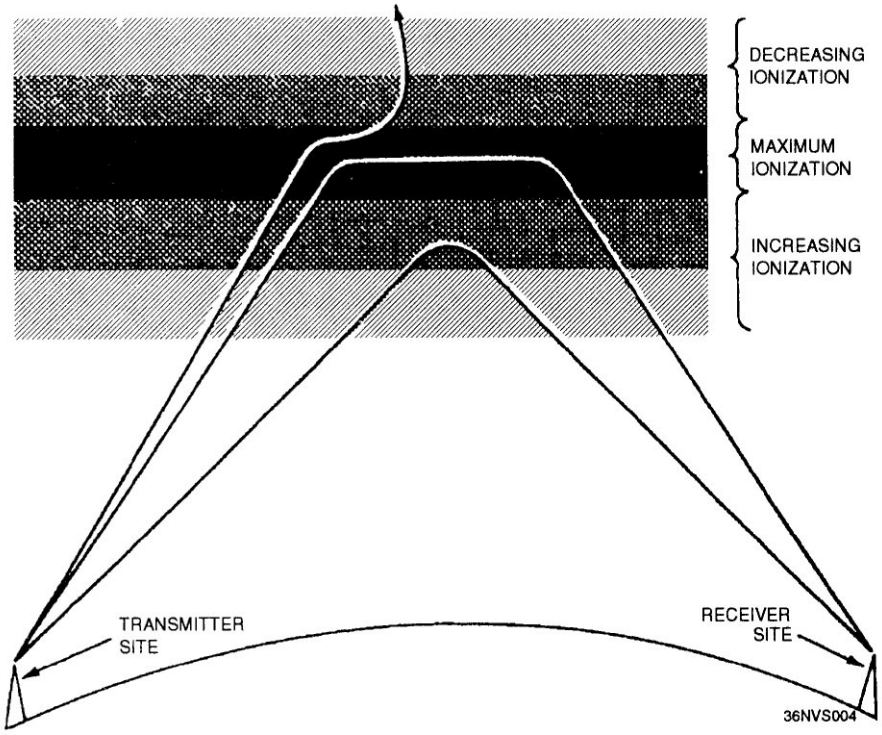

Figure 1-4.—Effects of ionospheric density on radio waves.

Layer Density

Figure 1-4 shows the relationship between radio waves and ionization density. Each ionized layer has a middle region of relatively dense ionization with less intensity above and below. As a radio wave enters a region of **increasing** ionization, a velocity increase causes it to bend back **toward** the earth. In the highly dense middle region, refraction occurs more slowly because the ionization density is uniform. As the wave enters the upper less dense region, the velocity of the upper part of the wave decreases and the wave is bent away from the earth.

Frequency

The lower the frequency of a radio wave, the more rapidly the wave is refracted by a given degree of ionization. Figure 1-5 shows three separate waves of differing frequencies entering the ionosphere at the same angle. You can see that the 5-MHz wave is refracted quite sharply, while the 20-MHz wave is refracted less sharply and returns to earth at a greater distance than the 5-MHz wave. Notice that the 100-MHz wave is lost into space. For any given ionized layer, there is a frequency, called the *escape point*, at which energy transmitted directly upward will escape into space. The maximum frequency just below the escape point is called the **critical frequency.** In this example, the 100-MHz wave's frequency is greater than the critical frequency for that ionized layer.

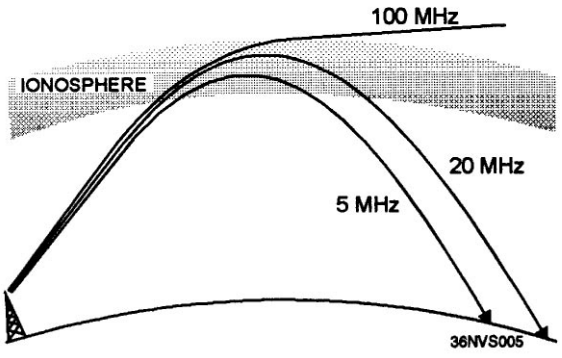

Figure 1-5.—Frequency versus refraction and distance.

The critical frequency of a layer depends upon the layer's density. If a wave passes through a

particular layer, it may still be refracted by a higher layer if its frequency is lower than the higher layer's critical frequency.

Angle of Incidence and Critical Angle

When a radio wave encounters a layer of the ionosphere, that wave is returned to earth at the same angle (roughly) as its *angle of incidence.* Figure 1-6 shows three radio waves of the same frequency entering a layer at different incidence angles. The angle at which wave A strikes the layer is too nearly vertical for the wave to be refracted to earth, However, wave B is refracted back to earth. The angle between wave B and the earth is called the **critical angle.** Any wave, at a given frequency, that leaves the antenna at an incidence angle greater than the critical angle will be lost into space. This is why wave A was not refracted. Wave C leaves the antenna at the smallest angle that will allow it to be refracted and still return to earth. The critical angle for radio waves depends on the layer density and the wavelength of the signal.

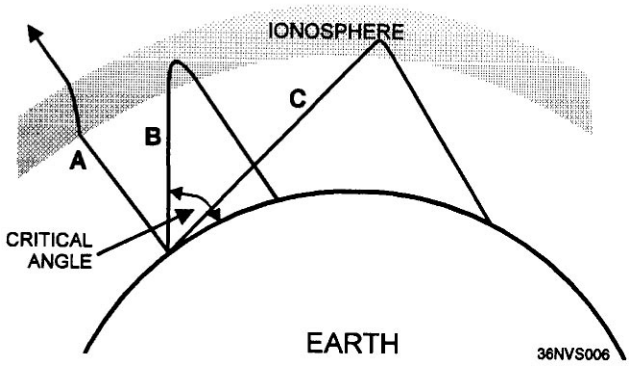

Figure 1-6.—Incidence angles of radio waves.

As the frequency of a radio wave is increased, the critical angle must be reduced for refraction to occur. Notice in figure 1-7 that the 2-MHz wave strikes the ionosphere at the critical angle for that frequency and is refracted. Although the 5-MHz line (broken line) strikes the ionosphere at a less critical angle, it still penetrates the layer and is lost As the angle is lowered, a critical angle is finally reached for the 5-MHz wave and it is refracted back to earth.

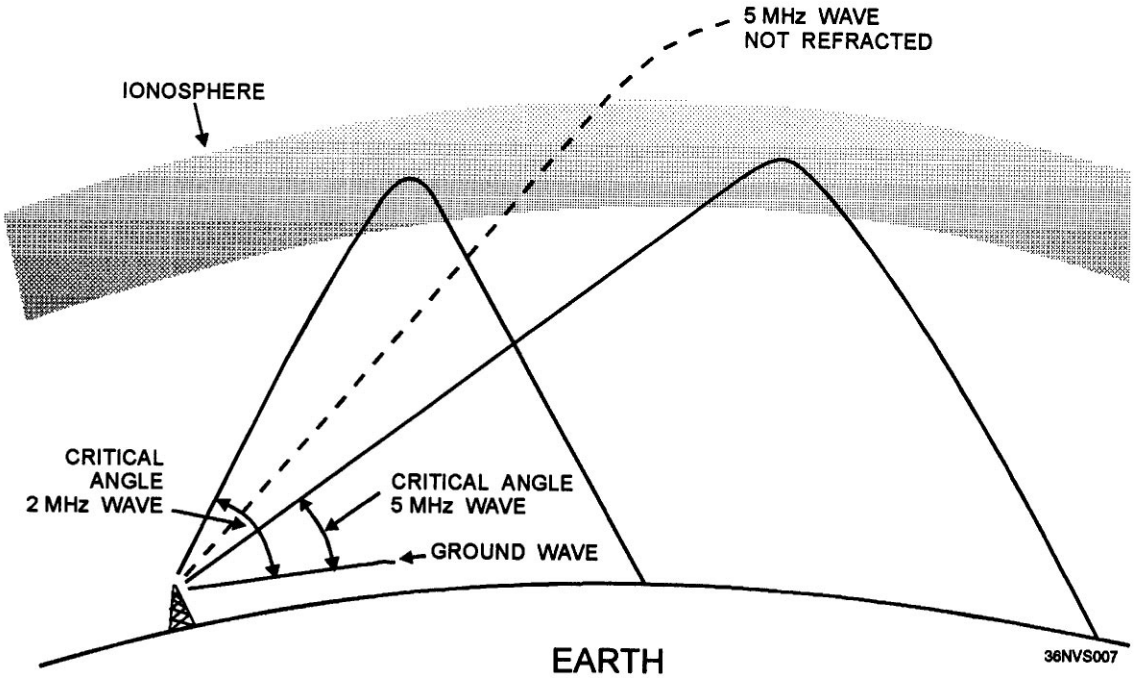

Figure 1-7.—Effect of frequency on the critical angle.

SKIP DISTANCE AND ZONE

Recall from your previous study that a transmitted radio wave separates into two parts, the sky wave and the ground wave. With those two components in mind, we will now briefly discuss *skip distance* and *skip zone.*

Skip Distance

Look at the relationship between the sky wave skip distance, skip zone, and ground wave coverage shown in figure 1-8. The *skip distance* is the distance from the transmitter to the point where the sky wave first returns to the earth. The skip distance depends on the wave's frequency and angle of incidence, and the degree of ionization.

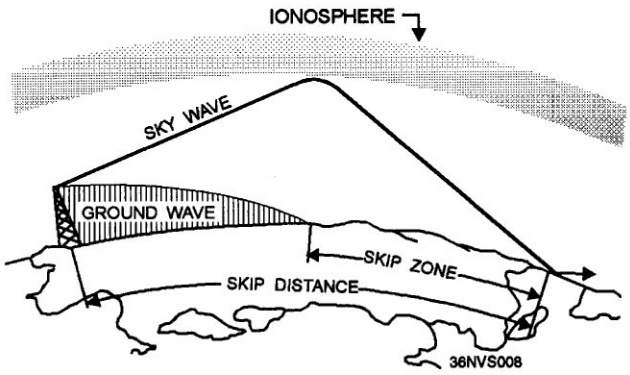

Figure 1-8.—Relationship between skip zone, skip distance, and ground wave.

Skip Zone

The *skip zone* is a zone of silence between the point where the ground wave is too weak for reception and the point where the sky wave is first returned to earth. The outer limit of the skip zone varies considerably, depending on the operating frequency, the time of day, the season of the year, sunspot activity, and the direction of transmission.

At very-low, low, and medium frequencies, a skip zone is never present. However, in the high-frequency spectrum, a skip zone is often present. As the operating frequency is increased, the skip zone widens to a point where the outer limit of the skip zone might be several thousand miles away. At frequencies above a certain maximum, the outer limit of the skip zone disappears completely, and no F-layer propagation is possible.

Occasionally, the first sky wave will return to earth within the range of the ground wave. In this case, severe fading can result from the phase difference between the two waves (the sky wave has a longer path to follow).

REFLECTION

Reflection occurs when radio waves are "bounced" from a flat surface. There are basically two types of reflection that occur in the atmosphere: earth reflection and ionospheric reflection. Figure 1-9 shows two

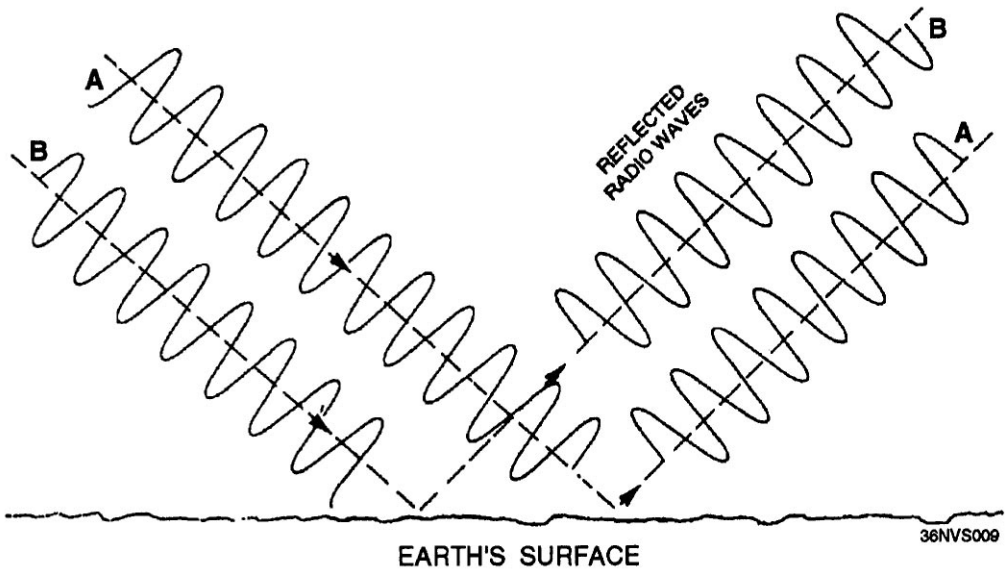

Figure 1-9.—Phase shift of reflected radio waves.

waves reflected from the earth's surface. Waves A and B bounce off the earth's surface like light off of a mirror. Notice that the positive and negative alternations of radio waves A and B are in phase before they strike the earth's surface. However, after reflection the radio waves are approximately 180 degrees out of phase. A phase shift has occurred.

The amount of phase shift that occurs is not constant. It varies, depending on the wave polarization and the angle at which the wave strikes the surface. Because reflection is not constant, fading occurs. Normally, radio waves reflected in phase produce stronger signals, while those reflected out of phase produce a weak or fading signal.

Ionospheric reflection occurs when certain radio waves strike a thin, highly ionized layer in the ionosphere. Although the radio waves are actually refracted, some may be bent back so rapidly that they appear to be reflected. For ionospheric reflection to occur, the highly ionized layer can be approximately no thicker than one wavelength of the wave. Since the ionized layers are often several miles thick, ionospheric reflection mostly occurs at long wavelengths (low frequencies).

DIFFRACTION

Diffraction is the ability of radio waves to turn sharp corners and bend around obstacles. Shown in figure 1-10, diffraction results in a change of direction of part of the radio-wave energy around the edges of an obstacle. Radio waves with long wavelengths compared to the diameter of an obstruction are easily propagated around the obstruction. However, as the wavelength decreases, the obstruction causes more and more attenuation, until at very-high frequencies a definite *shadow zone* develops. The shadow zone is basically a blank area on the opposite side of an obstruction in line-of-sight from the transmitter to the receiver.

Diffraction can extend the radio range beyond the horizon. By using high power and low-frequencies, radio waves can be made to encircle the earth by diffraction.

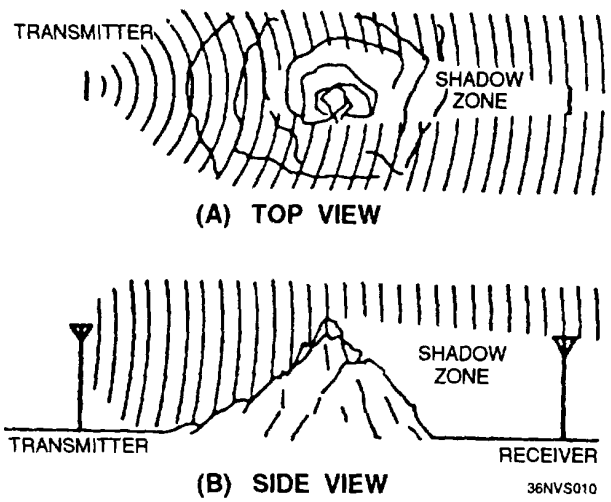

Figure 1-10.—Diffraction around an object.

ATMOSPHERIC EFFECTS ON PROPAGATION

As we stated earlier, changes in the ionosphere can produce dramatic changes in the ability to communicate. In some cases, communications distances are greatly extended. In other cases, communications distances are greatly reduced or eliminated. The paragraphs below explain the major problem of reduced communications because of the phenomena of fading and selective fading.

Fading

The most troublesome and frustrating problem in receiving radio signals is variations in signal strength, most commonly known as FADING. Several conditions can produce fading. When a radio wave is refracted by the ionosphere or reflected from the earth's surface, random changes in the polarization of the wave may occur. Vertically and horizontally mounted receiving antennas are designed to receive vertically and horizontally polarized waves, respectively. Therefore, changes in polarization cause changes in the received signal level because of the inability of the antenna to receive polarization changes.

Fading also results from absorption of the rf energy in the ionosphere. Most ionospheric absorption occurs in the lower regions of the ionosphere where ionization

density is the greatest. As a radio wave passes into the ionosphere, it loses some of its energy to the free electrons and ions present there. Since the amount of absorption of the radio-wave energy varies with the density of the ionospheric layers, there is no fixed relationship between distance and signal strength for ionospheric propagation. Absorption fading occurs for a longer period than other types of fading, since absorption takes place slowly. Under certain conditions, the absorption of energy is so great that communication over any distance beyond the line of sight becomes difficult.

Although fading because of absorption is the most serious type of fading, fading on the ionospheric circuits is mainly a result of multipath propagation.

Multipath Fading

MULTIPATH is simply a term used to describe the multiple paths a radio wave may follow between transmitter and receiver. Such propagation paths include the ground wave, ionospheric refraction, reradiation by the ionospheric layers, reflection from the earth's surface or from more than one ionospheric layer, and so on. Figure 1-11 shows a few of the paths that a signal can travel between two sites in a typical circuit. One path, XYZ, is the basic ground wave. Another path, XFZ, refracts the wave at the F layer and passes it on to the receiver at point Z. At point Z, the received signal is a combination of the ground wave and the sky wave. These two signals, having traveled different paths, arrive at point Z at different times. Thus, the arriving waves may or may not be in phase with each other. A similar situation may result at point A. Another path, XFZFA, results from a greater angle of incidence and two refractions from the F layer. A wave traveling that path and one traveling the XEA path may or may not arrive at point A in phase. Radio waves that are received in phase reinforce each other and produce a stronger signal at the receiving site, while those that are received out of phase produce a weak or fading signal. Small alterations in the transmission path may change the phase relationship of the two signals, causing periodic fading.

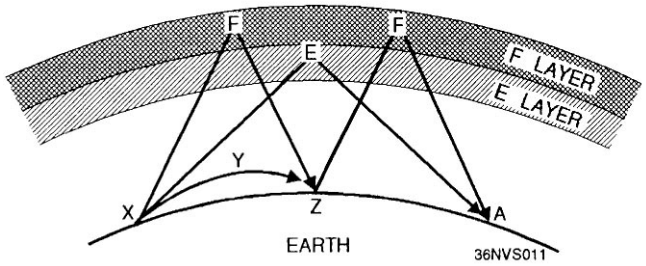

Figure 1-11.—Multipath transmission.

Multipath fading may be minimized by practices called SPACE DIVERSITY and FREQUENCY DIVERSITY In space diversity, two or more receiving antennas are spaced some distance apart. Fading does not occur simultaneously at both antennas. Therefore, enough output is almost always available from one of the antennas to provide a useful signal.

In frequency diversity, two transmitters and two receivers are used, each pair tuned to a different frequency, with the same information being transmitted simultaneously over both frequencies. One of the two receivers will almost always produce a useful signal.

Selective Fading

Fading resulting from multipath propagation varies with frequency since each frequency arrives at the
receiving point via a different radio path. When a wide band of frequencies is transmitted simultaneously,
each frequency will vary in the amount of fading. This variation is called SELECTIVE FADING. When selective fading occurs, all frequencies of the transmitted signal do not retain their original phases and relative amplitudes. This fading causes severe distortion of the signal and limits the total signal transmitted.

Frequency shifts and distance changes because of daily variations of the different ionospheric layers are summarized in table 1-1.

Table 1-1.–Daily Ionospheric Communications

D LAYER: reflects vlf waves for long-range communications; refracts lf and mf for short-range communications; has little effect on vhf and above; gone at night.
E LAYER: depends on the angle of the sun: refracts hf waves during the day up to 20 MHz to distances of 1200 miles: greatly reduced at night.
F LAYER: structure and density depend on the time of day and the angle of the sun: consists of one layer at night and splits into two layers during daylight hours.
F1 LAYER: density depends on the angle of the sun; its main effect is to absorb hf waves passing through to the F2 layer.
F2 LAYER: provides long-range hf communications; very variable; height and density change with time of day, season, and sunspot activity.

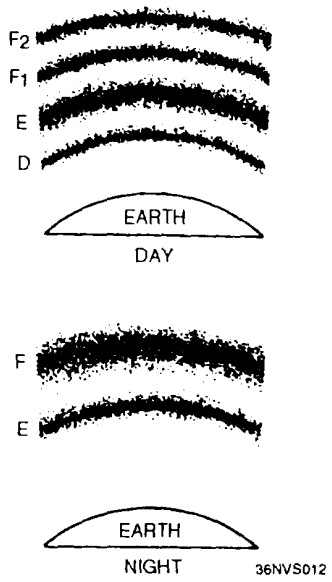

Figure 1-12.—Ionospheric layers.

OTHER PHENOMENA THAT AFFECT COMMUNICATIONS

Although daily changes in the ionosphere have the greatest effect on communications, other phenomena also affect communications, both positively and negatively. Those phenomena are discussed briefly in the following paragraphs.

SEASONAL VARIATIONS IN THE IONOSPHERE

Seasonal variations are the result of the earth's revolving around the sun, because the relative position of the sun moves from one hemisphere to the other with the changes in seasons. Seasonal variations of the D, E, and F1 layers are directly related to the highest angle of the sun, meaning the ionization density of these layers is greatest during the summer. The F2 layer is just the opposite. Its ionization is greatest during the winter, Therefore, operating frequencies for F2 layer propagation are higher in the winter than in the summer.

SUNSPOTS

One of the most notable occurrences on the surface of the sun is the appearance and disappearance of dark, irregularly shaped areas known as SUNSPOTS. Sunspots are believed to be caused by violent eruptions on the sun and are characterized by strong magnetic fields. These sunspots cause variations in the ionization level of the ionosphere.

Sunspots tend to appear in two cycles, every 27 days and every 11 years.

Twenty-Seven Day Cycle

The number of sunspots present at any one time is constantly changing as some disappear and new ones emerge. As the sun rotates on its own axis, these sunspots are visible at 27-day intervals, which is the approximate period for the sun to make one complete revolution. During this time period, the fluctuations in ionization are greatest in the F2 layer. For this reason, calculating critical frequencies for long-distance communications for the F2 layer is not possible and allowances for fluctuations must be made.

Eleven-Year Cycle

Sunspots can occur unexpectedly, and the life span of individual sunspots is variable. The ELEVEN-YEAR SUN SPOT CYCLE is a regular cycle of sunspot activity that has a minimum and maximum level of activity that occurs every 11 years. During periods of maximum activity, the ionization density of all the layers increases. Because of this, the absorption in the D layer increases and the critical frequencies for the E, F1, and F2 layers are higher. During these times, higher operating frequencies must be used for long-range communications.

IRREGULAR VARIATIONS

Irregular variations are just that, unpredictable changes in the ionosphere that can drastically affect our ability to communicate. The more common variations are sporadic E, ionospheric disturbances, and ionospheric storms.

Sporadic E

Irregular cloud-like patches of unusually high ionization, called the sporadic E, often format heights near the normal E layer. Their exact cause is not known and their occurrence cannot be predicted. However, sporadic E is known to vary significantly with latitude. In the northern latitudes, it appears to be closely related to the aurora borealis or northern lights.

The sporadic E layer can be so thin that radio waves penetrate it easily and are returned to earth by the upper layers, or it can be heavily ionized and extend up to several hundred miles into the ionosphere. This condition may be either harmful or helpful to radio-wave propagation.

On the harmful side, sporadic E may blank out the use of higher more favorable layers or cause additional absorption of radio waves at some frequencies. It can also cause additional multipath problems and delay the arrival times of the rays of RF energy.

On the helpful side, the critical frequency of the sporadic E can be greater than double the critical frequency of the normal ionospheric layers. This may permit long-distance communications with unusually high frequencies. It may also permit short-distance communications to locations that would normally be in the skip zone.

Sporadic E can appear and disappear in a short time during the day or night and usually does not occur at same time for all transmitting or receiving stations.

Sudden Ionospheric Disturbances

Commonly known as SID, these disturbances may occur without warning and may last for a few minutes to several hours. When SID occurs, long-range hf communications are almost totally blanked out. The radio operator listening during this time will believe his or her receiver has gone dead.

The occurrence of SID is caused by a bright solar eruption producing an unusually intense burst of ultraviolet light that is not absorbed by the F1, F2, or E layers. Instead, it causes the D-layer ionization density to greatly increase. As a result, frequencies above 1 or 2 megahertz are unable to penetrate the D layer and are completely absorbed.

Ionospheric Storms

Ionospheric storms are caused by disturbances in the earth's magnetic field. They are associated with both solar eruptions and the 27-day cycle, meaning they are related to the rotation of the sun. The effects of ionospheric storms are a turbulent ionosphere and very erratic sky-wave propagation. The storms affect mostly the F2 layer, reducing its ion density and causing the critical frequencies to be lower than

normal. What this means for communication purposes is that the range of frequencies on a given circuit is smaller than normal and that communications are possible only at lower working frequencies.

Weather

Wind, air temperature, and water content of the atmosphere can combine either to extend radio communications or to greatly attenuate wave propagation. making normal communications extremely difficult. Precipitation in the atmosphere has its greatest effect on the higher frequency ranges. Frequencies in the hf range and below show little effect from this condition.

RAIN.— Attenuation because of raindrops is greater than attenuation for any other form of precipitation. Raindrop attenuation may be caused either by absorption, where the raindrop acts as a poor dielectric, absorbs power from the radio wave and dissipates the power by heat loss; or by scattering (fig. 1-13). Raindrops cause greater attenuation by scattering than by absorption at frequencies above 100 megahertz. At frequencies above 6 gigahertz, attenuation by raindrop scatter is even greater.

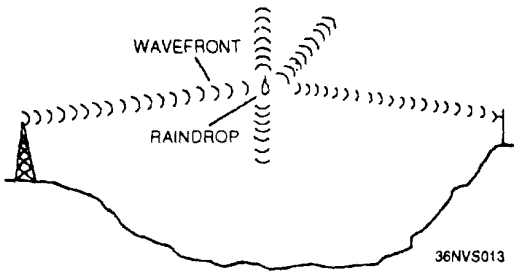

Figure 1-13.–Rf energy losses from scattering.

FOG.— Since fog remains suspended in the atmosphere, the attenuation is determined by the quantity of water per unit volume (density of the fog) and by the size of the droplets. Attenuation because of fog has little effect on frequencies lower than 2 gigahertz, but can cause serious attenuation by absorption at frequencies above 2 gigahertz.

SNOW.— Since snow has about 1/8 the density of rain, and because of the irregular shape of the snowflake, the scattering and absorption losses are difficult to compute, but will be less than those caused by raindrops.

HAIL.— Attenuation by hail is determined by the size of the stones and their density. Attenuation of radio waves by scattering because of hailstones is considerably less than by rain.

TEMPERATURE INVERSION

When layers of warm air form above layers of cold air, the condition known as temperature inversion develops. This phenomenon causes ducts or channels to be formed, by sandwiching cool air either between the surface of the earth and a layer of warm air, or between two layers of warm air. If a transmitting antenna extends into such a duct, or if the radio wave enters the duct at a very low angle of incidence, vhf and uhf transmissions may be propagated far beyond normal line-of-sight distances. These long distances are possible because of the different densities and refractive qualities of warm and cool air. The sudden change in densities when a radio wave enters the warm air above the duct causes the wave to be refracted back toward earth. When the wave strikes the earth or a warm layer below the duct, it is again reflected or refracted upward and proceeds on through the duct with a multiple-hop type of action. An example of radio-wave propagation by ducting is shown in figure 1-14.

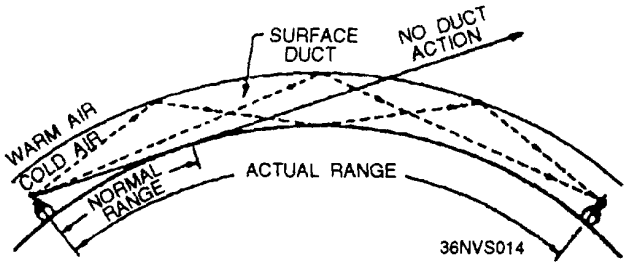

Figure 1-14.—Duct effect caused by temperature inversion.

TRANSMISSION LOSSES

All radio waves propagated over the ionosphere undergo energy losses before arriving at the receiving site. As we discussed earlier, absorption and lower

atmospheric levels in the ionosphere account for a large part of these energy losses. There are two other types of losses that also significantly affect propagation. These losses are known as *ground reflection losses* and *freespace loss.* The combined effect of absorption ground reflection loss, and freespace loss account for most of the losses of radio transmissions propagated in the ionosphere.

GROUND REFLECTION LOSS

When propagation is accomplished via multihop refraction, rf energy is lost each time the radio wave is reflected from the earth's surface. The amount of energy lost depends on the frequency of the wave, the angle of incidence, ground irregularities, and the electrical conductivity of the point of reflection.

FREESPACE LOSS

Normally, the major loss of energy is because of the spreading out of the wavefront as it travels from the transmitter. As distance increases, the area of the wavefront spreads out, much like the beam of a flashlight. This means the amount of energy contained within any unit of area on the wavefront decreases as distance increases. By the time the energy arrives at the receiving antenna, the wavefront is so spread out that the receiving antenna extends into only a small portion of the wavefront. This is illustrated in figure 1-15.

FREQUENCY SELECTION

You must have a thorough knowledge of radio-wave propagation to exercise good judgment when selecting transmitting and receiving antennas and operating frequencies. Selecting a usable operating frequency within your given allocations and availability is of prime importance to maintaining reliable communications.

For successful communication between any two specified locations at any given time of the day, there is a maximum frequency, a lowest frequency and an optimum frequency that can be used.

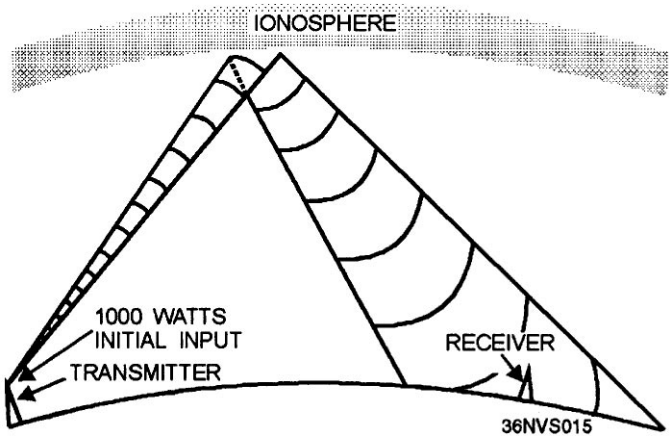

Figure 1-15.—Freespace loss principle.

MAXIMUM USABLE FREQUENCY

The higher the frequency of a radio wave, the lower the rate of refraction by the ionosphere. Therefore, for a given angle of incidence and time of day, there is a maximum frequency that can be used for communications between two given locations. This frequency is known as the **MAXIMUM USABLE FREQUENCY** (muf).

Waves at frequencies above the muf are normally refracted so slowly that they return to earth beyond the desired location or pass on through the ionosphere and are lost. Variations in the ionosphere that can raise or lower a predetermined muf may occur at anytime. his is especially true for the highly variable F2 layer.

LOWEST USABLE FREQUENCY

Just as there is a muf that can be used for communications between two points, there is also a minimum operating frequency that can be used known as the LOWEST USABLE FREQUENCY (luf). As the frequency of a radio wave is lowered, the rate of refraction increases. So a wave whose frequency is below the established luf is refracted back to earth at a shorter distance than desired, as shown in figure 1-16.

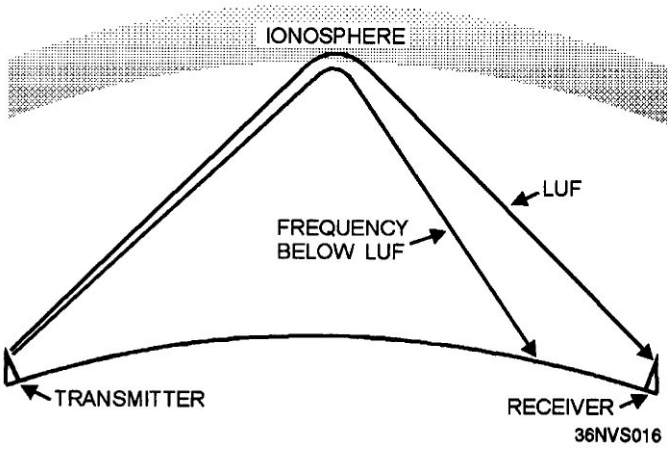

Figure 1-16.—Refraction of frequencies below the lowest usable frequency (luf).

As a frequency is lowered, absorption of the radio wave increases. A wave whose frequency is too low is absorbed to such an extent that it is too weak for reception. Atmospheric noise is also greater at lower frequencies. A combination of higher absorption and atmospheric noise could result in an unacceptable signal-to-noise ratio.

For a given angle ionospheric conditions, of incidence and set of the luf depends on the refraction properties of the ionosphere, absorption considerations, and the amount of noise present.

OPTIMUM WORKING FREQUENCY

The most practical operating frequency is one that you can rely onto have the least number of problems. It should be high enough to avoid the problems of multipath fading, absorption, and noise encountered at the lower frequencies; but not so high as to be affected by the adverse effects of rapid changes in the ionosphere.

A frequency that meets the above criteria is known as the OPTIMUM WORKING FREQUENCY It is abbreviated “fot” from the initial letters of the French words for optimum working frequency, “frequence optimum de travail.” The fot is roughly about 85% of the muf, but the actual percentage varies and may be considerably more or less than 85 percent.

In this chapter, we discussed the basics of radio-wave propagation and how atmospheric conditions determine the operating parameters needed to ensure successful communications. In chapter 2, we will discuss basic antenna operation and design to complete your understanding of radio-wave propagation.

CHAPTER 2

ANTENNAS

As an Electronics Technician, you are responsible for maintaining systems that both radiate and receive electromagnetic energy. Each of these systems requires some type of antenna to make use of this electromagnetic energy. In this chapter we will discuss antenna characteristics, different antenna types, antenna tuning, and antenna safety.

ANTENNA CHARACTERISTICS

An antenna may be defined as a conductor or group of conductors used either for radiating electromagnetic energy into space or for collecting it from space. Electrical energy from the transmitter is converted into electromagnetic energy by the antenna and radiated into space. On the receiving end, electromagnetic energy is converted into electrical energy by the antenna and fed into the receiver.

The electromagnetic radiation from an antenna is made up of two components, the E field and the H field. The total energy in the radiated wave remains constant in space except for some absorption of energy by the earth. However, as the wave advances, the energy spreads out over a greater area. This causes the amount of energy in a given area to decrease as distance from the source increases.

The design of the antenna system is very important in a transmitting station. The antenna must be able to radiate efficiently so the power supplied by the transmitter is not wasted. An efficient transmitting antenna must have exact dimensions, determined by the frequency being transmitted. The dimensions of the receiving antenna are not critical for relatively low frequencies, but their importance increases drastically as the transmitted frequency increases.

Most practical transmitting antennas are divided into two basic classifications, HERTZ ANTENNAS (half-wave) and MARCONI (quarter-wave) ANTENNAS. Hertz antennas are generally installed some distance above the ground and are positioned to radiate either vertically or horizontally. Marconi antennas operate with one end grounded and are mounted perpendicular to the earth or a surface acting as a ground. The Hertz antenna, also referred to as a dipole, is the basis for some of the more complex antenna systems used today. Hertz antennas are generally used for operating frequencies of 2 MHz and above, while Marconi antennas are used for operating frequencies below 2 MHz.

All antennas, regardless of their shape or size, have four basic characteristics: reciprocity, directivity, gain, and polarization.

RECIPROCITY

RECIPROCITY is the ability to use the same antenna for both transmitting and receiving. The electrical characteristics of an antenna apply equally, regardless of whether you use the antenna for transmitting or receiving. The more efficient an antenna is for transmitting a certain frequency, the more efficient it will be as a receiving antenna for the same frequency. This is illustrated by figure 2-1, view A. When the antenna is used for transmitting, maximum radiation occurs at right angles to its axis. When the same antenna is used for receiving (view B), its best reception is along the same path; that is, at right angles to the axis of the antenna.

DIRECTIVITY

The DIRECTIVITY of an antenna or array is a measure of the antenna's ability to focus the energy in one or more specific directions. You can determine an antenna's directivity by looking at its radiation pattern. In an array propagating a given amount of energy, more radiation takes place in certain directions than in others. The elements in the array can be arranged so they change the pattern and distribute the energy more evenly in all directions. The opposite is also possible. The elements can be arranged so the radiated energy is *focused* in one direction. The

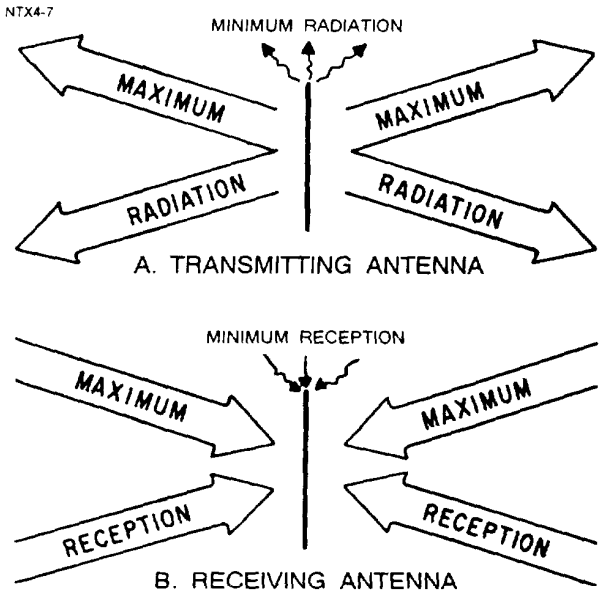

Figure 2-1.—Reciprocity of antennas.

elements can be considered as a group of antennas fed from a common source.

GAIN

As we mentioned earlier, some antennas are highly directional. That is, they propagate more energy in certain directions than in others. The ratio between the amount of energy propagated in these directions and the energy that would be propagated if the antenna were not directional is known as antenna GAIN. The gain of an antenna is constant. whether the antenna is used for transmitting or receiving.

POLARIZATION

Energy from an antenna is radiated in the form of an expanding sphere. A small section of this sphere is called a wavefront. positioned perpendicular to the direction of the radiation field (fig. 2-2). Within this wavefront. all energy is in phase. Usually, all points on the wavefront are an equal distance from the antenna. The farther from the antenna the wave is, the less curved it appears. At a considerable distance, the wavefront can be considered as a plane surface at right angles to the direction of propagation.

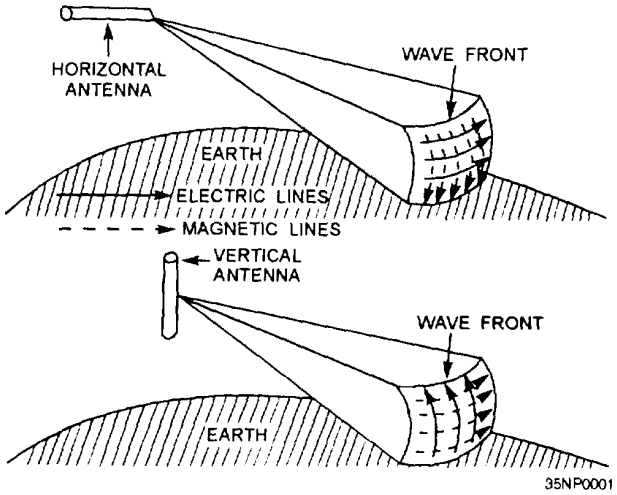

Figure 2-2.—Horizontal and vertical polarization.

The radiation field is made up of magnetic and electric lines of force that are always at right angles to each other. Most electromagnetic fields in space are said to be linearly polarized. The direction of polarization is the direction of the electric vector. That is, if the electric lines of force (E lines) are horizontal, the wave is said to be horizontally polarized (fig. 2-2), and if the E lines are vertical, the wave is said to be vertically polarized. Since the electric field is parallel to the axis of the dipole, the antenna is in the plane of polarization.

A horizontally placed antenna produces a horizontally polarized wave, and a vertically placed antenna produces a vertically polarized wave.

In general, the polarization of a wave does not change over short distances. Therefore, transmitting and receiving antennas are oriented alike, especially if they are separated by short distances.

Over long distances, polarization changes. The change is usually small at low frequencies, but quite drastic at high frequencies. (For radar transmissions, a received signal is actually a wave reflected from an object. Since signal polarization varies with the type of object, no set position of the receiving antenna is correct for all returning signals). Where separate antennas are used for transmitting and receiving, the receiving antenna is generally polarized in the same direction as the transmitting antenna.

When the transmitting antenna is close to the ground, it should be polarized vertically, because vertically polarized waves produce a greater signal strength along the earth's surface. On the other hand, when the transmitting antenna is high above the ground, it should be horizontally polarized to get the greatest signal strength possible to the earth's surface.

RADIATION OF ELECTROMAGNETIC ENERGY

Various factors in the antenna circuit affect the radiation of electromagnetic energy. In figure 2-3, for example, if an alternating current is applied to the A end of wire antenna AB, the wave will travel along the wire until it reaches the B end. Since the B end is free, an open circuit exists and the wave cannot travel further. This is a point of high impedance. The wave bounces back (reflects) from this point of high impedance and travels toward the starting point, where it is again reflected. Theoretically, the energy of the wave should be gradually dissipated by the resistance of the wire during this back-and-forth motion (oscillation). However, each time the wave reaches the starting point, it is reinforced by an impulse of energy sufficient to replace the energy lost during its travel along the wire. This results in continuous oscillations of energy along the wire and a high voltage at the A end of the wire. These oscillations move along the antenna at a rate equal to the frequency of the rf voltage and are sustained by properly timed impulses at point A.

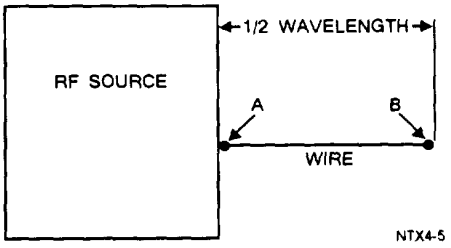

Figure 2-3.—Antenna and rf source.

The rate at which the wave travels along the wire is constant at approximately 300,000,000 meters per second. The length of the antenna must be such that a wave will travel from one end to the other and back again during the period of 1 cycle of the rf voltage. The distance the wave travels during the period of 1 cycle is known as the wavelength. It is found by dividing the rate of travel by the frequency.

Look at the current and voltage distribution on the antenna in figure 2-4. A maximum movement of electrons is in the center of the antenna at all times; therefore, the center of the antenna is at a low impedance.

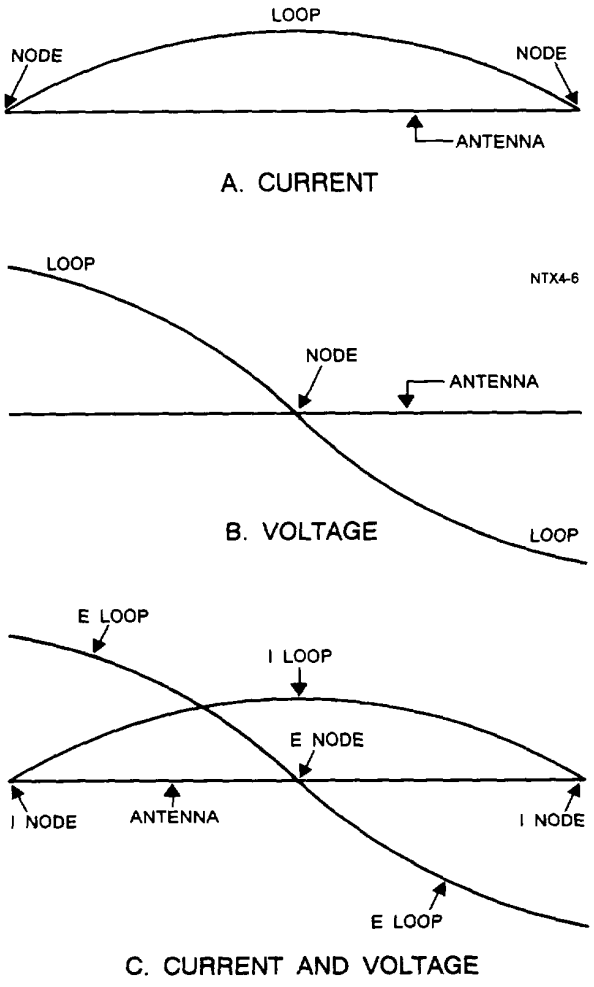

Figure 2-4.—Standing waves of current and voltage on an antenna.

This condition is called a STANDING WAVE of current. The points of high current and high voltage are known as current and voltage LOOPS. The points of minimum current and minimum voltage are known as current and voltage NODES. View A shows a current loop and two current nodes. View B shows two voltage loops and a voltage node. View C shows

the resultant voltage and current loops and nodes. The presence of standing waves describes the condition of resonance in an antenna. At resonance, the waves travel back and forth in the antenna, reinforcing each other, and are transmitted into space at maximum radiation. When the antenna is not at resonance, the waves tend to cancel each other and energy is lost in the form of heat.

RADIATION TYPES AND PATTERNS

A logical assumption is that energy leaving an antenna radiates equally over 360 degrees. This is not the case for every antenna.

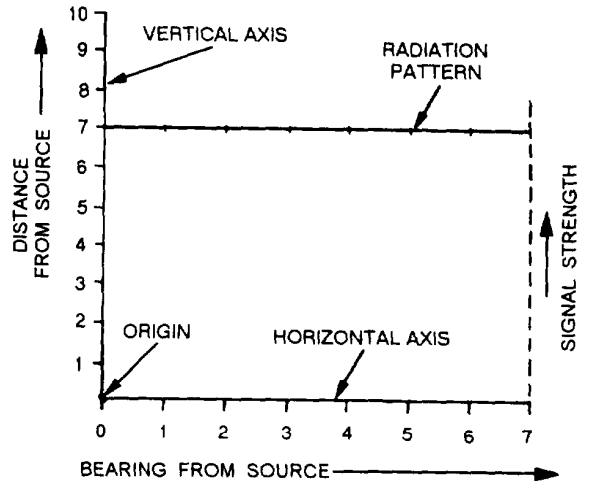
The energy radiated from an antenna forms a field having a definite RADIATION PATTERN. The radiation pattern for any given antenna is determined by measuring the radiated energy at various angles at constant distances from the antenna and then plotting the energy values on a graph. The shape of this pattern depends on the type of antenna being used.

Some antennas radiate energy equally in all directions. Radiation of this type is known as ISOTROPIC RADIATION. The sun is a good example of an isotropic radiator. If you were to measure the amount of radiated energy around the sun's circumference, the readings would all be fairly equal (fig. 2-5).

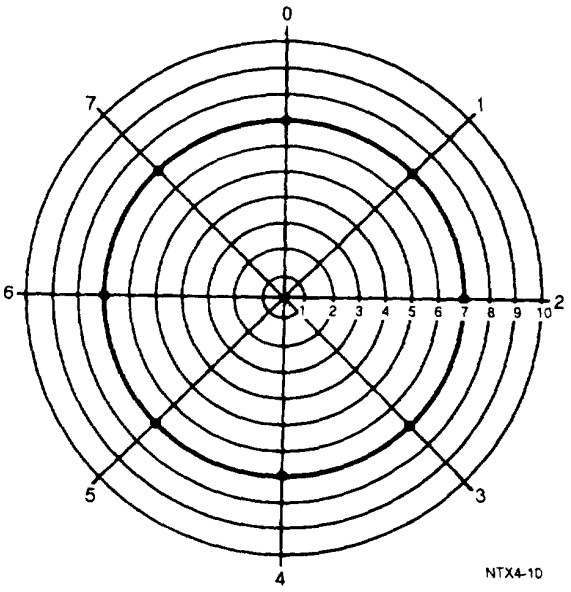
Most radiators emit (radiate) energy more strongly in one direction than in another. These radiators are referred to as ANISOTROPIC radiators. A flashlight is a good example of an anisotropic radiator (fig. 2-6). The beam of the flashlight lights only a portion of the space surrounding it. The area behind the flashlight remains unlit, while the area in front and to either side is illuminated.

MAJOR AND MINOR LOBES

The pattern shown in figure 2-7, view B, has radiation concentrated in two lobes. The radiation intensity in one lobe is considerably stronger than in the other. The lobe toward point X is called a MAJOR LOBE; the other is a MINOR LOBE. Since the complex radiation patterns associated with antennas frequently contain several lobes of varying intensity,



A. RECTANGULAR-COORDINATE GRAPH



B. POLAR-COORDINATE GRAPH

Figure 2-5.—Isotropic radiation graphs.

you should learn to use the appropriate terminology, In general, major lobes are those in which the greatest amount of radiation occurs. Minor lobes are those in which the least amount of radiation occurs.

ANTENNA LOADING

There will be times when you may want to use one antenna system to transmit on several different frequencies. Since the antenna must always be in resonance with the applied frequency, you must either lengthen it or shorten it to produce the required

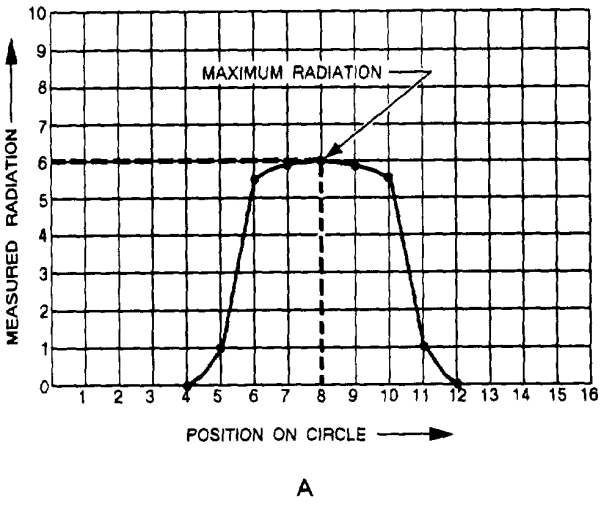


Figure 2-6.—Anisotropic radiator.

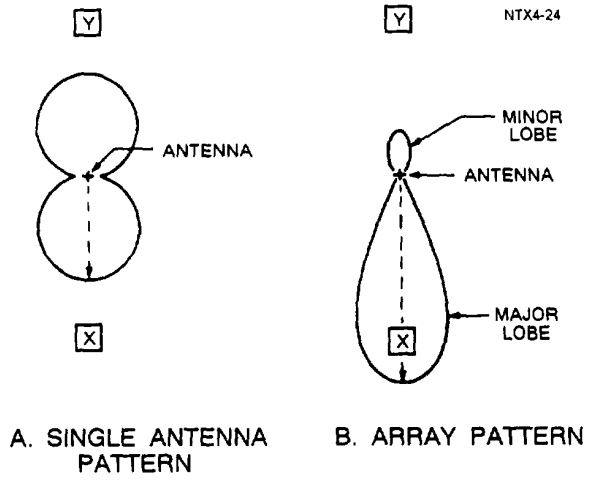

Figure 2-7.—Major and minor lobes.

resonance. Changing the antenna dimensions physically is impractical, but changing them electrically is relatively simple. To change the electrical length of an antenna, you can insert either an inductor or a capacitor in series with the antenna. This is shown in figure 2-8, views A and B. Changing the electrical length by this method is known as LUMPED-IMPEDANCE TUNING or LOADING. If the antenna is too short for the wavelength being used, it will be resonant at a higher frequency. Therefore, it offers a capacitive reactance at the excitation frequency. This capacitive reactance can be compensated for by introducing a lumped inductive reactance, as shown in view A. Similarly, if the antenna is too long for the transmitting frequency, it will be resonant at a lower frequency and offers an inductive reactance. Inductive reactance can be compensated for by introducing a lumped capacitive reactance, as shown in view B. An antenna with normal loading is represented in view C.

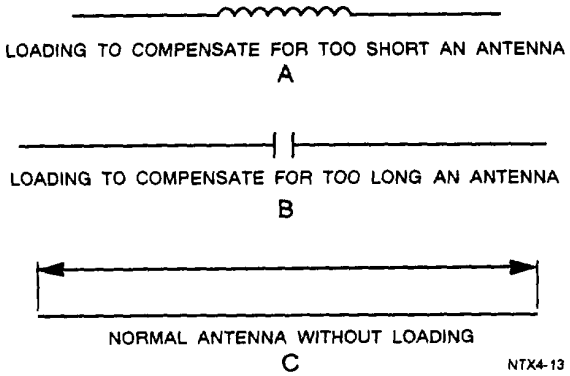

Figure 2-8.—Electrical antenna loading.

GROUND EFFECTS

As we discussed earlier, ground losses affect radiation patterns and cause high signal losses for some frequencies. Such losses can be greatly reduced if a good conducting ground is provided in the vicinity of the antenna. This is the purpose of the GROUND SCREEN (fig. 2-9, view A) and COUNTERPOISE (fig. 2-9, view B).

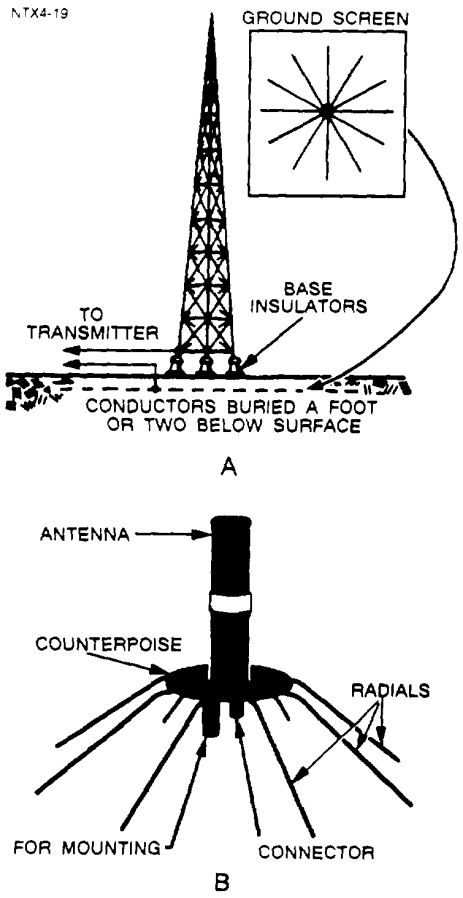

Figure 2-9.—Ground screen and counterpoise.

The ground screen in view A is composed of a series of conductors arranged in a radial pattern and buried 1 or 2 feet below the surface of the earth. These conductors, each usually 1/2 wavelength long, reduce ground absorption losses in the vicinity of the antenna.

A counterpoise (view B) is used when easy access to the base of the antenna is necessary. It is also used when the area below the antenna is not a good conducting surface, such as solid rock or ground that is sandy. The counterpoise serves the same purpose as the ground screen but is usually elevated above the earth. No specific dimensions are necessary for a counterpoise, nor is the number of wires particularly critical. The primary requirement is that the counterpoise be insulated from ground and form a grid of reflector elements for the antenna system.

COMMUNICATIONS ANTENNAS

Some antennas can be used in both shore-based and ship-based applications. Others, however, are designed to be used primarily in one application or the other. The following paragraphs discuss, by frequency range, antennas used for shore-based communications.

VERY LOW FREQUENCY (VLF)

The main difficulty in vlf and lf antenna design is the physical disparity between the maximum practical size of the antenna and the wavelength of the frequency it must propagate. These antennas must be large to compensate for wavelength and power handling requirements (0.25 to 2 MW), Transmitting antennas for vlf have multiple towers 600 to 1500 feet high, an extensive flat top for capacitive loading, and a copper ground system for reducing ground losses. Capacitive top-loading increases the bandwidth characteristics, while the ground plane improves radiation efficiency.

Representative antenna configurations are shown in figures 2-10 through 2-12. Variations of these basic antennas are used at the majority of the Navy vlf sites.

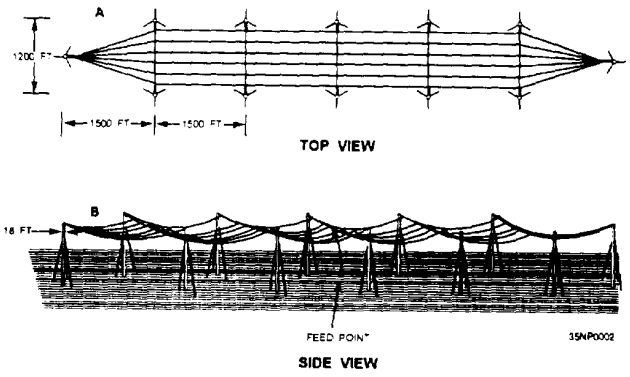

Figure 2-10.—Triatic-type antenna.

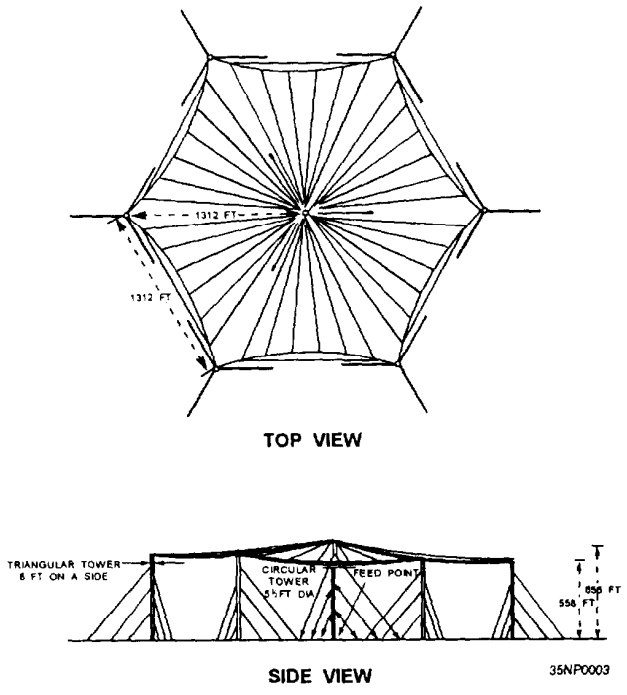

Figure 2-11.—Goliath-type antenna.

LOW FREQUENCY (LF)

Antennas for lf are not quite as large as antennas for vlf, but they still occupy a large surface area. Two examples of If antenna design are shown in figures 2-13 and 2-14. The Pan polar antenna (fig. 2-1 3) is an umbrella top-loaded monopole. It has three loading loops spaced 120 degrees apart, interconnected between the tower guy cables. Two of the loops terminate at ground, while the other is used as a feed. The NORD antenna (fig. 2-14), based on the the folded-unipole principle, is a vertical tower radiator grounded at the base and fed by one or more wires connected to the top of the tower. The three top loading wires extend from the top of the antenna at 120-degree intervals to three terminating towers. Each loading wire has a length approximately equal to the height of the main tower plus 100 feet. The top loading wires are insulated from ground and their tower supports are one-third the height of the transmitting antenna.

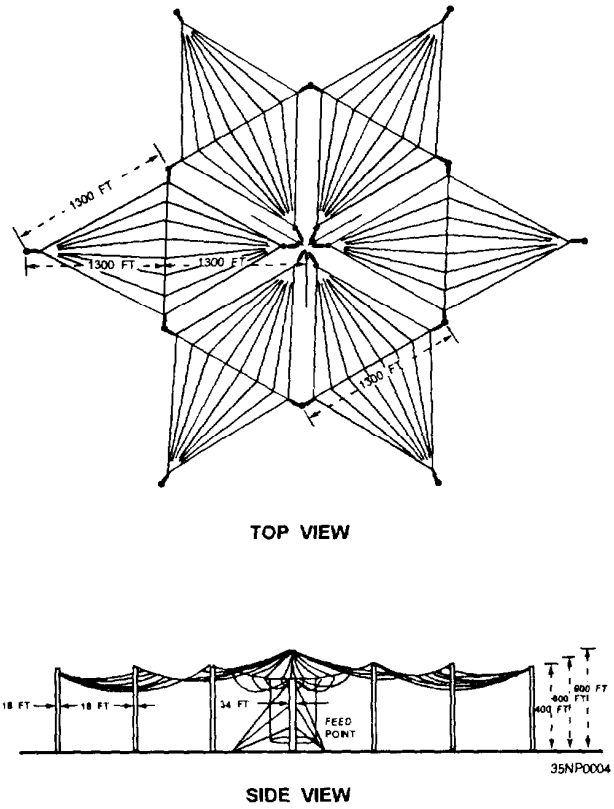

Figure 2-12.—Trideco-type antenna.

HIGH FREQUENCY (HF)

High-frequency (hf) radio antenna systems are used to support many different types of circuits, including ship-to-shore, point-to-point, and ground-to-air broadcast. These diverse applications require the use of various numbers and types of antennas that we will review on the following pages.

Yagi

The Yagi antenna is an end-fired parasitic array. It is constructed of parallel and coplaner dipole elements arranged along a line perpendicular to the axis of the dipoles, as illustrated in figure 2-15. The most limiting characteristic of the Yagi antenna is its extremely narrow bandwidth. Three percent of the center frequency is considered to be an acceptable bandwidth ratio for a Yagi antenna. The width of the array is determined by the lengths of the elements. The length of each element is approximately one-half

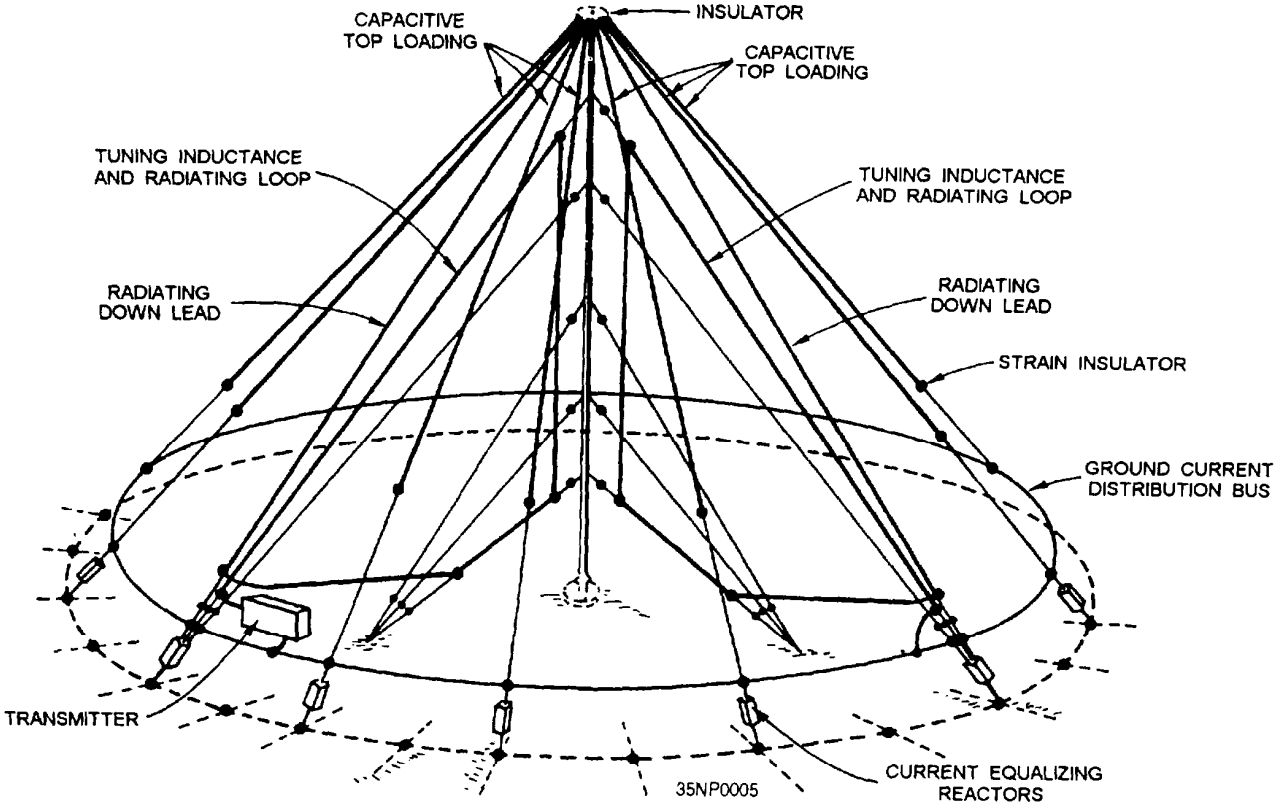

Figure 2-13.—Pan polar antenna.

wavelength, depending on its intended use (driver, reflector, or director). The required length of the array depends on the desired gain and directivity. Typically, the length will vary from 0.3 wavelength for three-element arrays, to 3 wavelengths for arrays with numerous elements. For hf applications, the maximum practical array length is 2 wavelengths. The array's height above ground will determine its vertical radiation angle. Normally, array heights vary from 0.25 to 2.5 wavelengths. The dipole elements are usually constructed from tubing, which provides for better gain and bandwidth characteristics and provides sufficient mechanical rigidity for self-support. Yagi arrays of four elements or less are not structurally complicated. Longer arrays and arrays for lower frequencies, where the width of the array exceeds 40 feet, require elaborate booms and supporting structures. Yagi arrays may be either fixed-position or rotatable.

LOG-PERIODIC ANTENNAS (LPAs)

An antenna arranged so the electrical length and spacing between successive elements causes the input impedance and pattern characteristics to be repeated periodically with the logarithm of the driving frequency is called a LOG-PERIODIC ANTENNA (LPA). The LPA, in general, is a medium-power, high-gain, moderately-directive antenna of extremely broad bandwidth. Bandwidths of up to 15:1 are possible, with up to 15 dB power gain. LPAs are rather complex antenna systems and are relatively expensive. The installation of LPAs is normally more difficult than for other hf antennas because of the tower heights involved and the complexity of suspending the radiating elements and feedlines from the towers.

Vertical Monopole LPA

The log-periodic vertical monopole antenna (fig. 2-16) has the plane containing the radiating elements in a vertical field. The longest element is approximately one-quarter wavelength at the lower cutoff frequency. The ground system for the monopole arrangement provides the image equivalent of the other quarter wavelength for the half-dipole radiating elements. A typical vertical monopole designed to

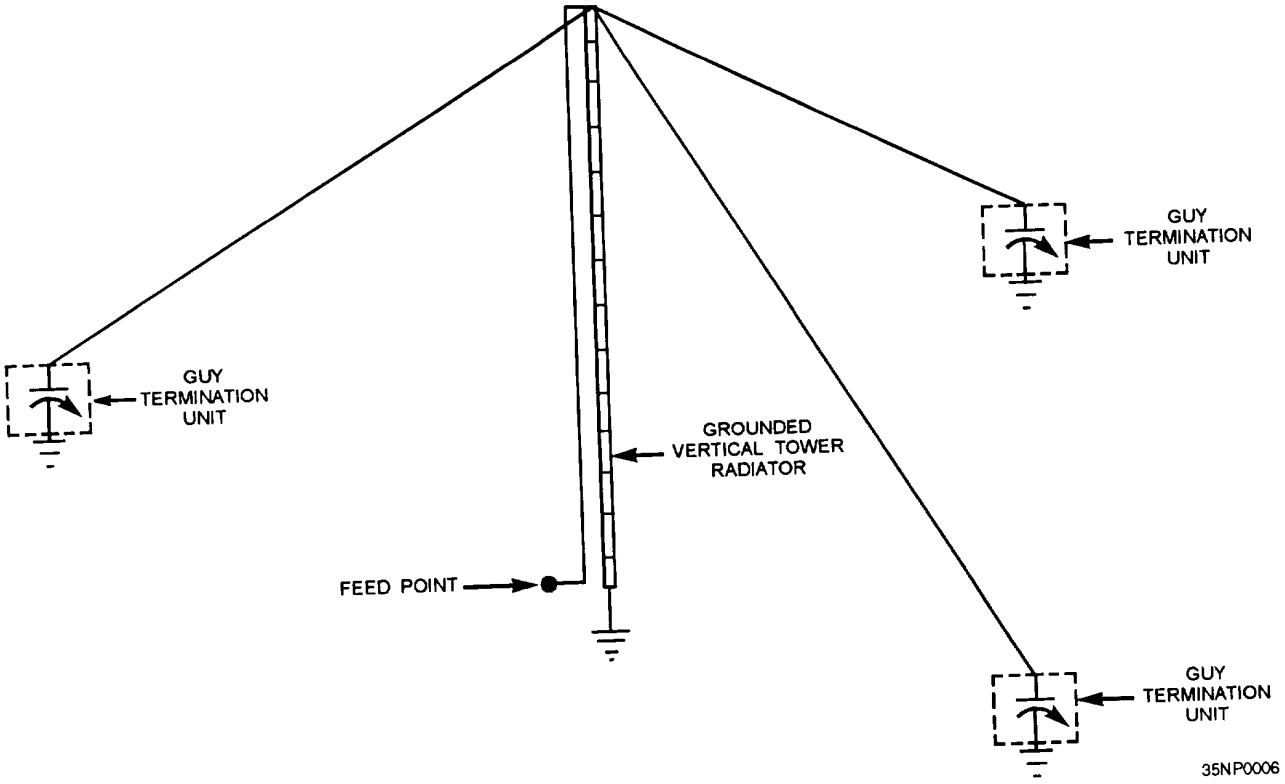

Figure 2-14.—NORD antenna.

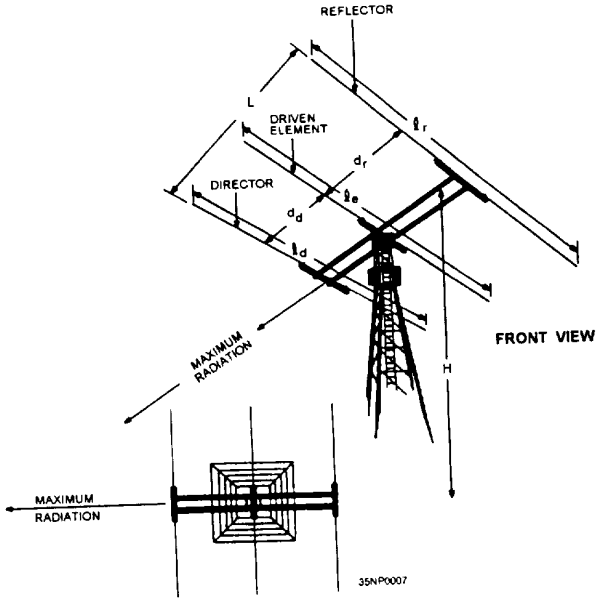

Figure 2-15.—Yagi antenna.

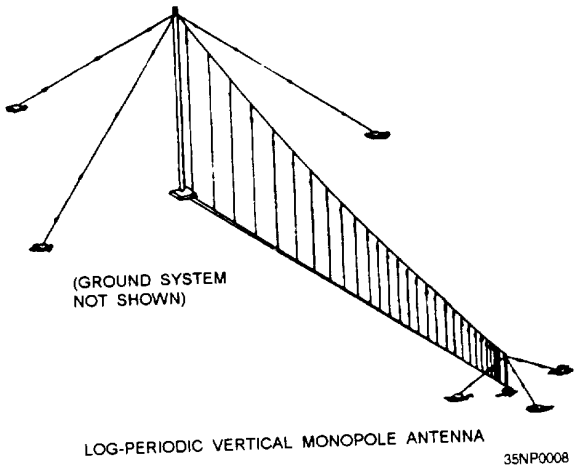

Figure 2-16.—Log-periodic vertical monopole antenna.

cover a frequency range of 2 to 30 MHz requires one tower approximately 140 feet high and an antenna length of around 500 feet, with a ground system that covers approximately 3 acres of land in the immediate vicinity of the antenna.

Sector Log-Periodic Array

This version of a vertically polarized fixed-azimuth LPA consists of four separate curtains supported by a common central tower, as shown in figure 2-17. Each of the four curtains operates independently, providing antennas for a minimum of four transmit or receive systems. and a choice of sector coverage. The four curtains are also capable of radiating a rosette pattern of overlapping sectors for full coverage, as shown by the radiation pattern in figure 2-17. The central supporting tower is constructed of steel and may range to approximately 250 feet in height, with the length of each curtain reaching 250 feet, depending on its designed operating frequencies. A sector antenna that uses a ground plane designed to cover the entire hf spectrum takes up 4 to 6 acres of land area.

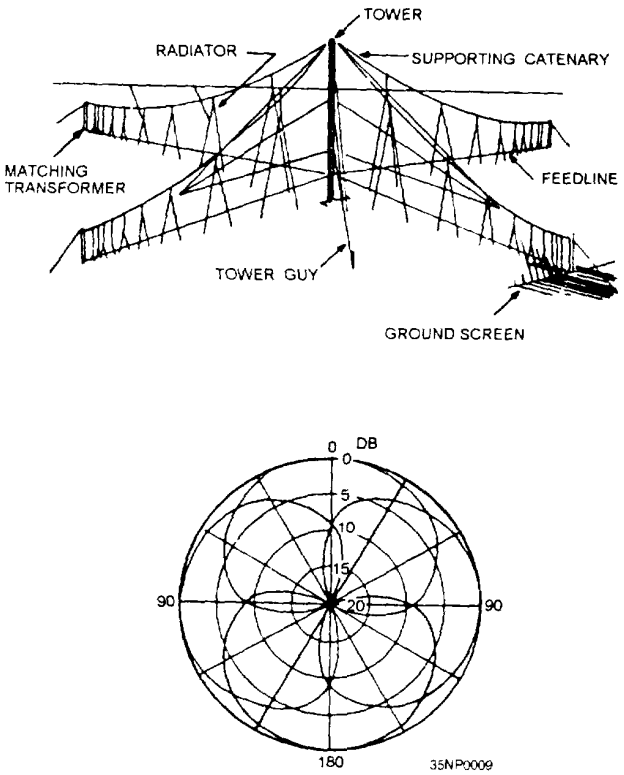

Figure 2-17.—Sector LPA and its horizontal radiation pattern.

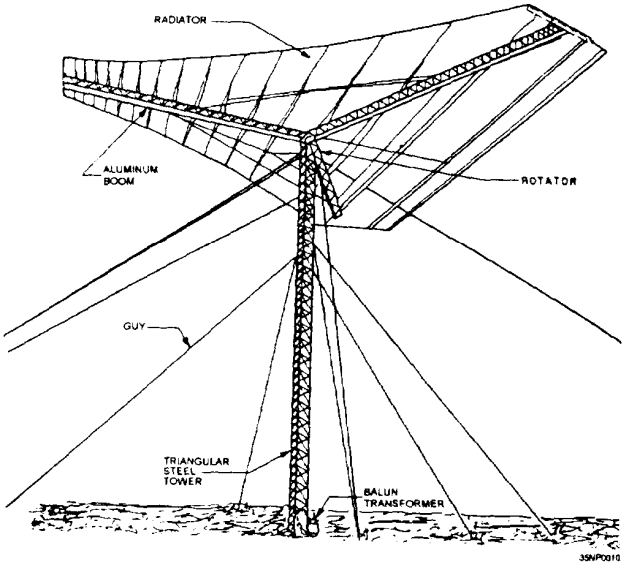

Figure 2-18.—Rotatable log-periodic antenna.

Rotatable LPA (RLPA)

RLPAs (fig. 2-18) are commonly used in ship-to-shore-to-ship and in point-to-point ecm-u-nunications. Their distinct advantage is their ability to rotate 360 degrees. RLPAs are usually constructed with either tubular or wire antenna elements. The RLPA in figure 2-18 has wire elements strung on three aluminum booms of equal length, spaced equally and arranged radially about a central rotator on top of a steel tower approximately 100 feet high. The frequency range of this antema is 6 to 32 MHz. The gain is 12 dB with respect to isotropic antennas. Power handling capability is 20 kw average, and vswr is 2:1 over the frequency range.

INVERTED CONE ANTENNA

Inverted cone antennas are vertically polarized, omnidirectional, and have an extremely broad bandwidth. They are widely used for ship-to-shore and ground-to-air communications. Inverted cone antennas are installed over a radial ground plane system and are supported by poles, as shown in figure 2-19. The equally-spaced vertical radiator wires terminate in a feed ring assembly located at the bottom center, where a 50-ohm coaxial transmission line feeds the antenna. Inverted cones usually have gains of 1 to 5 dB above isotropic antennas, with a vswr not

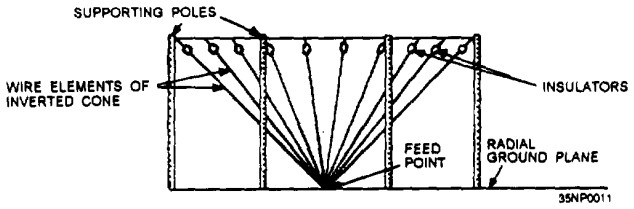

Figure 2-19.—Inverted cone antenna.

greater than 2:1. They are considered medium- to high-power radiators, with power handling capabilities of 40 kW average power.

CONICAL MONOPOLE ANTENNA

Conical monopoles are used extensively in hf communications. A conical monopole is an efficient broadband, vertically polarized, omnidirectional antenna in a compact size. Conical monopoles are shaped like two truncated cones connected base-to-base. The basic conical monopole configuration, shown in figure 2-20, is composed of equally-spaced wire radiating elements arranged in a circle around an aluminum center tower. Usually, the radiating elements are connected to the top and bottom discs, but on some versions, there is a center waist disc where the top and bottom radiators are connected. The conical monopole can handle up to 40 kW of average power. Typical gain is -2 to +2 dB, with a vswr of up to 2.5:1.

RHOMBIC ANTENNA

Rhombic antennas can be characterized as high-power, low-angle, high-gain, horizontally-polarized, highly-directive, broadband antennas of simple, inexpensive construction. The rhombic antenna (fig. 2-21) is a system of long-wire radiators that depends on radiated wave interaction for its gain and directivity. A properly designed rhombic antenna presents to the transmission line an input impedance insensitive to frequency variations up to 5:1. It maintains a power gain above 9 dB anywhere within a 2:1 frequency variation. At the design-center frequency, a gain of 17 dB is typical. The radiation pattern produced by the four radiating legs of a rhombic antenna is modified by reflections from the earth under, and immediately in front of, the antenna. Because of the importance of these ground

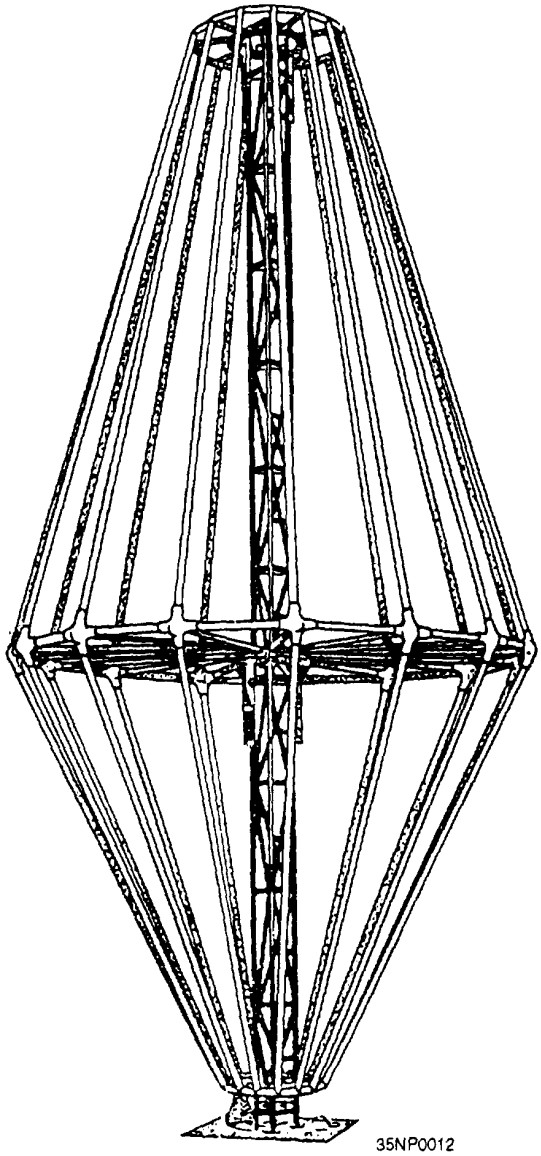

Figure 2-20.—Conical monopole antenna.

reflections in the proper formation of the main lobe, the rhombic should be installed over reasonably smooth and level ground. The main disadvantage of the rhombic antenna is the requirement for a large land area, usually 5 to 15 acres.

QUADRANT ANTENNA

The hf quadrant antenna (fig. 2-22) is a special-purpose receiving antenna used in ground-to-air-to-ground communications. It is unique among horizontally-polarized antennas because its

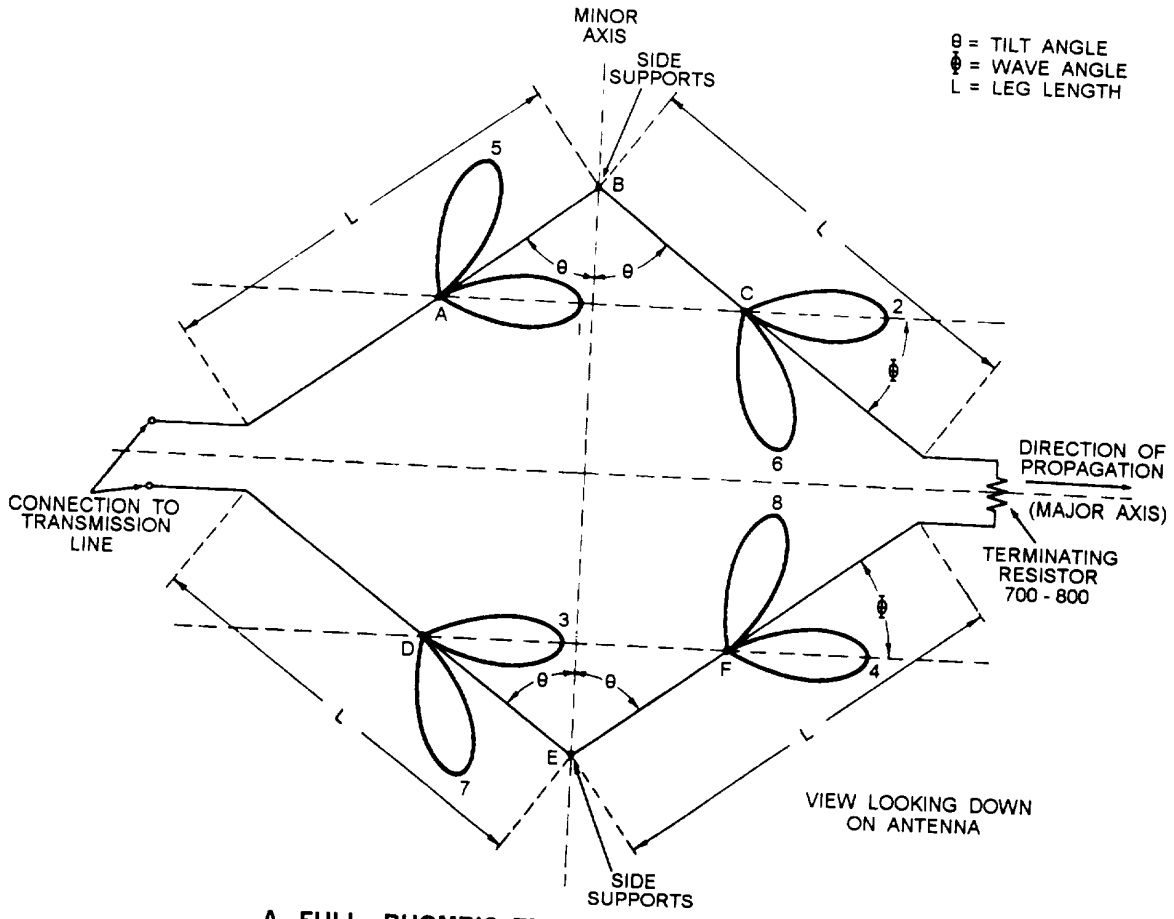

Figure 2-21.—Three-wire rhombic antenna.

element arrangement makes possible a radiation pattern resembling that of a vertically-polarized, omnidirectional antenna. Construction and installation of this antenna is complex because of the physical relationships between the individual elements and the requirement for a separate transmission line for each dipole. Approximately 2.2 acres of land are required to accommodate the quadrant antenna.

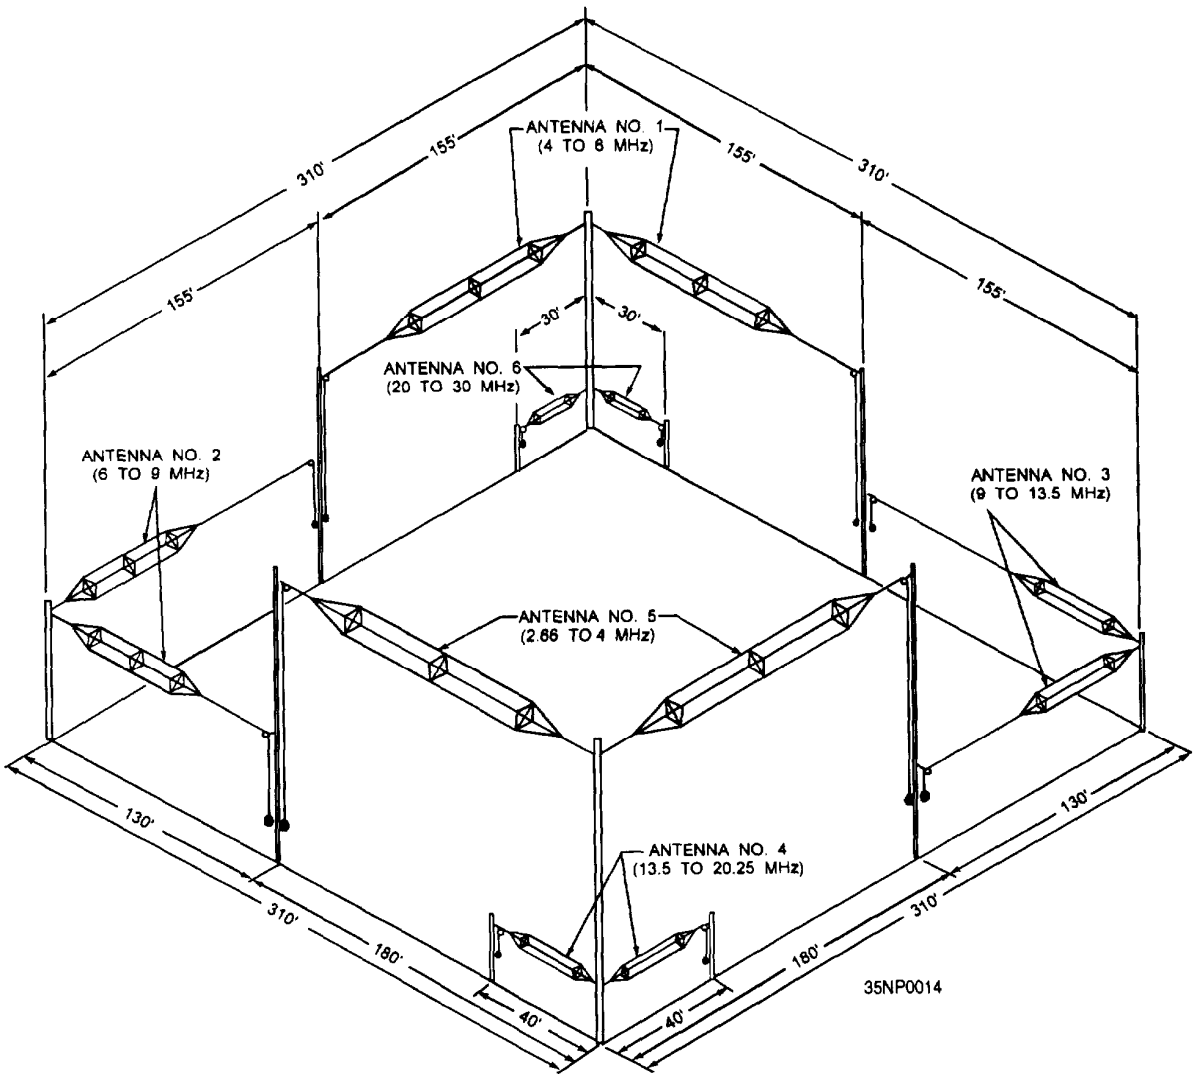

Figure 2-22.—Quadrant antenna.

WHIP ANTENNAS

Hf whip antennas (fig. 2-23) are vertically-polarized omnidirectional monopoles that are used for short-range, ship-to-shore and transportable communications systems. Whip antennas are made of tubular metal or fiberglass, and vary in length from 12 feet to 35 feet, with the latter being the most prevalent. Although whips are not considered as highly efficient antennas, their ease of installation and low cost provide a compromise for receiving and low-to-medium power transmitting installations.

The self-supporting feature of the whip makes it particularly useful where space is limited. Whips can be tilted, a design feature that makes them suited for use along the edges of aircraft carrier flight decks. Aboard submarines, they can be retracted into the sail structure.

Most whip antennas require some sort of tuning system and a ground plane to improve their radiation efficiency throughout the hf spectrum. Without an antenna tuning system, whips generally have a narrow bandwidth and are limited in their power handling

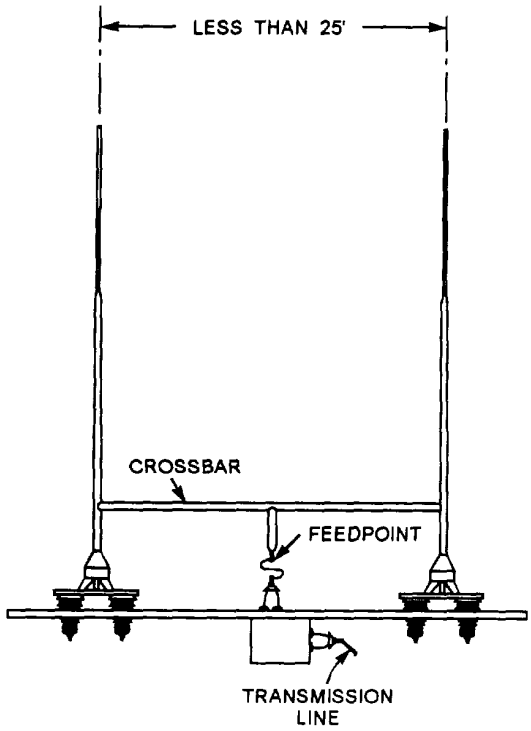

Figure 2-23.—Whip antennas.

capabilities. Power ratings for most whips range from 1 to 5 kW PEP.

WIRE-ROPE FAN ANTENNAS

Figure 2-24 shows a five-wire vertical fan antenna. This is a broadband antenna composed of five wires,

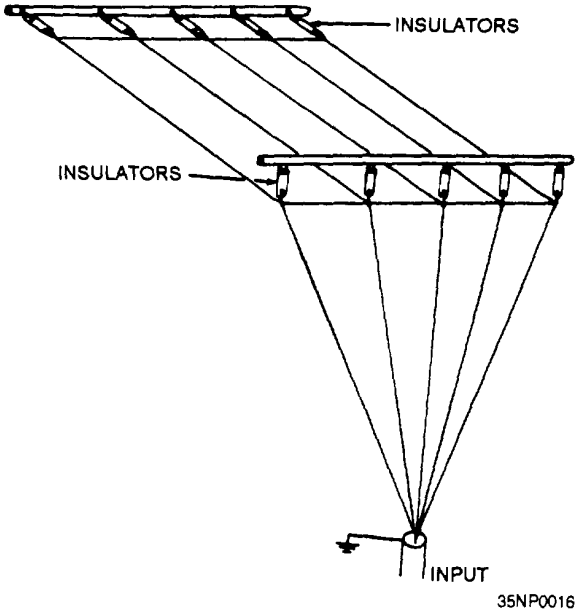

Figure 2-24.—Vertical fan antenna.

each cut for one-quarter wavelength at the lowest frequency to be used. The wires are fanned 30 degrees between adjacent wires. The fan antenna provides satisfactory performance and is designed for use as a random shipboard antenna in the hf range (2-30 MHz).

DISCAGE ANTENNA

The discage antenna (fig. 2-25) is a broadband omnidirectional antenna. The diseage structure consists of two truncated wire rope cones attached base-to-base and supported by a central mast. The lower portion of the structure operates as a cage monopole for the 4- to 12-MHz frequency range. The upper portion operates as a discone radiator in the 10- to 30-MHz frequency range. Matching networks limit the vswr to not greater than 3:1 at each feed point. Vinyl-covered phosphor bronze wire rope is used for the wire portions. The support mast and other portions are aluminum.

VHF/UHF

At vhf and uhf frequencies, the shorter wavelength makes the physical size of the antenna relatively small. Aboard ship these antennas are installed as high as

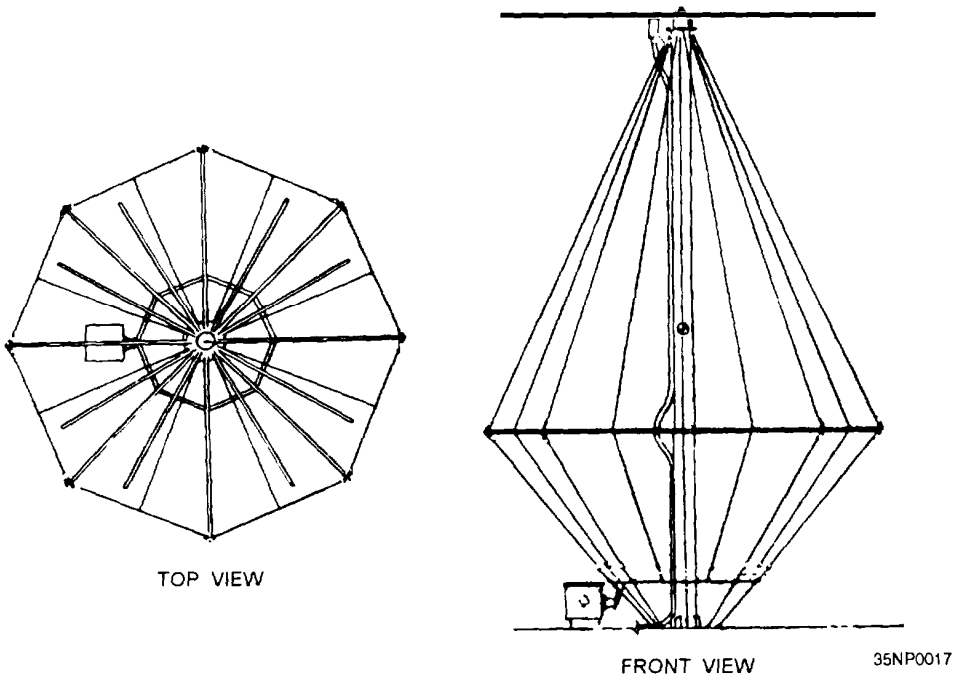

Figure 2-25.—AS-2802/SCR discage antenna.

possible and away from any obstructions. The reason for the high installation is that vertical conductors, such as masts, rigging, and cables in the vicinity, cause unwanted directivity in the radiation pattern.

For best results in the vhf and uhf ranges, both transmitting and receiving antennas must have the same polarization. Vertically polarized antennas (primarily dipoles) are used for all ship-to-ship, ship-to-shore, and air-to-ground vhf and uhf communications.

The following paragraphs describe the most common uhf/vhf dipole antennas. All the examples are vertically-polarized, omnidirectional, broadband antennas.

Biconical Dipole

The biconical dipole antenna (fig. 2-26) is designed for use at a normal rf power rating of around 250 watts, with a vswr not greater than 2:1. All major components of the radiating and support structures are aluminum. The central feed section is protected and waterproofed by a laminated fiberglass cover.

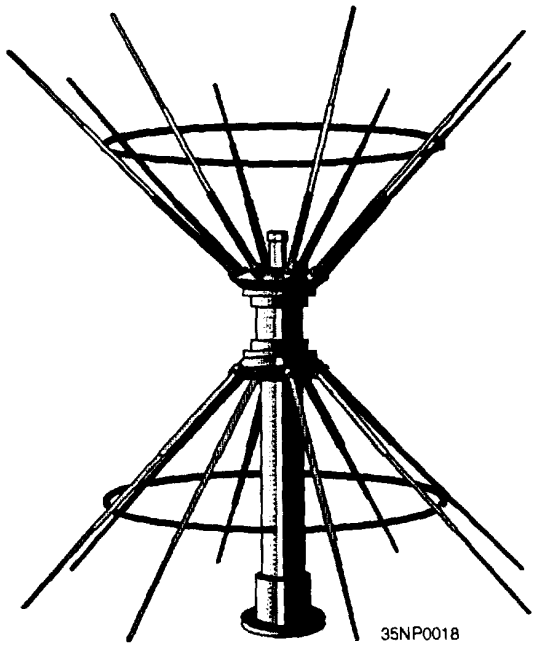

Figure 2-26.—AS-2811/SCR biconical dipole antenna.

Center-Fed Dipole

The center-fed dipole (fig. 2-27) is designed for use at an average power rating of 100 watts. All major components of the radiating and support structures are aluminum. The central feed section and radiating elements are protected by a laminated fiberglass cover. Center-fed dipole antennas range from 29 to 47 inches in height and have a radiator diameter of up to 3 inches.

Coaxial Dipole

Figure 2-28 shows two types of coaxial dipoles. The coaxial dipole antenna is designed for use in the uhf range, with an rf power rating of 200 watts. The AT-150/SRC (fig. 2-28, view A) has vertical radiating elements and a balun arrangement that electrically balances the antenna to ground.

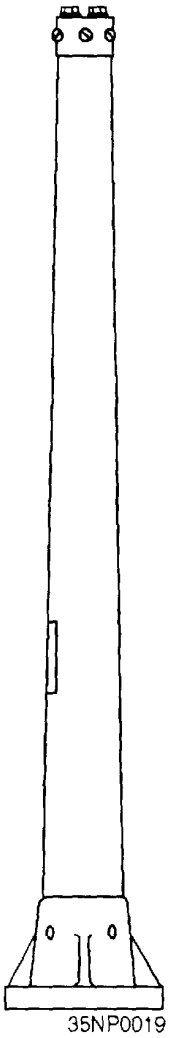

Figure 2-27.—AS-2809/RC center-fed dipole antenna.

Figure 2-28, view B, shows an AS-390/SRC antenna assembly. This antenna is an unbalanced broadband coaxial stub antenna. It consists of a radiator and a ground plane. The ground plane (or counterpoise) consists of eight elements bent downward 37 degrees from horizontal. The lower ends of the elements form points of a circle 23 inches in diameter. The lower section of the radiator assembly contains a stub for adjusting the input impedance of the antenna. The antenna is vertically polarized, with an rf power rating of 200 watts, and a vswr not greater than 2:1.

SATELLITE SYSTEMS

The Navy Satellite Communication System (SATCOM) provides communications links, via satellites, between designated mobile units and shore sites. These links supply worldwide communications coverage. The following paragraphs describe some of the more common SATCOM antenna systems to which you will be exposed.

AS-2815/SRR-1

The AS-2815/SSR-1 fleet broadcast receiving antenna (fig. 2-29) has a fixed 360-degree horizontal pattern with a maximum gain of 4 dB at 90 degrees from the antenna's horizontal plane. The maximum loss in the antenna's vertical pattern sector is 2 dB. The vswr is less than 1.5:1, referenced to 50 ohms. This antenna should be positioned to protect it from interference and possible front end burnout from radar and uhf transmitters.

ANTENNA GROUPS OE-82B/WSC-1(V) AND OE-82C/WSC-1(V)

Designed primarily for shipboard installations, these antenna groups interface with the AN/WSC-3 transceiver. The complete installation consists of an antenna, bandpass amplifier-filter, switching unit, and antenna control (figs. 2-30 and 2-31), Depending on requirements, one or two antennas may be installed to provide a view of the satellite at all times. The antenna assembly is attached to a pedestal that permits

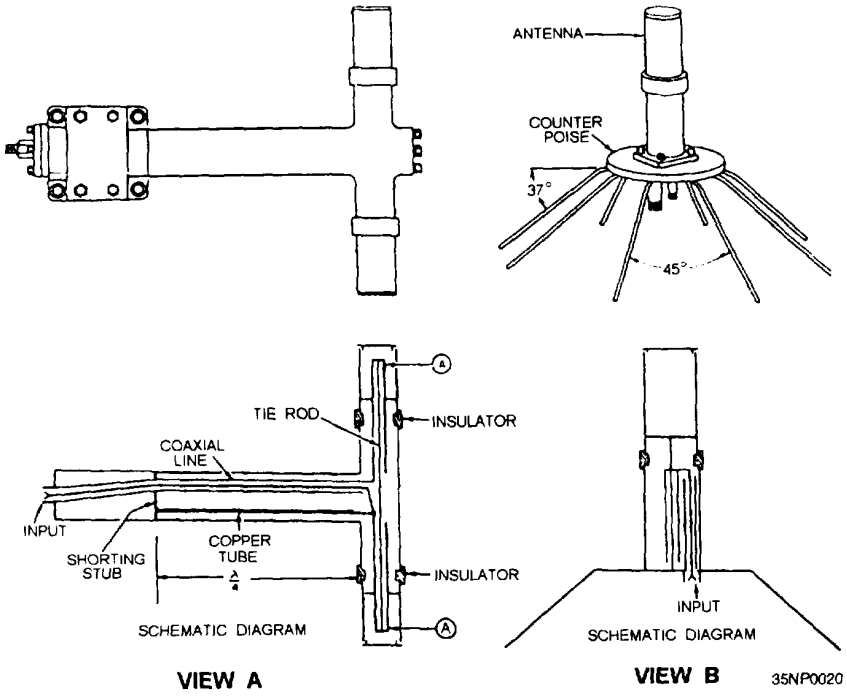

Figure 2-28.—Coaxial dipole.

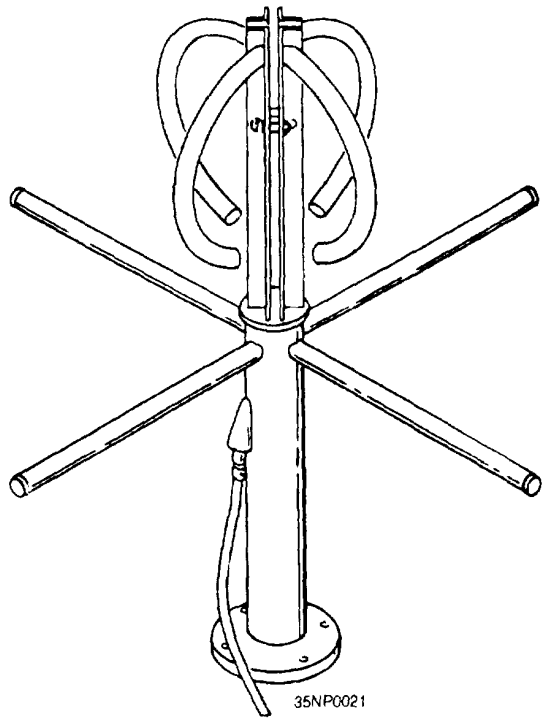

Figure 2-29.—AS-2815/SSR-1 fleet broadcast satellite receiving antenna.

it to rotate 360 degrees and to elevate from near horizontal to approximately 20 degrees beyond zenith (elevation angles from +2 to +110 degrees). The antenna tracks automatically in azimuth and manually in elevation. Frequency bands are 248-272 MHz for receive and 292-312 MHz for transmit. Polarization is right-hand circular for both transmit and receive. Antenna gain characteristics are nominally 12 dB in transmit and 11 dB in receive.

AN/WSC-5(V) SHORE STATION ANTENNA

The AN/WSC-5(V) shore station antenna (fig. 2-32) consists of four OE-82A/WSC-1(V) backplane assemblies installed on a pedestal. This antenna is intended for use with the AN/WSC-5(V) transceiver at major shore stations. The antenna is oriented manually and can be locked in position to receive maximum signal strength upon capture of the satellite signal. Hemispherical coverage is 0 to 110 degrees above the horizon. Polarization is right-hand circular in both transmit and receive. The antenna's operating frequency range is 240 to 318 MHz. With its mount,

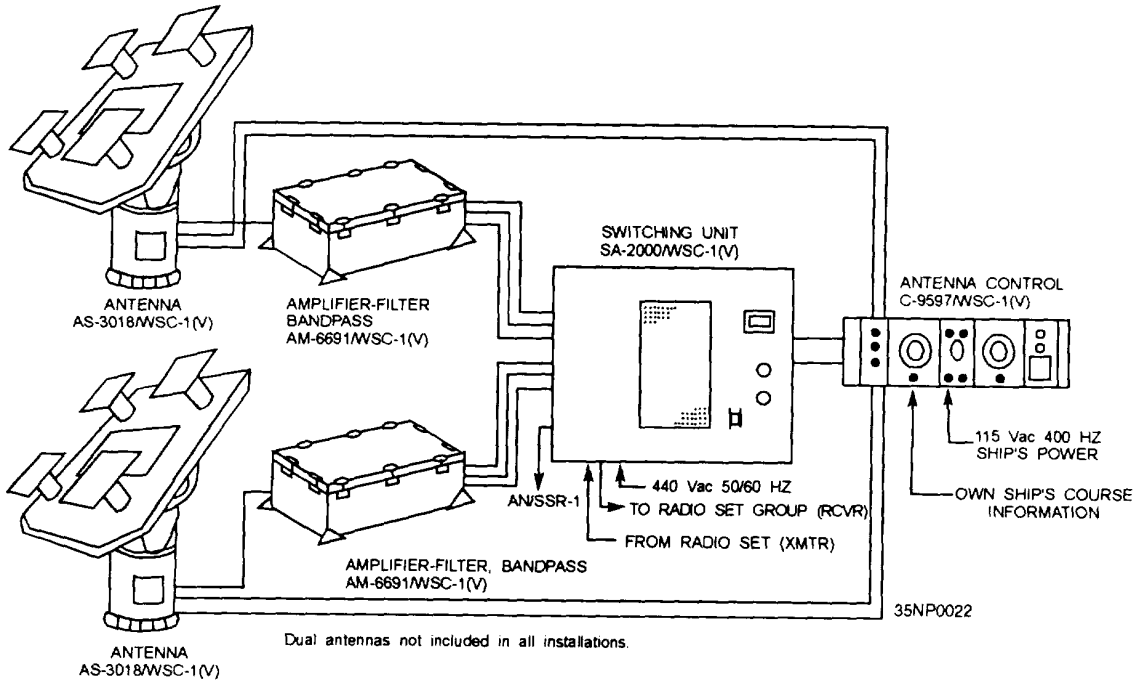

Figure 2-30.—OE-82/WSC-1(V) antenna group.

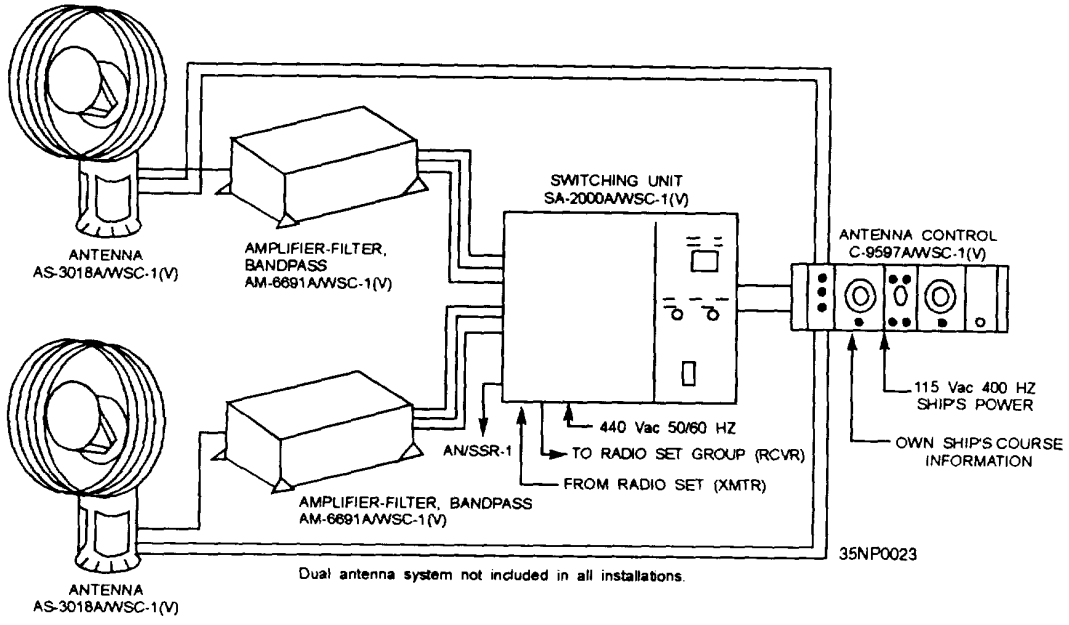

Figure 2-31.—OE-82C/WSC-1(V) antenna group.

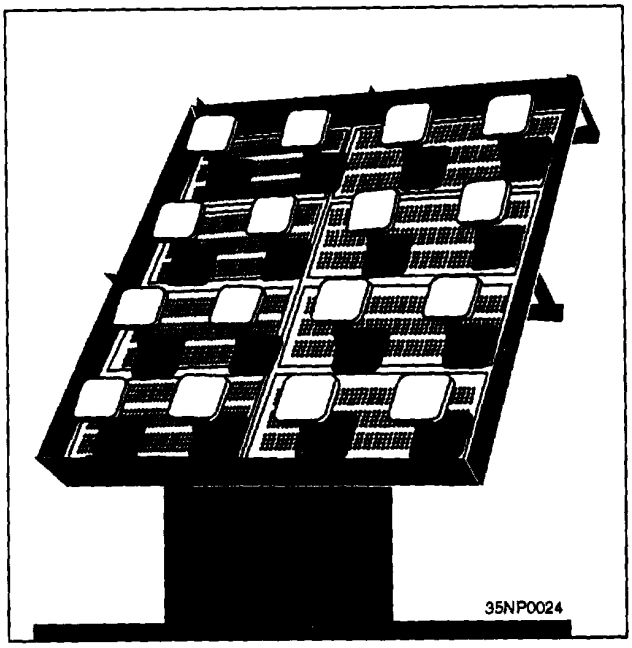

Figure 2-32.—OE-82A/WSC-1(V)/AN/WSC-5(V) shore station antenna.

the antenna weighs 2500 pounds and is 15 feet high, 10 feet wide, and 10 feet deep. The gain characteristics of this antenna are nominally 15 dB in transmit and 18 dB in receive.

ANDREW 58622 SHORE ANTENNA

The Andrew 58622 antenna (fig. 2-33) is a bifilar, 16-turn helical antenna right-hand circularly polarized, with gain varying between 11.2 and 13.2 dB in the 240-315 MKz frequency band. It has a 39-inch ground plate and is about 9 feet, 7 inches long. It can be adjusted manually in azimuth and elevation. This antenna is used at various shore installations, other than NCTAMS, for transmit and receive operations.

AN/WSC-6(V) SHF SATCOM ANTENNA

The antennas used on current shf SATCOM shipboard terminals are parabolic reflectors with casseegrain feeds. These antennas provide for LPI (low probability of intercept), with beamwidths less than 2.5 degrees (fig. 2-34). The reflectors are mounted on three-axis pedestals and provide autotracking of a beacon or communication signal by conical scanning

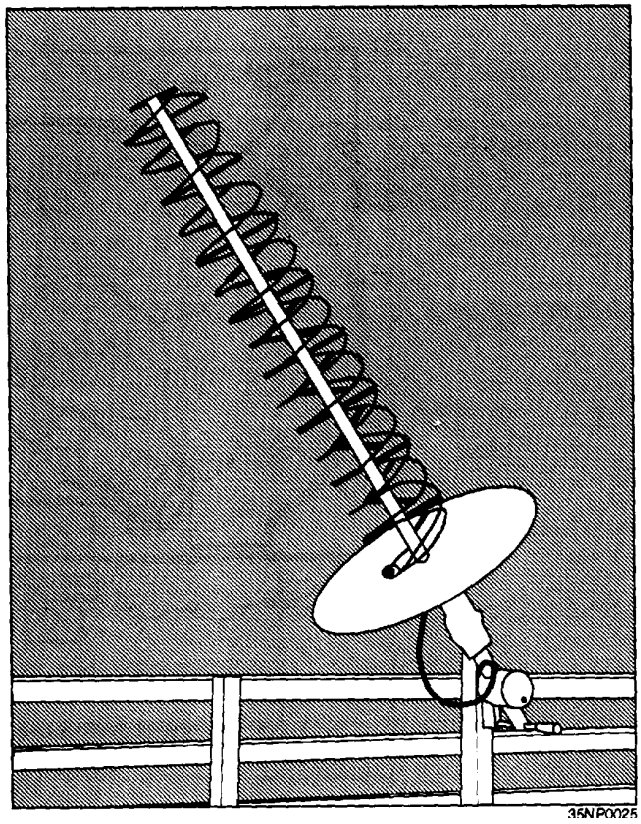

Figure 2-33.—Andrew 58622 shore antenna.

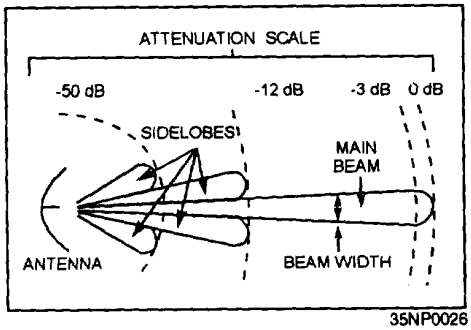

Figure 2-34.—AN/WSC-6(V) attenuation scale.

techniques. The antennas are radome enclosed and include various electronic components. Both a 7-foot model (fig. 2-35) and a 4-foot model (fig. 2-36) are operational in the fleet.

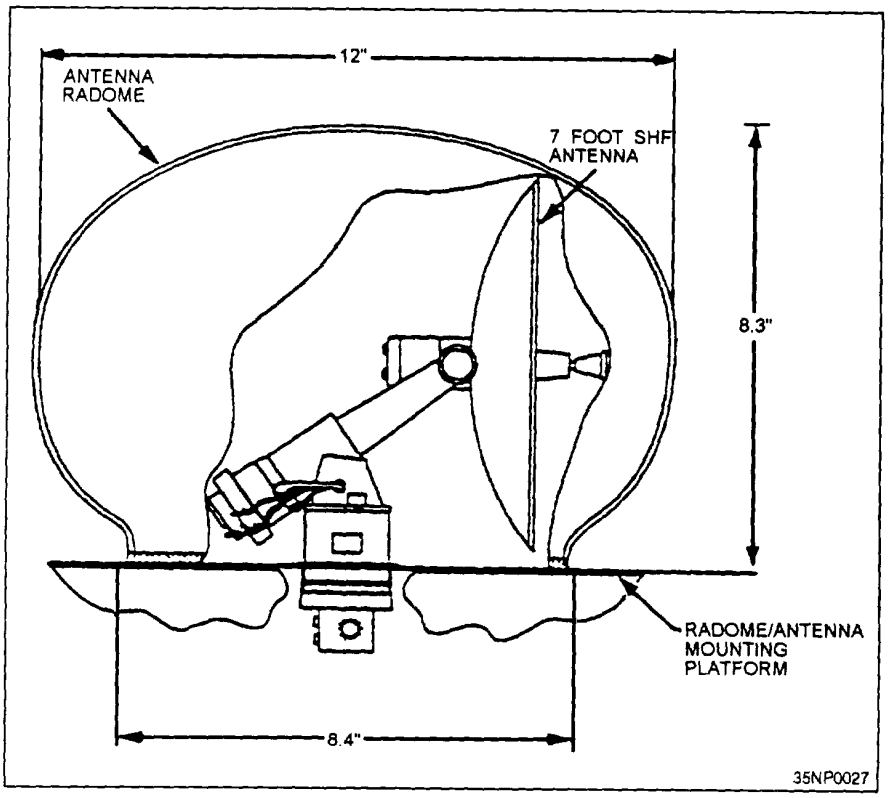

Figure 2-35.—Seven-foot shf SATCOM antenna.

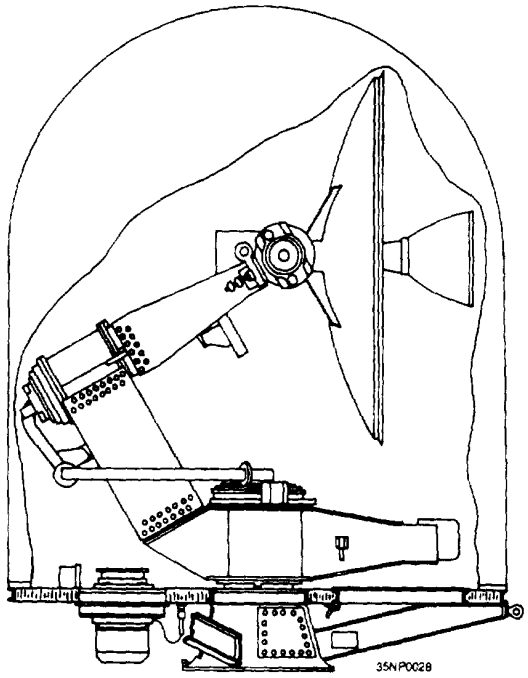

Figure 2-36.—Four-foot shf SATCOM antenna.

MATCHING NETWORKS

An antenna matching network consists of one or more parts (such as coils, capacitors, and lengths of transmission line) connected in series or parallel with the transmission line to reduce the standing wave ratio on the line. Matching networks are usually adjusted when they are installed and require no further adjustment for proper operation. Figure 2-37 shows a matching network outside of the antenna feedbox, with a sample matching network schematic.

Matching networks can also be built with variable components so they can be used for impedance matching over a range of frequencies. These networks are called antenna tuners.

Antenna tuners are usually adjusted automatically or manually each time the operating frequency is changed. Standard tuners are made with integral enclosures. Installation consists simply of mounting

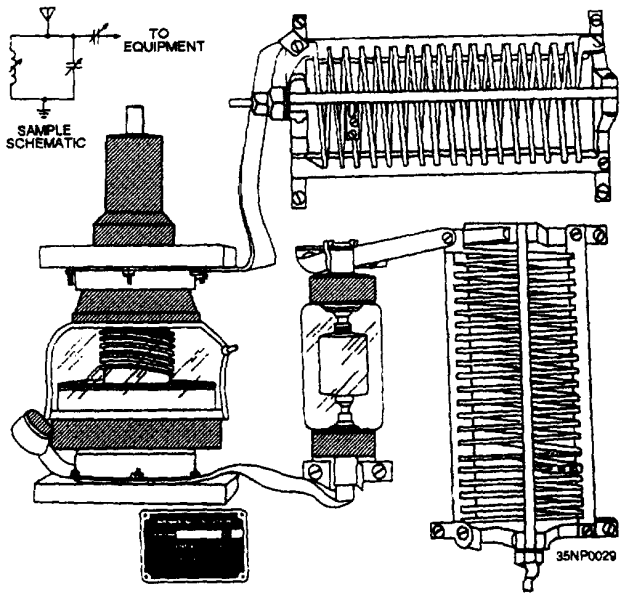

Figure 2-37.—Matching network.

the tuner, assembling the connections with the antenna and transmission line, and pressurizing the tuner, if necessary. Access must be provided to the pressure gauge and pressurizing and purging connections.

ANTENNA TUNING

For every frequency in the frequency spectrum, there is an antenna that is perfect for radiating at that frequency. By that we mean that all of the power being transmitted from the transmitter to the antenna will be radiated into space. Unfortunately, this is the ideal and not the rule. Normally, some power is lost between the transmitter and the antenna. This power loss is the result of the antenna not having the perfect dimensions and size to radiate perfectly all of the power delivered to it from the transmitter. Naturally, it would be unrealistic to carry a separate antenna for every frequency that a communications center is capable of radiating; a ship would have to have millions of antennas on board, and that would be impossible.

To overcome this problem, we use ANTENNA TUNING to lengthen and shorten antennas electrically to better match the frequency on which we want to transmit. The rf tuner is connected electrically to the antenna and is used to adjust the apparent physical length of the antenna by electrical means. This simply means that the antenna does not physically change length; instead, it is adapted electrically to the output frequency of the transmitter and "appears" to change its physical length. Antenna tuning is done by using antenna couplers, tuners, and multicouplers.

Antenna couplers and tuners are used to match a single transmitter or receiver to one antenna whereas antenna multicouplers are used to match more than one transmitter or receiver to one antenna for simultaneous operation. Some of the many antenna couplers that are in present use are addressed in the following paragraphs. For specific information on a particular coupler, refer to the appropriate equipment technical manual.

Antenna Coupler Group AN/URA-38

Antenna Coupler Group AN/URA-38 is an automatic antenna tuning system intended primarily for use with the AN/URT-23(V) operating in the high-frequency range. The equipment also includes provisions for manual and semiautomatic tuning, making the system readily adaptable for use with other radio transmitters. The manual tuning feature is useful when a failure occurs in the automatic tuning circuitry. Tuning can also be done without the use of rf power (silent tuning). This method is useful in installations where radio silence must be maintained except for brief transmission periods.

The antenna coupler matches the impedance of a 15-, 25-, 28-, or 35-foot whip antenna to a 50-ohm transmission line, at any frequency in the 2-to 30-MHz range. When the coupler is used with the AN/URT-23(V), control signals from the associated antenna coupler control unit automatically tune the coupler's matching network in less than 5 seconds. During manual and silent operation, the operator uses the controls mounted on the antenna coupler control unit to tune the antenna. A low-power (less than 250 watts) cw signal is required for tuning. Once tuned, the CU 938A/URA-38 is capable of handling 1000 watts PEP.

Antenna Coupler Groups AN/SRA-56, -57, and -58

Antenna coupler groups AN/SRA-56, -57, and -58 are designed primarily for shipboard use. Each

coupler group permits several transmitters to operate simultaneously into a single, associated, broadband antenna, thus reducing the total number of antennas required in the limited space aboard ship.

These antenna coupler groups provide a coupling path of prescribed efficiency between each transmitter and the associated antenna. They also provide isolation between transmitters, tunable bandpass filters to suppress harmonic and spurious transmitter outputs, and matching networks to reduce antenna impedances.

The three antenna coupler groups (AN/SRA-56, -57, -58) are similar in appearance and function, but they differ in frequency ranges. Antenna coupler group AN/SRA-56 operates in the 2- to 6-MHz frequency range. The AN/SRA-57 operates from 4 to 12 MHz, and the AN/SRA-58 operates from 10 to 30 MHz. When more than one coupler is used in the same frequency range, a 15 percent frequency separation must be maintained to avoid any interference.

Antenna Coupler Group AN/SRA-33

Antenna coupler group AN/SRA-33 operates in the uhf (225-400 Mhz) frequency range. It provides isolation between as many as four transmitter and receiver combinations operating simultaneously into a common uhf antenna without degrading operation. The AN/SRA-33 is designed for operation with shipboard radio set AN/WSC-3. The AN/SRA-33 consists of four antenna couplers (CU-1131/SRA-33 through CU-1134/SRA-33), a control power supply C-4586/SRA-33, an electronic equipment cabinet CY-3852/SRA-33, and a set of special-purpose cables.

OA-9123/SRC

The OA-9123/SRC multicoupler enables up to four uhf transceivers, transmitters, or receivers to operate on a common antenna. The multicoupler provides low insertion loss and highly selective filtering in each of the four ports. The unit is interface compatible with the channel select control signals from radio sets AN/WSC-3(V) (except (V)1). The unit is self-contained and is configured to fit into a standard 19-inch open equipment rack.

The OA-9123/SRC consists of a cabinet assembly, control power supply assembly, and four identical filter assemblies. This multicoupler is a state-of-the-art replacement for the AN/SRA-33 and only requires about half of the space.

RECEIVING ANTENNA DISTRIBUTION SYSTEMS

Receiving antenna distribution systems operate at low power levels and are designed to prevent multiple signals from being received. The basic distribution system has several antenna transmission lines and several receivers, as shown in figure 2-38. The system includes two basic patch panels, one that terminates the antenna transmission lines, and the other that terminates the lines leading to the receivers. Thus, any antenna can be patched to any receiver via patch cords.

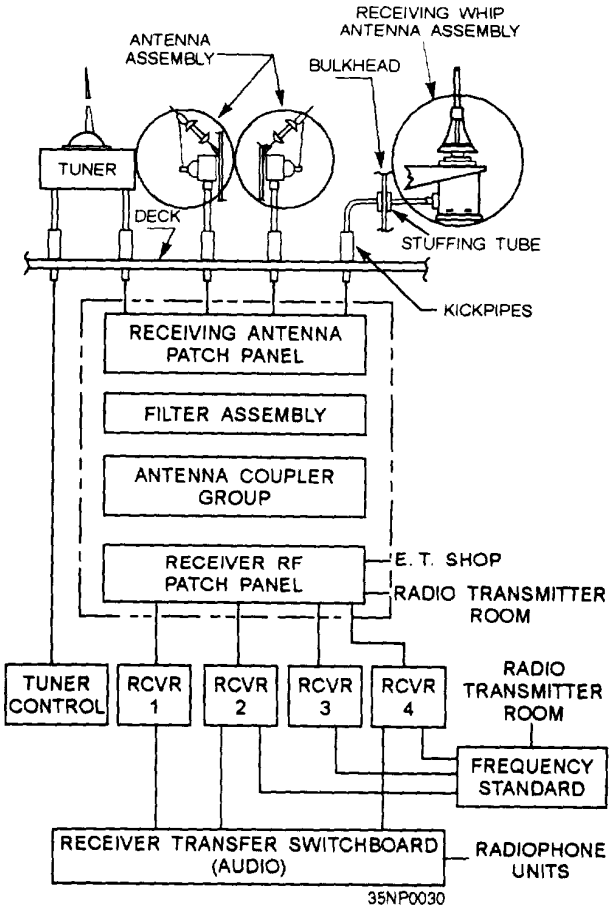

Figure 2-38.—Receive signal distribution system.

Some distribution systems will be more complex. That is, four antennas can be patched to four receivers, or one antenna can be patched to more than one receiver via the multicouplers.

RECEIVING MULTICOUPLER AN/SRA-12

The AN/SRA-12 filter assembly multicoupler provides seven radio frequency channels in the 14-kHz to 32-MHz frequency range. Any of these channels may be used independently of the other channels, or they may operate simultaneously. Connections to the receiver are made by coaxial patch cords, which are short lengths of cable with a plug attached to each end.

ANTENNA COUPLER GROUPS AN/SRA-38, AN/SRA-39, AN/SRA-40, AN/SRA-49, AN/SRA-49A, and AN/SRA-50

These groups are designed to connect up to 20 mf and hf receivers to a single antenna, with a highly selective degree of frequency isolation. Each of the six coupler groups consists of 14 to 20 individual antenna couplers and a single-power supply module, all are slide-mounted in a special electronic equipment rack. An antenna input distribution line termination (dummy load) is also supplied. In addition, there are provisions for patching the outputs from the various antenna couplers to external receivers.

RADAR ANTENNAS

Radar antennas are usually directional antennas that radiate energy in one lobe or beam. The two most important characteristics of directional antennas are directivity and power gain. Most radar systems use parabolic antennas. These antennas use parabolic reflectors in different variations to focus the radiated energy into a desired beam pattern.

While most radar antennas are parabolic, other types such as the corner reflector, the broadside array, and horn radiators may also be used.

PARABOLIC REFLECTORS

To understand why parabolic reflectors are used for most radar antennas, you need to understand how radio waves behave. A point source, such as an omnidirectional antenna produces a spherical radiation pattern, or spherical wavefront. As the sphere expands, the energy contained in a given surface area decreases rapidly. At a relatively short distance from the antenna, the energy level is so small that its reflection from a target would be useless in a radar system.

A solution to this problem is to form the energy into a PLANE wavefront, In a plane wavefront, all of the energy travels in the same direction, thus providing more energy to reflect off of a target. To concentrate the energy even further, a parabolic reflector is used to shape the plane wavefront's energy into a beam of energy. This concentration of energy provides a maximum amount of energy to be reflected off of a target, making detection of the target much more probable.

How does the parabolic reflector focus the radio waves? Radio waves behave much as light waves do. Microwaves travel in straight lines as do light rays. They may be focused or reflected, just as light rays may be. In figure 2-39, a point-radiation source is placed at the focal point F. The field leaves this antema with a spherical wavefront. As each part of the wavefront moving toward the reflector reaches the reflecting surface, it is shifted 180 degrees in phase and sent outward at angles that cause all parts of the field to travel in parallel paths. Because of the shape of a parabolic surface, all paths from F to the reflector and back to line XY are the same length. Therefore, all parts of the field arrive at line XY at the same time after reflection.

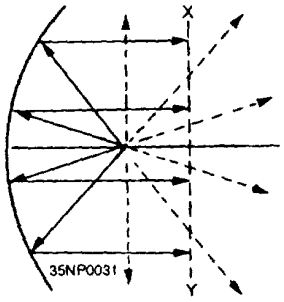

Figure 2-39.—Parabolic reflector radiation.

Energy that is not directed toward the paraboloid (dotted lines in fig. 2-39) has a wide-beam characteris-

tic that would destroy the narrow pattern from the parabolic reflector. This destruction is prevented by the use of a hemispherical shield (not shown) that directs most of what would otherwise be spherical radiation toward the parabolic surface. Without the shield, some of the radiated field would leave the radiator directly, would not be reflected, and would serve no useful purpose. The shield makes the beamsharper, and concentrates the majority of the power in the beam. The same results can be obtained by using either a parasitic array to direct the radiated field back to the reflector, or a feed horn pointed at the paraboloid.

The radiation pattern of the paraboloid contains a major lobe, which is directed along the axis of the paraboloid, and several minor lobes, as shown in figure 2-40. Very narrow beams are possible with this type of reflector. View A of figure 2-41 illustrates the parabolic reflector.

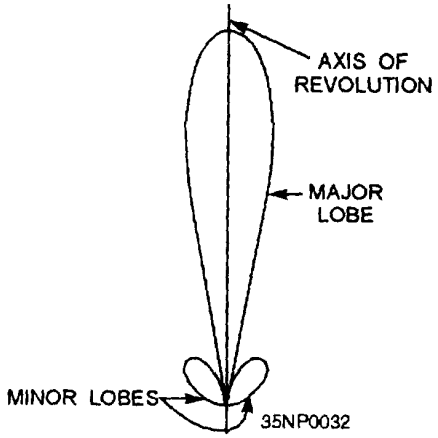

Figure 2-40.—Parabolic radiation pattern.

Truncated Paraboloid

While the complete parabolic reflector produces a pencil-shaped beam, partial parabolic reflectors produce differently shaped beams. View B of figure 2-41 shows a horizontally truncated, or vertically shortened, paraboloid. This type of reflector is designed to produce a beam that is narrow horizontally but wide vertically. Since the beam is wide vertically, it will detect aircraft at different altitudes without changing the tilt of the antenna. It also works well for surface search radars to overcome the pitch and roll of the ship.

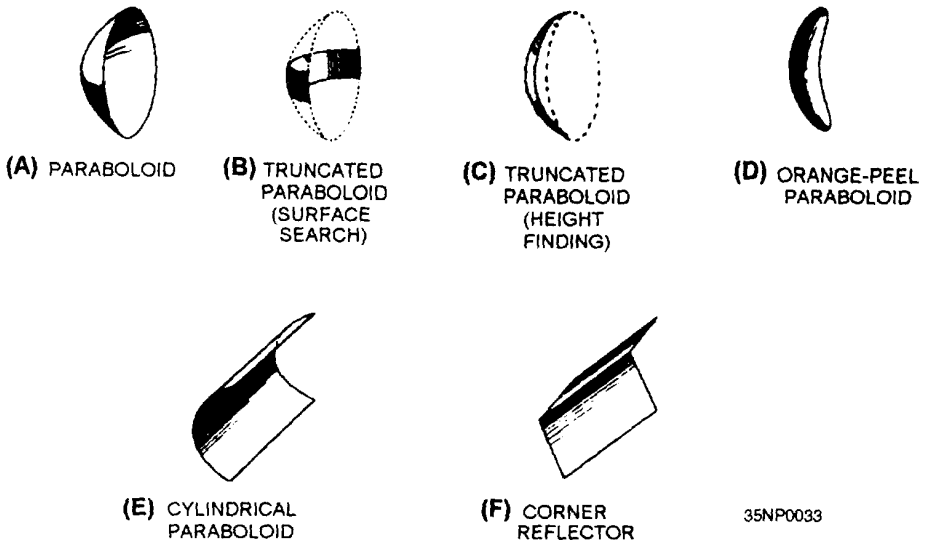

Figure 2-41.—Reflector shapes.

The truncated paraboloid reflector may be used in height-finding systems if the reflector is rotated 90 degrees, as shown in view C of figure 2-41. This type of reflector produces a beam that is wide horizontally but narrow vertically. The beam pattern is spread like a horizontal fan. Such a fan-shaped beam can be used to determine elevation very accurately.

Orange-Peel Paraboloid

A section of a complete circular paraboloid, often called an ORANGE-PEEL REFLECTOR because of its shape, is shown in view D of figure 2-41. Since the reflector is narrow in the horizontal plane and wide in the vertical, it produces a beam that is wide in the horizontal plane and narrow in the vertical. In shape, the beam resembles a huge beaver tail. This type of antenna system is generally used in height-finding equipment.

Cylindrical Paraboloid

When a beam of radiated energy noticeably wider in one cross-sectional dimension than in the other is desired, a cylindrical paraboloid section approximating a rectangle can be used. View E of figure 2-41 illustrates this antenna. A parabolic cross section is in one dimension only; therefore, the reflector is directive in one plane only. The cylindrical paraboloid reflector is either fed by a linear array of dipoles, a slit in the side of a waveguide, or by a thin waveguide radiator. Rather than a single focal point, this type of reflector has a series of focal points forming a straight line. Placing the radiator, or radiators, along this focal line produces a directed beam of energy. As the width of the parabolic section is changed, different beam shapes are produced. This type of antenna system is used in search systems and in ground control approach (gca) systems.

CORNER REFLECTOR

The corner-reflector antenna consists of two flat conducting sheets that meet at an angle to form a corner, as shown in view F of figure 2-41. This reflector is normally driven by a half-wave radiator located on a line that bisects the angle formed by the sheet reflectors.

BROADSIDE ARRAY

Desired beam widths are provided for some vhf radars by a broadside array, such as the one shown in figure 2-42. The broadside array consists of two or more half-wave dipole elements and a flat reflector. The elements are placed one-half wavelength apart and parallel to each other. Because they are excited in phase, most of the radiation is perpendicular or broadside to the plane of the elements. The flat reflector is located approximately one-eighth wavelength behind the dipole elements and makes possible the unidirectional characteristics of the antenna system.

HORN RADIATORS

Horn radiators, like parabolic reflectors, may be used to obtain directive radiation at microwave frequencies. Because they do not involve resonant elements, horns have the advantage of being usable over a wide frequency band.

The operation of a horn as an electromagnetic directing device is analogous to that of acoustic horns. However, the throat of an acoustic horn usually has dimensions much smaller than the sound wavelengths for which it is used, while the throat of the electromagnetic horn has dimensions that are comparable to the wavelength being used.

Horn radiators are readily adaptable for use with waveguides because they serve both as an impedance-

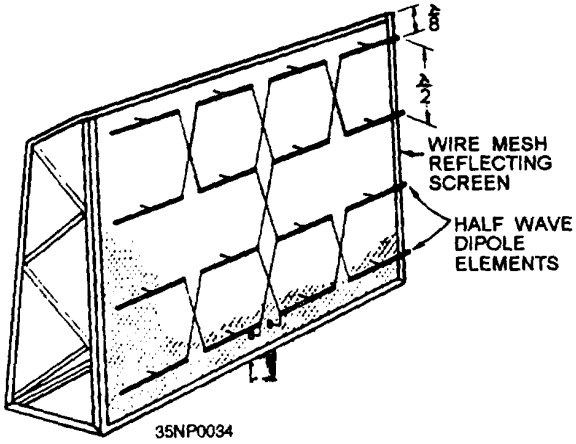

Figure 2-42.—Broadside array.

matching device and as a directional radiator. Horn radiators may be fed by coaxial or other types of lines.

Horns are constructed in a variety of shapes as illustrated in figure 2-43. The shape of the horn and the dimensions of the length and mouth largely determine the field-pattern shape. The ratio of the horn length to mouth opening size determines the beam angle and, thus, the directivity. In general, the larger the opening of the horn, the more directive is the resulting field pattern.

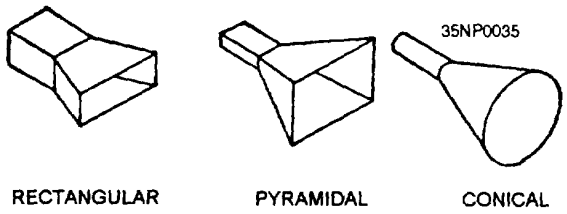

Figure 2-43.—Horn radiators.

FEEDHORNS

A waveguide horn, called a FEEDHORN, may be used to feed energy into a parabolic dish. The directivity of this feedhorn is added to that of the parabolic dish. The resulting pattern is a very narrow and concentrated beam. In most radars, the feedhorn is covered with a window of polystyrene fiberglass to prevent moisture and dirt from entering the open end of the waveguide.

One problem associated with feedhorns is the SHADOW introduced by the feedhorn if it is in the path of the beam. (The shadow is a dead spot directly in front of the feedhorn.) To solve this problem the feedhorn can be offset from center. This location change takes the feedhorn out of the path of the rf beam and eliminates the shadow. An offset feedhorn is shown in figure 2-44.

RADAR SYSTEMS

Now that you have a basic understanding of how radar antennas operate, we will introduce you to a few of the radar systems currently in use.

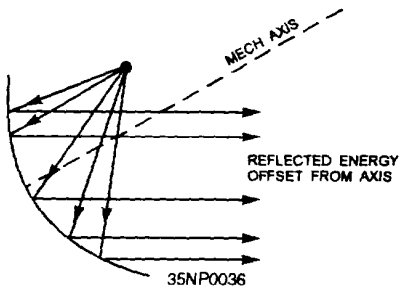

Figure 2-44.—Offset feedhorn.

AN/GPN-27(ASR-8) AIR SURVEILLANCE RADAR

The AN/GPN-27(ASR-8) (fig. 2-45) antenna radiates a beam 1.5 degrees in azimuth and shaped in elevation to produce coverage of up to approximately 32 degrees above the horizon. This provides a maplike presentation of aircraft within 55 nautical miles of an airport terminal. The antenna azimuth

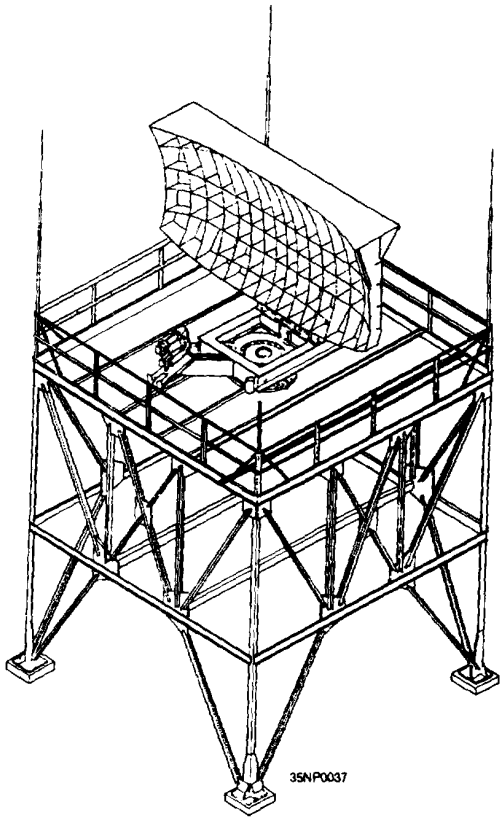

Figure 2-45.—AN/GPN-27(ASR-8) air surveillance radar.

pulse generator (APG), located in the rotary joint, transmits to the radar indicator azimuth information corresponding to beam direction. Polarization of the radiated energy can be remotely switched to either linear or circular polarization. The reflector has a modified parabolic shape designed to produce an approximately cosecant squared beam in the elevation plane. The reflector surface, covered with expanded aluminum screen, is 16.1 feet wide and 9 feet high. The antenna feedhorn, which mounts on the polarizer, provides impedance matching between the waveguide system and free space, and produces the desired feed pattern to illuminate the reflector. A radome over the horn aperture excludes moisture and foreign matter, and provides a pressure seal.

AS-3263/SPS-49(V)

The AS-3263/SPS-49(V) antenna (fig. 2-46) consists of three major sections: the antenna base and pedestal assembly, the feedhorn and feedhorn support boom, and the reflector assembly.

The base assembly provides a surface for mounting the antenna to the ship. It also contains the azimuth drive gearbox. The gearbox is driven by the azimuth drive motor, which drives the pedestal in azimuth through a pinion gear mated to a ring gear located at the bottom of the cone-shaped pedestal assembly, The azimuth drive circuits rotate the antenna through 360 degrees at speeds of 6 rpm and 12 rpm.

The reflector and the feedhorn support boom are mounted on a trunnion, allowing the elevation angle of the rf beam to be controlled by a jackscrew located behind the reflector. The jackscrew is rotated by the elevation drive gearbox, which is connected to two dc motors. The rf energy to the feedhorn is routed through elevation and azimuth rotary joints located within the pedestal.

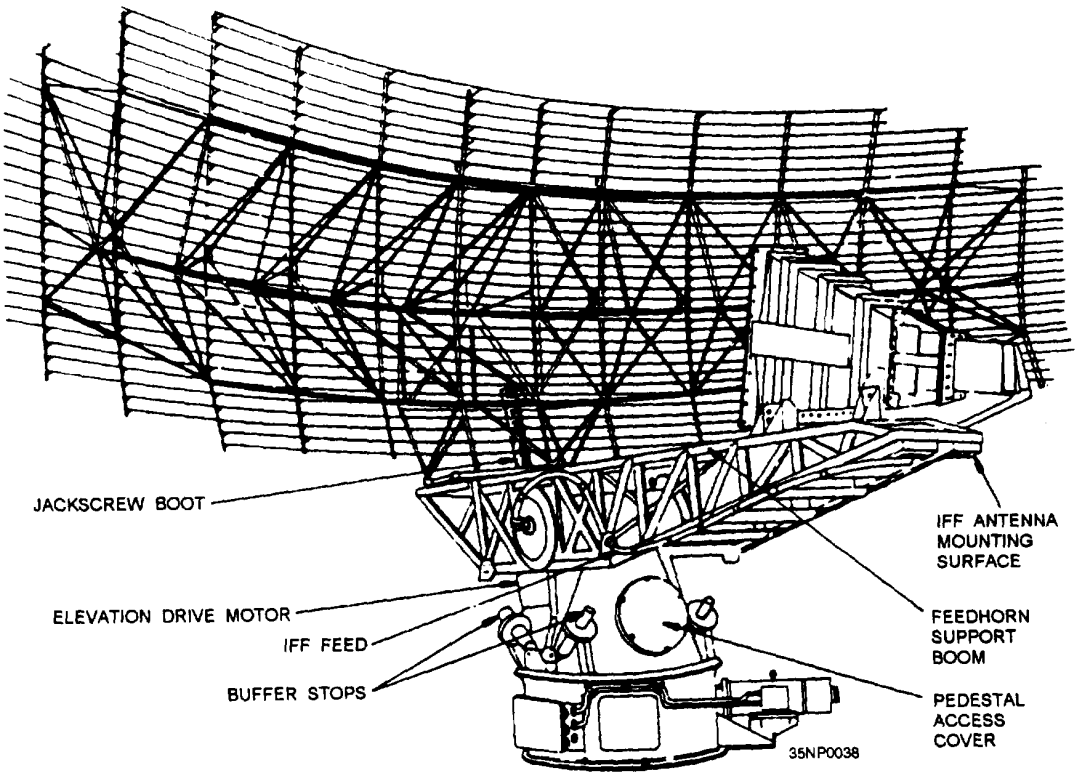

Figure 2-46.—AS-3263/SPS-49(V) antenna.

The reflector is 24 feet wide and has a double-curved surface composed of a series of horizontal members that form a reflecting surface for the horizontally polarized C-band energy. The antenna has a 28-dB gain, with a beamwidth of 9 degrees minimum vertically and approximately 3.3 degrees horizontally. Antenna roll and pitch stabilization limits are plus or minus 25 degrees, Stabilization accuracy is plus or minus 1 degree with the horizontal plane.

The antenna is equipped with a safety switch located near the antenna pedestal area. The safety switch disables the azimuth and elevation functions in the antenna and the radiate function in the transmitter to provide protection for personnel working on the antenna.

OE-172/SPS-55

The OE-172/SPS-55 antenna group consists of the antenna and the antenna pedestal. The antenna group is mast-mounted by means of four bolt holes on the base of the pedestal.

The antenna consists of two waveguide slotted arrays mounted back-to-back. One array provides linear polarization, while the other provides circular polarization. The array used is selected by means of a remotely controlled waveguide switch located on the pedestal. Linear polarization is used for most conditions. Circular polarization is used to reduce return echoes from precipitation. Each antenna forms a fan beam that is narrow in the azimuth plane and moderately broad in the elevation plane.

Figure 2-47 shows a cross-section of the SPS-55 antenna. During transmission, the rf signal enters the antenna through a feed waveguide and then enters a feed manifold region of 80 periodic narrow-wall slots. The slots are skewed in angle and alternated in direction of skew. They are separated by approximately one-half wavelength, resulting in broadside radiation into the sectoral horn region of the antenna. The horizontally polarized radiation from the manifold travels in the horn region toward the aperture, where it encounters an array of vertical sheet metal slats.

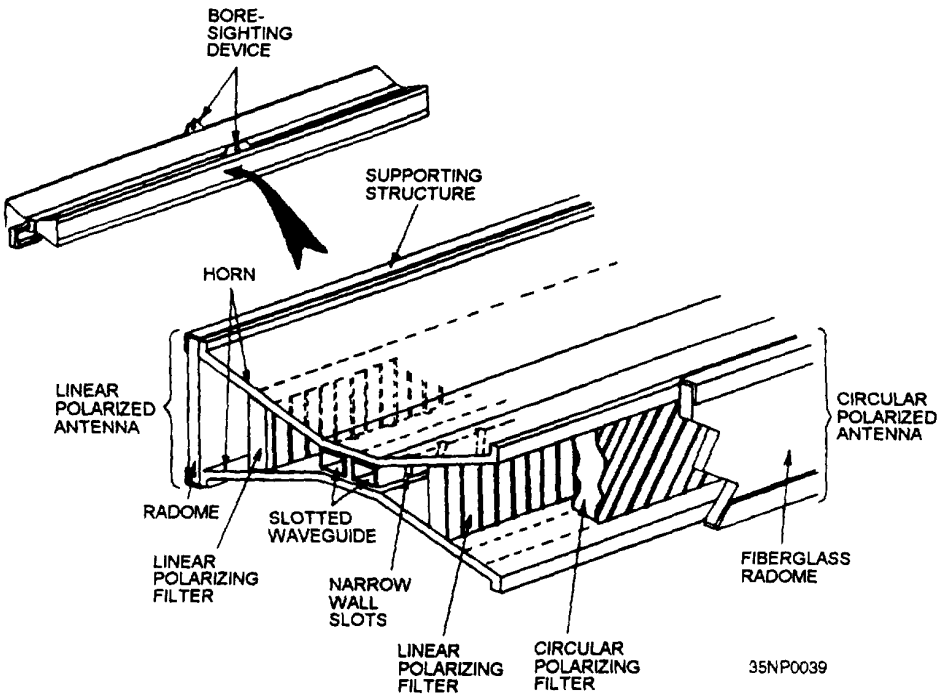

Figure 2-47.—SPS-55 antenna cross section.

This array is a polarizing filter, which ensures that only horizontally polarized energy travels from the horn region. The antenna scans at a rate of 16 rpm and produces an absolute gain of 31 dB at midband.

AN/SPN-35A AIRCRAFT CONTROL APPROACH RADAR

The AN/SPN-35A (fig 2-48) is a carrier-controlled-approach (CCA) radar set used for precision landing approaches during adverse weather conditions. The radar displays both azimuth and elevation data, which enables the radar operator to direct aircraft along a predetermined glide path and azimuth course line to a transition point approximately 2 miles from the ramp of the flight deck.

The azimuth antenna, AS-1292/TPN-8, functions in the azimuth rf line for radiation and reception of X-band rf pulses. The azimuth antenna comprises a truncated paraboloid-type reflector with an offset feedhorn and a polarizer assembly that provides remote-controlled selection of either horizontal or circular polarization. The antenna is located above the azimuth drive assembly on the stabilized yoke. The azimuth drive can rotate the antenna in either 360 degrees or in limited-sector modes of operation in the horizontal plane.

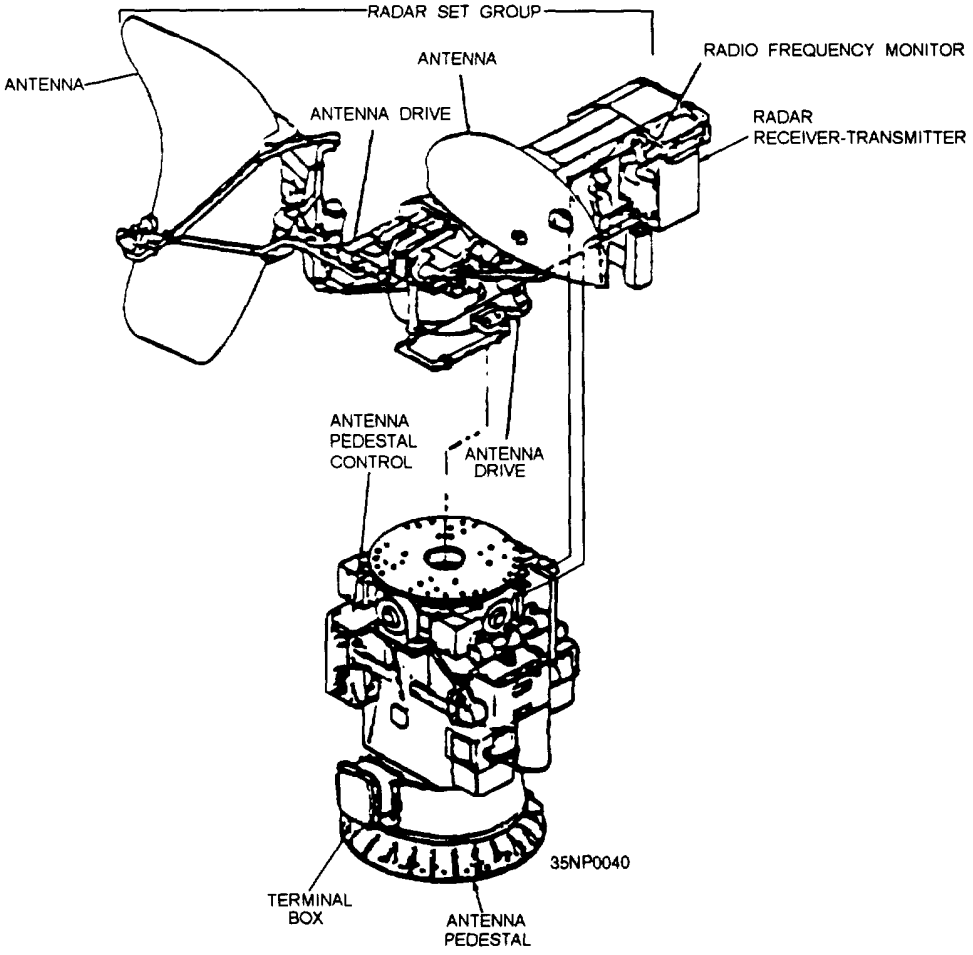

Figure 2-48.—AN/SPN-3SA aircraft control approach radar.

The elevation antenna, AS-1669/SPN-35, is a truncated paraboloid-type reflector with a dual-channel feedhorn and a polarizer assembly providing monopulse-type radiation and reception of X-band rf pulses. The horizontal shape of the laminated fiberglass reflector is cosecanted. The dual-channel feedhorn and polarizer are fixed in circular polarization by an external grid device. The elevation antenna is stabilized-yoke mounted on the elevation drive assembly adjacent to the azimuth antenna. The elevation drive provides the required motion for the elevation antenna and locks electrically with the search drive when the radar set operates in the precision mode.

The radar operates in three modes, final, surveillance, and simultaneous, with each antenna acting independently. In the final (precision) mode, the azimuth antenna scans a 30-degree sector (60-degree sector optional) while the elevation antenna scans a 10-degree sector (35-degree sector optional). In the surveillance mode the azimuth antenna rotates through the full 360-degree search pattern at 16 rpm while the elevation antenna scans a 10-degree sector. In the simultaneous mode, the azimuth antenna rotates through the full 360-degrees search pattern in 60-degree increments while the elevation antenna scans a 10-degree sector. The data rate in this mode is approximately 16 azimuth sweeps and 24 elevation sweeps every 60 seconds.

The antenna pedestal control stabilizes the azimuth and elevation antennas for plus or minus 3 degrees of pitch and plus or minus 10 degrees of roll.

RF SAFETY PRECAUTIONS

Although radio frequency emissions are usually harmless, there are still certain safety precautions you should follow whenever you are near high-power rf sources. Normally, electromagnetic radiation from transmission lines and antennas isn't strong enough to electrocute personnel. However, it may lead to other accidents and can compound injuries. Voltages may be induced into metal objects both above and below ground, such as wire guys, wire cable, hand rails, and ladders. If you come into contact with these objects, you may receive a shock or an rf burn. The shock can cause you to jump involuntarily, to fall into nearby equipment, or, when working aloft, to fall from the elevated work area. Take care to ensure that all transmission lines or antennas are de-energized before working on or near them.

When working aloft aboard ship, be sure to use a working aloft chit. This will ensure that all radiators, not only those on your own ship but also those nearby are secured while you are aloft.

ALWAYS obey rf radiation warning signs and keep a safe distance from radiating antennas. The six types of warning signs for rf radiation hazards are shown in figure 2-49.

The two primary safety concerns associated with rf fields are rf burns and injuries caused by dielectric heating.

RF BURNS

Close or direct contact with rf transmission lines or antennas may result in rf burns caused by induced voltages. These burns are usually deep, penetrating, third-degree burns. To heal properly, rf burns must heal from the inside toward the skin's surface. Do **NOT** take rf burns lightly. To prevent infection, you must give proper attention to **ALL** rf burns, including the small pinhole burns. **ALWAYS** seek treatment for any rf burn or shock and report the incident to your supervisor so appropriate action can be taken to correct the hazard.

DIELECTRIC HEATING

While the severity of rf burns may vary from minor to major, burns or other damage done by DIELECTRIC HEATING may result in long-term injury, or even death. Dielectric heating is the heating of an insulating material caused by placing it in a high-frequency electric field. The heat results from the rapid reversal of molecular polarization dielectric material.

When a human is in an rf field, the body acts as the dielectric. If the power in the rf field exceeds 10 milliwatts per centimeter, the individual will have a noticeable rise in body temperature. Basically, the body is “cooking” in the rf field. The vital organs

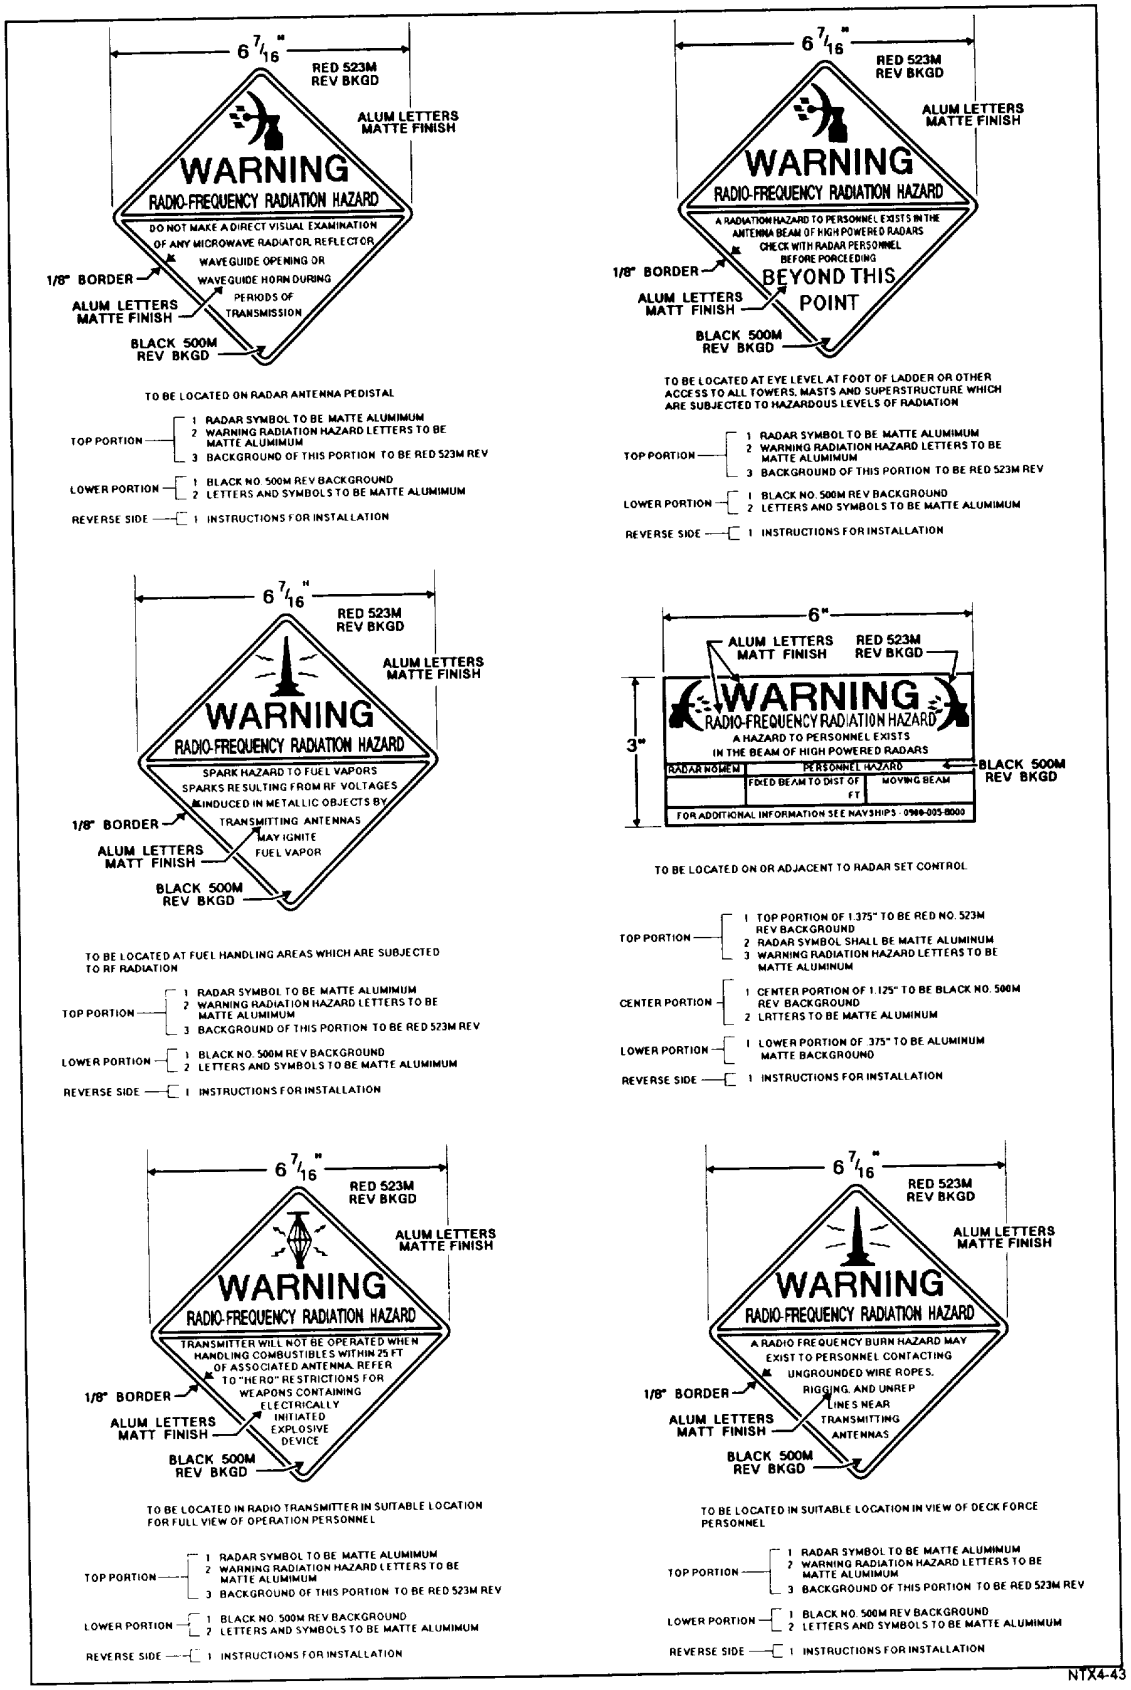

Figure 2-49.—Rf radiation warning signs

of the body are highly susceptible to dielectric heating. The eyes are also highly susceptible to dielectric heating. Do NOT look directly into devices radiating rf energy. Remember, rf radiation can be dangerous. For your own safety, you must NOT stand directly in the path of rf radiating devices.

PRECAUTIONS WHEN WORKING ALOFT

As we mentioned earlier, it is extremely important to follow all safety precautions when working aloft. Before you work on an antenna, ensure that it is tagged out properly at the switchboard to prevent it from becoming operational. Always be sure to secure the motor safety switches for rotating antennas. Have the switches tagged and locked open before you begin working on or near the antenna.

When working near a stack, draw and wear the recommended oxygen breathing apparatus. Among other toxic substances, stack gas contains carbon monoxide. Carbon monoxide is too unstable to build up to a high concentration in the open, but prolonged exposure to even small quantities is dangerous.

For more detailed information concerning the dangers and hazards of rf radiation, refer to the NAVELEX technical manual, *Electromagnetic Radiation Hazards.* NAVELEX 0967-LP-624-6010.

This completes chapter 2. In chapter 3, we will discuss transmission lines and waveguides.

CHAPTER 3

INTRODUCTION TO TRANSMISSION LINES AND WAVEGUIDES

A TRANSMISSION LINE is a device designed to guide electrical energy from one point to another. It is used, for example, to transfer the output rf energy of a transmitter to an antenna. This energy will not travel through normal electrical wire without great losses. Although the antenna can be connected directly to the transmitter, the antenna is usually located some distance away from the transmitter. On board ship, the transmitter is located inside a radio room, and its associated antenna is mounted on a mast. A transmission line is used to connect the transmitter and the antenna.

The transmission line has a single purpose for both the transmitter and the antenna. This purpose is to transfer the energy output of the transmitter to the antenna with the least possible power loss. How well this is done depends on the special physical and electrical characteristics (impedance and resistance) of the transmission line.

TRANSMISSION LINE THEORY

The electrical characteristics of a two-wire transmission line depend primarily on the construction of the line. The two-wire line acts like a long capacitor. The change of its capacitive reactance is noticeable as the frequency applied to it is changed. Since the long conductors have a magnetic field about them when electrical energy is being passed through them, they also exhibit the properties of inductance. The values of inductance and capacitance presented depend on the various physical factors that we discussed earlier. For example, the type of line used, the dielectric in the line, and the length of the line must be considered. The effects of the inductive and capacitive reactance of the line depend on the frequency applied. Since no dielectric is perfect, electrons manage to move from one conductor to the other through the dielectric. Each type of two-wire transmission line also has a conductance value. This conductance value represents the value of the current flow that may be expected through the insulation, If the line is uniform (all values equal at each unit length), then one small section of the line may represent several feet. This illustration of a two-wire transmission line will be used throughout the discussion of transmission lines; but, keep in mind that the principles presented apply to all transmission lines. We will explain the theories using LUMPED CONSTANTS and DISTRIBUTED CONSTANTS to further simplify these principles.

LUMPED CONSTANTS

A transmission line has the properties of inductance, capacitance, and resistance just as the more conventional circuits have. Usually, however, the constants in conventional circuits are lumped into a single device or component. For example, a coil of wire has the property of inductance. When a certain amount of inductance is needed in a circuit, a coil of the proper dimensions is inserted. The inductance of the circuit is lumped into the one component. Two metal plates separated by a small space, can be used to supply the required capacitance for a circuit. In such a case, most of the capacitance of the circuit is lumped into this one component. Similarly, a fixed resistor can be used to supply a certain value of circuit resistance as a lumped sum. Ideally, a transmission line would also have its constants of inductance, capacitance, and resistance lumped together, as shown in figure 3-1. Unfortunately, this is not the case. Transmission line constants are as described in the following paragraphs.

DISTRIBUTED CONSTANTS

Transmission line constants, called distributed constants, are spread along the entire length of the transmission line and cannot be distinguished separately. The amount of inductance, capacitance, and resistance depends on the length of the line, the size of the conducting wires, the spacing between the

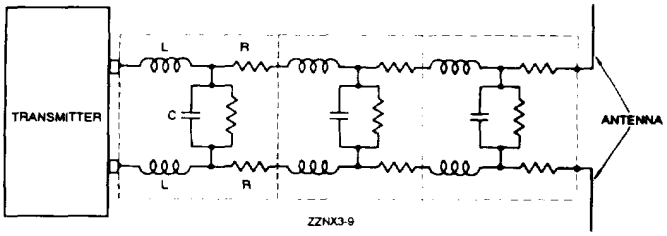

Figure 3-1.—Two-wire transmission line.

wires, and the dielectric (air or insulating medium) between the wires. The following paragraphs will be useful to you as you study distributed constants on a transmission line.

Inductance of a Transmission Line

When current flows through a wire, magnetic lines of force are set up around the wire. As the current increases and decreases in amplitude, the field around the wire expands and collapses accordingly. The energy produced by the magnetic lines of force collapsing back into the wire tends to keep the current flowing in the same direction. This represents a certain amount of inductance, which is expressed in microhenrys per unit length. Figure 3-2 illustrates the inductance and magnetic fields of a transmission line.

Capacitance of a Transmission Line

Capacitance also exists between the transmission line wires, as illustrated in figure 3-3. Notice that the two parallel wires act as plates of a capacitor and that the air between them acts as a dielectric. The capacitance between the wires is usually expressed in picofarads per unit length. This electric field between the wires is similar to the field that exists between the two plates of a capacitor.

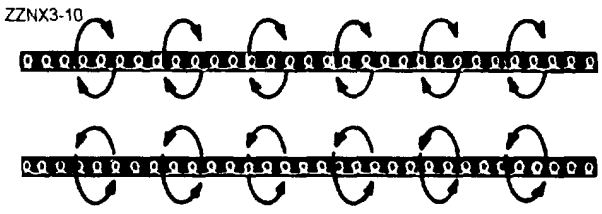

Figure 3-2.—Distributed inductance.

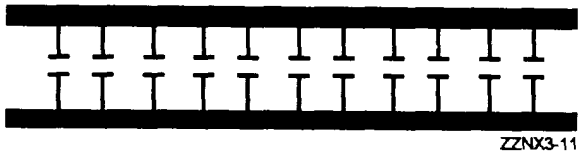

Figure 3-3.—Distributed capacitance.

Resistance of a Transmission Line

The transmission line shown in figure 3-4 has electrical resistance along its length. This resistance is usually expressed in ohms per unit length and is shown as existing continuously from one end of the line to the other.

Figure 3-4.—Distributed resistance.

Leakage Current

Since any dielectric, even air, is not a perfect insulator, a small current known as LEAKAGE CURRENT flows between the two wires. In effect, the insulator acts as a resistor, permitting current to pass between the two wires. Figure 3-5 shows this leakage path as resistors in parallel connected between the two lines. This property is called CONDUCTANCE (G) and is the opposite of resistance. Conductance in transmission lines is expressed as the reciprocal of resistance and is usually given in micromhos per unit length.

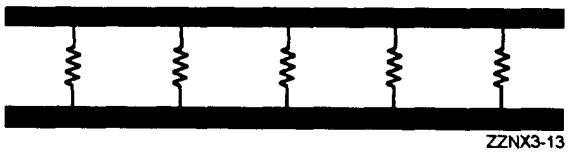

Figure 3-5.—Leakage in a transmission line.

ELECTROMAGNETIC FIELDS

The distributed constants of resistance, inductance, and capacitance are basic properties common to all transmission lines and exist whether or not any current flow exists. As soon as current flow and voltage exist in a transmission line, another property becomes quite evident. This is the presence of an electromagnetic field, or lines of force, about the wires of the transmission line. The lines of force themselves are not visible; however, understanding the force that an electron experiences while in the field of these lines is very important to your understanding of energy transmission.

There are two kinds of fields; one is associated with voltage and the other with current. The field associated with voltage is called the ELECTRIC (E) FIELD. It exerts a force on any electric charge placed in it. The field associated with current is called a MAGNETIC (H) FIELD, because it tends to exert a force on any magnetic pole placed in it. Figure 3-6 illustrates the way in which the E fields and H fields tend to orient themselves between conductors of a typical two-wire transmission line. The illustration shows a cross section of the transmission lines. The E field is represented by solid lines and the H field by dotted lines. The arrows indicate the direction of the lines of force. Both fields normally exist together and are spoken of collectively as the electromagnetic field.

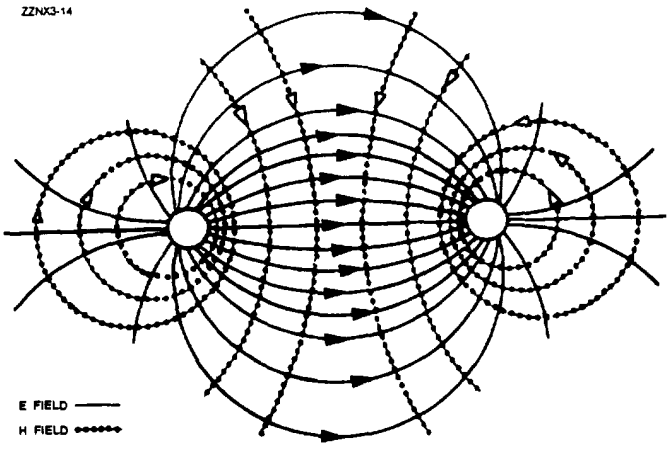

Figure 3-6.—Fields between conductors.

CHARACTERISTIC IMPEDANCE

You can describe a transmission line in terms of its impedance. The ratio of voltage to current (E_{in}/I_{in}) at the input end is known as the INPUT IMPEDANCE (Z_{in}). This is the impedance presented to the transmitter by the transmission line and its load, the antenna. The ratio of voltage to current at the output (E_{OUT}/I_{OUT}) end is known as the OUTPUT IMPEDANCE (Z_{OUT}). This is the impedance presented to the load by the transmission line and its source. If an infinitely long transmission line could be used, the ratio of voltage to current at any point on that transmission line would be some particular value of impedance. This impedance is known as the CHARACTERISTIC IMPEDANCE.

The maximum (and most efficient) transfer of electrical energy takes place when the source impedance is matched to the load impedance. This fact is very important in the study of transmission lines and antennas. If the characteristic impedance of the transmission line and the load impedance are equal, energy from the transmitter will travel down the transmission line to the antenna with no power loss caused by reflection.

LINE LOSSES

The discussion of transmission lines so far has not directly addressed LINE LOSSES; actually some losses occur in all lines. Line losses may be any of three types—COPPER, DIELECTRIC, and RADIATION or INDUCTION LOSSES.

NOTE: Transmission lines are sometimes referred to as rf lines. In this text the terms are used interchangeably.

Copper Losses

One type of copper loss is I^2R LOSS. In rf lines the resistance of the conductors is never equal to zero. Whenever current flows through one of these conductors, some energy is dissipated in the form of heat. This heat loss is a POWER LOSS. With copper braid, which has a resistance higher than solid tubing, this power loss is higher.

Another type of copper loss is due to SKIN EFFECT. When dc flows through a conductor, the movement of electrons through the conductor's cross section is uniform, The situation is somewhat different when ac is applied. The expanding and collapsing fields about each electron encircle other electrons. This phenomenon, called SELF INDUCTION, retards the movement of the encircled electrons. The flux density at the center is so great that electron movement at this point is reduced. As frequency is increased, the opposition to the flow of current in the center of the wire increases. Current in the center of the wire becomes smaller and most of the electron flow is on the wire surface. When the frequency applied is 100 megahertz or higher, the electron movement in the center is so small that the center of the wire could be removed without any noticeable effect on current. You should be able to see that the effective cross-sectional area decreases as the frequency increases. Since resistance is inversely proportional to the cross-sectional area, the resistance will increase as the frequency is increased. Also, since power loss increases as resistance increases, power losses increase with an increase in frequency because of skin effect.

Copper losses can be minimized and conductivity increased in an rf line by plating the line with silver. Since silver is a better conductor than copper, most of the current will flow through the silver layer. The tubing then serves primarily as a mechanical support.

Dielectric Losses

DIELECTRIC LOSSES result from the heating effect on the dielectric material between the conductors. Power from the source is used in heating the dielectric. The heat produced is dissipated into the surrounding medium. When there is no potential difference between two conductors, the atoms in the dielectric material between them are normal and the orbits of the electrons are circular. When there is a potential difference between two conductors, the orbits of the electrons change. The excessive negative charge on one conductor repels electrons on the dielectric toward the positive conductor and thus distorts the orbits of the electrons. A change in the path of electrons requires more energy, introducing a power loss.

The atomic structure of rubber is more difficult to distort than the structure of some other dielectric materials. The atoms of materials, such as polyethylene, distort easily. Therefore, polyethylene is often used as a dielectric because less power is consumed when its electron orbits are distorted.

Radiation and Induction Losses

RADIAION and INDUCTION LOSSES are similar in that both are caused by the fields surrounding the conductors. Induction losses occur when the electromagnetic field about a conductor cuts through any nearby metallic object and a current is induced in that object. As a result, power is dissipated in the object and is lost.

Radiation losses occur because some magnetic lines of force about a conductor do not return to the conductor when the cycle alternates. These lines of force are projected into space as radiation, and this results in power losses. That is, power is supplied by the source, but is not available to the load.

VOLTAGE CHANGE

In an electric circuit, energy is stored in electric and magnetic fields. These fields must be brought to the load to transmit that energy. At the load, energy contained in the fields is converted to the desired form of energy.

Transmission of Energy

When the load is connected directly to the source of energy, or when the transmission line is short, problems concerning current and voltage can be solved by applying Ohm's law. When the transmission line becomes long enough so the time difference between a change occurring at the generator and a change appearing at the load becomes appreciable, analysis of the transmission line becomes important.

Dc Applied to a Transmission Line

In figure 3-7, a battery is connected through a relatively long two-wire transmission line to a load at the far end of the line. At the instant the switch

is closed, neither current nor voltage exists on the line. When the switch is closed, point A becomes a positive potential, and point B becomes negative. These points of difference in potential move down the line. However, as the initial points of potential leave points A and B, they are followed by new points of difference in potential, which the battery adds at A and B. This is merely saying that the battery maintains a constant potential difference between points A and B. A short time after the switch is closed, the initial points of difference in potential have reached points A' and B'; the wire sections from points A to A' and points B to B' are at the same potential as A and B, respectively. The points of charge are represented by plus (+) and minus (-) signs along the wires, The directions of the currents in the wires are represented by the arrowheads on the line, and the direction of travel is indicated by an arrow below the line. Conventional lines of force represent the electric field that exists between the opposite kinds of charge on the wire sections from A to A' and B to B'. Crosses (tails of arrows) indicate the magnetic field created by the electric field moving down the line. The moving electric field and the accompanying magnetic field constitute an electromagnetic wave that is moving from the generator (battery) toward the load. This wave travels at approximately the speed of light in free space. The energy reaching the load is equal to that developed at the battery (assuming there are no losses in the transmission line). If the load absorbs all of the energy, the current and voltage will be evenly distributed along the line.

Ac Applied to a Transmission Line

When the battery of figure 3-7 is replaced by an ac generator (fig. 3-8), each successive instantaneous value of the generator voltage is propagated down the

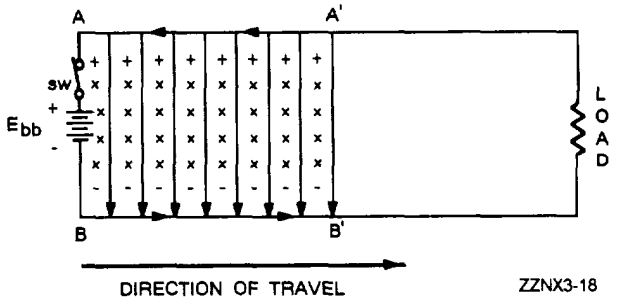

Figure 3-7.—Dc voltage applied to a line.

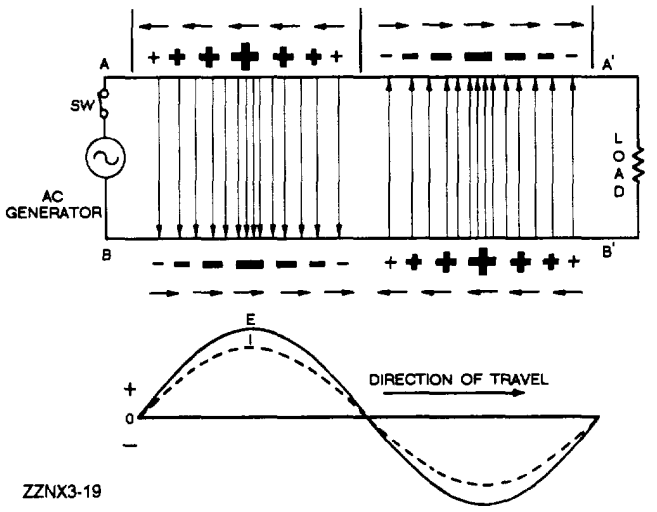

Figure 3-8.—Ac voltage applied to a line.

line at the speed of light. The action is similar to the wave created by the battery, except the applied voltage is sinusoidal instead of constant. Assume that the switch is closed at the moment the generator voltage is passing through zero and that the next half cycle makes point A positive. At the end of one cycle of generator voltage, the current and voltage distribution will be as shown in figure 3-8.

In this illustration the conventional lines of force represent the electric fields. For simplicity, the magnetic fields are not shown. Points of charge are indicated by plus (+) and minus (-) signs, the larger signs indicating points of higher amplitude of both voltage and current. Short arrows indicate direction of current (electron flow). The waveform drawn below the transmission line represents the voltage (E) and current (I) waves. The line is assumed to be infinite in length so there is no reflection. Thus, traveling sinusoidal voltage and current waves continually travel in phase from the generator toward the load, or far end of the line. Waves traveling from the generator to the load are called INCIDENT WAVES. Waves traveling from the load back to the generator are called REFLECTED WAVES and will be explained in later paragraphs.

STANDING-WAVE RATIO

The measurement of standing waves on a transmission line yields information about equipment operating

conditions. Maximum power is absorbed by the load when $Z_L = Z_0$. If a line has no standing waves, the termination for that line is correct and maximum power transfer takes place.

You have probably noticed that the variation of standing waves shows how near the rf line is to being terminated in Z_0. A wide variation in voltage along the length means a termination far from Z_0. A small variation means termination near Z_0. Therefore, the ratio of the maximum to the minimum is a measure of the perfection of the termination of a line. This ratio is called the STANDING-WAVE RATIO (swr) and is always expressed in whole numbers. For example, a ratio of 1:1 describes a line terminated in its characteristic impedance (Z_0).

Voltage Standing-Wave Ratio

The ratio of maximum voltage to minimum voltage on a line is called the VOLTAGE STANDING-WAVE RATIO (vswr). Therefore:

$$\text{vswr} = \left| \frac{E_{max}}{E_{min}} \right|$$

The vertical lines in the formula indicate that the enclosed quantities are absolute and that the two values are taken without regard to polarity, Depending on the nature of the standing waves, the numerical value of vswr ranges from a value of 1 ($Z_L = Z_0$, no standing waves) to an infinite value for theoretically complete reflection. Since there is always a small loss on a line, the minimum voltage is never zero and the vswr is always some finite value. However, if the vswr is to be a useful quantity. the power losses along the line must be small in comparison to the transmitted power.

Power Standing-Wave Ratio

The square of the vswr is called the POWER STANDING-WAVE RATIO (pswr). Therefore:

$$\text{pswr} = \frac{P_{max}}{P_{min}}$$

This ratio is useful because the instruments used to detect standing waves react to the square of the voltage. Since power is proportional to the square of the voltage, the ratio of the square of the maximum and minimum voltages is called the power standing-wave ratio. In a sense, the name is misleading because the power along a transmission line does not vary.

Current Standing-Wave Ratio

The ratio of maximum to minimum current along a transmission line is called CURRENT STANDING- WAVE RATIO (iswr). Therefore:

$$\text{iswr} = \left| \frac{I_{max}}{I_{min}} \right|$$

This ratio is the same as that for voltages. It can be used where measurements are made with loops that sample the magnetic field along a line. It gives the same results as vswr measurements.

TRANSMISSION MEDIUMS

The Navy uses many different types of TRANSMISSION MEDIUMS in its electronic applications. Each medium (line or waveguide) has a certain characteristic impedance value, current-carrying capacity, and physical shape and is designed to meet a particular requirement.

The five types of transmission mediums that we will discuss in this topic include PARALLEL-LINE, TWISTED PAIR, SHIELDED PAIR, COAXIAL LINE, and WAVEGUIDES. The use of a particular line depends, among other things, on the applied frequency, the power-handling capabilities, and the type of installation.

Parallel Line

One type of parallel line is the TWO-WIRE OPEN LINE, illustrated in figure 3-9. This line consists of two wires that are generally spaced from 2 to 6 inches apart by insulating spacers. This type of line is most often used for power lines, rural telephone lines, and telegraph lines. It is sometimes used as a transmission line between a transmitter and an antenna or between an antenna and a receiver. An advantage of this type

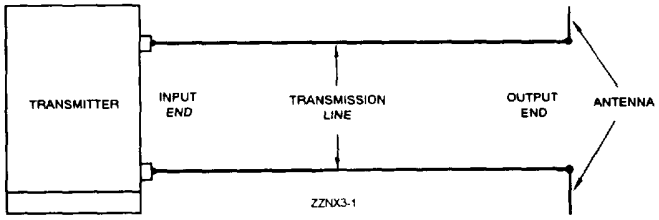

Figure 3-9.—Two-wire open line.

of line is its simple construction. The principal disadvantages of this type of line are the high radiation losses and electrical noise pickup because of the lack of shielding. Radiation losses are produced by the changing fields created by the changing current in each conductor.

Another type of parallel line is the TWO-WIRE RIBBON (TWIN LEAD) LINE, illustrated in figure 3-10. This type of transmission line is commonly used to connect a television receiving antenna to a home television set. This line is essentially the same as the two-wire open line except that uniform spacing is assured by embedding the two wires in a low-loss dielectric, usually polyethylene. Since the wires are embedded in the thin ribbon of polyethylene, the dielectric space is partly air and partly polyethylene.

Twisted Pair

The TWISTED PAIR transmission line is illustrated in figure 3-11. As the name implies, the line consists of two insulated wires twisted together to form a flexible line without the use of spacers. It is not used for transmitting high frequency because of the high dielectric losses that occur in the rubber insulation. When the line is wet, the losses increase greatly.

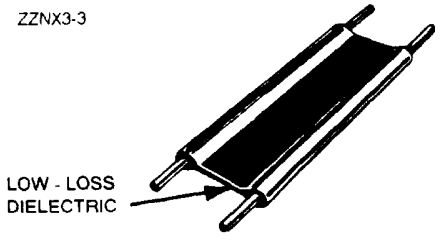

Figure 3-10.—Two-wire ribbon line.

Figure 3-11.—Twisted pair.

Shielded Pair

The SHIELDED PAIR, shown in figure 3-12, consists of parallel conductors separated from each other and surrounded by a solid dielectric. The conductors are contained within a braided copper tubing that acts as an electrical shield. The assembly is covered with a rubber or flexible composition coating that protects the line from moisture and mechanical damage. Outwardly, it looks much like the power cord of a washing machine or refrigerator.

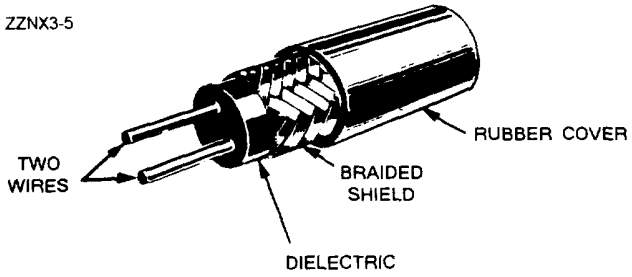

Figure 3-12.—Shielded pair.

The principal advantage of the shielded pair is that the conductors are balanced to ground; that is, the capacitance between the wires is uniform throughout the length of the line. This balance is due to the uniform spacing of the grounded shield that surrounds the wires along their entire length. The braided copper shield isolates the conductors from stray magnetic fields.

Coaxial Lines

There are two types of COAXIAL LINES, RIGID (AIR) COAXIAL LINE and FLEXIBLE (SOLID) COAXIAL LINE. The physical construction of both types is basically the same; that is, each contains two concentric conductors.

The rigid coaxial line consists of a central, insulated wire (inner conductor) mounted inside a tubular outer conductor. This line is shown in figure 3-13. In some applications, the inner conductor is also tubular. The inner conductor is insulated from the outer conductor by insulating spacers or beads at regular intervals. The spacers are made of Pyrex, polystyrene, or some other material that has good insulating characteristics and low dielectric losses at high frequencies.

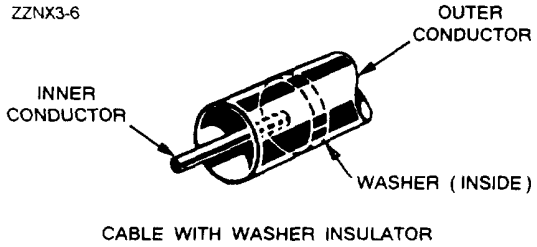

Figure 3-13.—Air coaxial line.

The chief advantage of the rigid line is its ability to minimize radiation losses. The electric and magnetic fields in a two-wire parallel line extend into space for relatively great distances and radiation losses occur. However, in a coaxial line no electric or magnetic fields extend outside of the outer conductor. The fields are confined to the space between the two conductors, resulting in a perfectly shielded coaxial line. Another advantage is that interference from other lines is reduced.

The rigid line has the following disadvantages: (1) it is expensive to construct; (2) it must be kept dry to prevent excessive leakage between the two conductors; and (3) although high-frequency losses are somewhat less than in previously mentioned lines, they are still excessive enough to limit the practical length of the line.

Leakage caused by the condensation of moisture is prevented in some rigid line applications by the use of an inert gas, such as nitrogen, helium, or argon. It is pumped into the dielectric space of the line at a pressure that can vary from 3 to 35 pounds per square inch. The inert gas is used to dry the line when it is first installed and pressure is maintained to ensure that no moisture enters the line.

Flexible coaxial lines (fig. 3-14) are made with an inner conductor that consists of flexible wire insulated from the outer conductor by a solid, continuous insulating material. The outer conductor is made of metal braid, which gives the line flexibility. Early attempts at gaining flexibility involved using rubber insulators between the two conductors. However, the rubber insulators caused excessive losses at high frequencies.

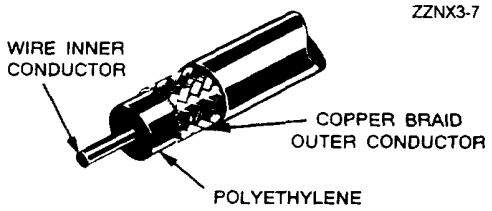

Figure 3-14.—Flexible coaxial line.

Because of the high-frequency losses associated with rubber insulators, polyethylene plastic was developed to replace rubber and eliminate these losses. Polyethylene plastic is a solid substance that remains flexible over a wide range of temperatures. It is unaffected by seawater, gasoline, oil, and most other liquids that may be found aboard ship. The use of polyethylene as an insulator results in greater high-frequency losses than the use of air as an insulator. However, these losses are still lower than the losses associated with most other solid dielectric materials.

This concludes our study of transmission lines. The rest of this chapter will be an introduction into the study of waveguides.

WAVEGUIDE THEORY

The two-wire transmission line used in conventional circuits is inefficient for transferring electromagnetic energy at microwave frequencies. At these frequencies, energy escapes by radiation because the fields are not confined in all directions, as illustrated in figure 3-15. Coaxial lines are more efficient than two-wire lines for transferring electromagnetic energy because the fields are completely confined by the conductors, as illustrated in figure 3-16. Waveguides are the most

efficient way to transfer electromagnetic energy. WAVEGUIDES are essentially coaxial lines without center conductors. They are constructed from conductive material and may be rectangular, circular, or elliptical in shape, as shown in figure 3-17.

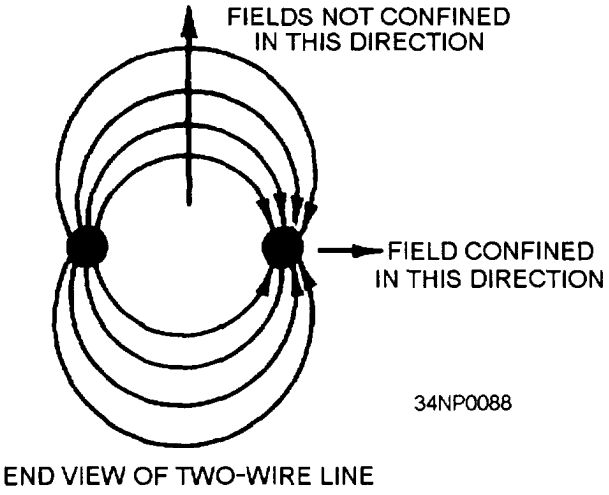

Figure 3-15.—Fields confined in two directions only.

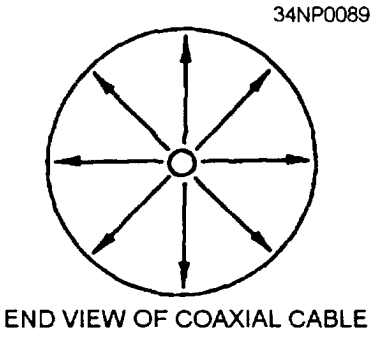

Figure 3-16.—Fields confined in all directions.

WAVEGUIDE ADVANTAGES

Waveguides have several advantages over two-wire and coaxial transmission lines. For example, the large surface area of waveguides greatly reduces COPPER (1^2R) LOSSES. Two-wire transmission lines have large copper losses because they have a relatively small surface area. The surface area of the outer conductor

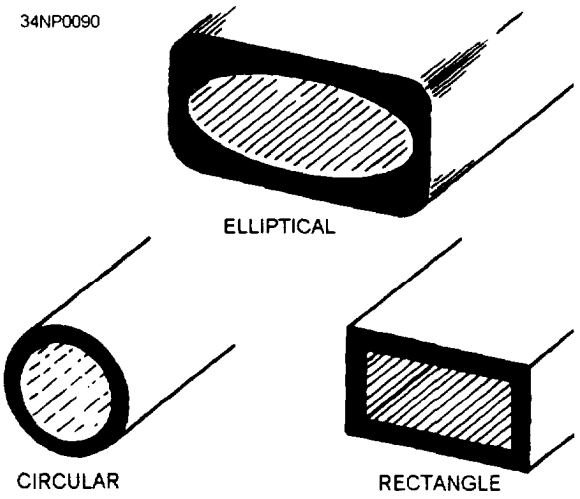

Figure 3-17.—Waveguide shapes.

of a coaxial cable is large, but the surface area of the inner conductor is relatively small. At microwave frequencies, the current-carrying area of the inner conductor is restricted to a very small layer at the surface of the conductor by an action called SKIN EFFECT.

Skin effect tends to increase the effective resistance of the conductor. Although energy transfer in coaxial cable is caused by electromagnetic field motion, the magnitude of the field is limited by the size of the current-carrying area of the inner conductor. The small size of the center conductor is even further reduced by skin effect, and energy transmission by coaxial cable becomes less efficient than by waveguides. DIELECTRIC LOSSES are also lower in waveguides than in two-wire and coaxial transmission lines. Dielectric losses in two-wire and coaxial lines are caused by the heating of the insulation between the conductors. The insulation behaves as the dielectric of a capacitor formed by the two wires of the transmission line. A voltage potential across the two wires causes heating of the dielectric and results in a power loss. In practical applications, the actual breakdown of the insulation between the conductors of a transmission line is more frequently a problem than is the dielectric loss.

This breakdown is usually caused by stationary voltage spikes or “nodes,” which are caused by standing waves. Standing waves are stationary and occur when part of the energy traveling down the line

is reflected by an impedance mismatch with the load. The voltage potential of the standing waves at the points of greatest magnitude can become large enough to break down the insulation between transmission line conductors.

The dielectric in waveguides is air, which has a much lower dielectric loss than conventional insulating materials. However, waveguides are also subject to dielectric breakdown caused by standing waves. Standing waves in waveguides cause arcing, which decreases the efficiency of energy transfer and can severely damage the waveguide. Also since the electromagnetic fields are completely contained within the waveguide, radiation losses are kept very low.

Power-handling capability is another advantage of waveguides. Waveguides can handle more power than coaxial lines of the same size because power-handling capability is directly related to the distance between conductors. Figure 3-18 illustrates the greater distance between conductors in a waveguide.

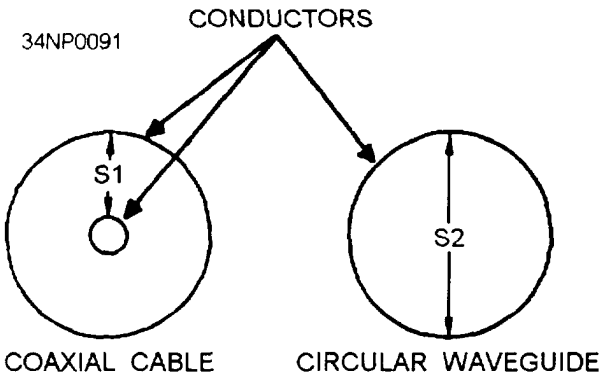

Figure 3-18.—Comparison of spacing in coaxial cable and a circular waveguide.

In view of the advantages of waveguides, you would think that waveguides should be the only type of transmission lines used. However, waveguides have certain disadvantages that make them practical for use only at microwave frequencies.

WAVEGUIDE DISADVANTAGES

Physical size is the primary lower-frequency limitation of waveguides. The width of a waveguide must be approximately a half wavelength at the frequency of the wave to be transported. For example, a waveguide for use at 1 megahertz would be about 700 feet wide. This makes the use of waveguides at frequencies below 1000 megahertz increasingly impractical. The lower frequency range of any system using waveguides is limited by the physical dimensions of the waveguides.

Waveguides are difficult to install because of their rigid, hollow-pipe shape. Special couplings at the joints are required to assure proper operation. Also, the inside surfaces of waveguides are often plated with silver or gold to reduce skin effect losses. These requirements increase the costs and decrease the practicality of waveguide systems at any other than microwave frequencies.

DEVELOPING THE WAVEGUIDE FROM PARALLEL LINES

You may better understand the transition from ordinary transmission line concepts to waveguide theories by considering the development of a waveguide from a two-wire transmission line. Figure 3-19 shows a section of a two-wire transmission line supported on two insulators. At the junction with the line, the insulators must present a very high impedance to ground for proper operation of the line. A low impedance insulator would obviously short-circuit the line to ground, and this is what happens at very high frequencies. Ordinary insulators display the characteristics of the dielectric of a capacitor formed by the wire and ground. As the frequency increases, the overall impedance decreases. A better high-frequency insulator is a quarter-wave section of transmission line shorted at one end. Such an insulator is shown in figure 3-20. The impedance of a shorted quarter-wave section is very high at the open-end junction with the two-wire transmission line. This type of insulator is known as a METALLIC INSULATOR and may be placed anywhere along a two-wire line.

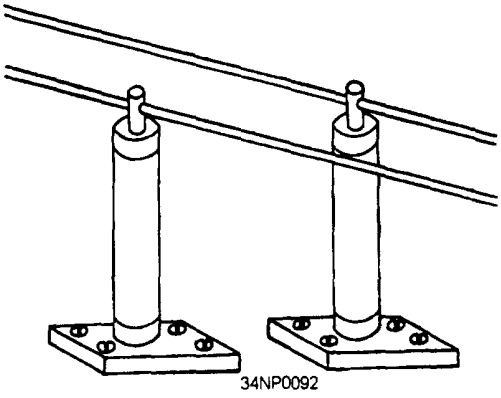

Figure 3-19.—Two-wire transmission line.

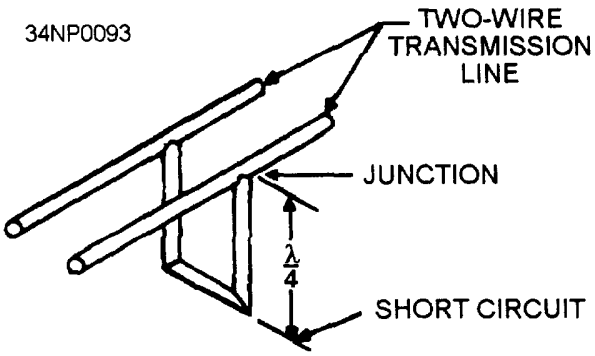

Figure 3-20.—Quarter-wave section of transmission line shorted at one end.

Note that quarter-wave sections are insulators at only one frequency. This severely limits the bandwidth, efficiency, and application of this type of two-wire line.

Figure 3-21 shows several metallic insulators on each side of a two-wire transmission line. As more insulators are added, each section makes contact with the next, and a rectangular waveguide is formed. The lines become part of the walls of the waveguide, as illustrated in figure 3-22. The energy is then conducted within the hollow waveguide instead of along the two-wire transmission line.

The comparison of the way electromagnetic fields work on a transmission line and in a waveguide is not exact. During the change from a two-wire line to a waveguide, the electromagnetic field configurations also undergo many changes. As a result of these changes, the waveguide does not actually operate

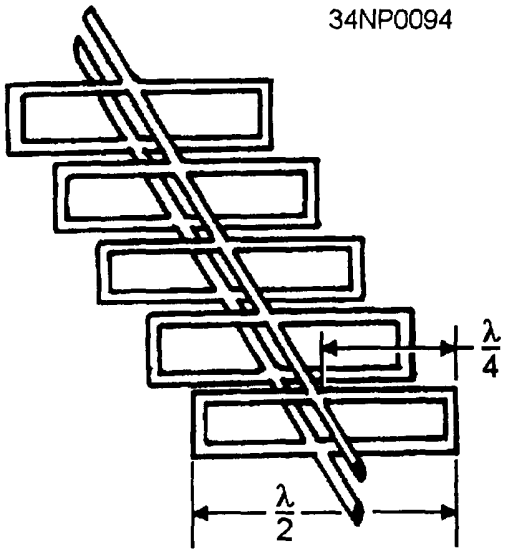

Figure 3-21.—Metallic insulator on each side of a two-wire line.

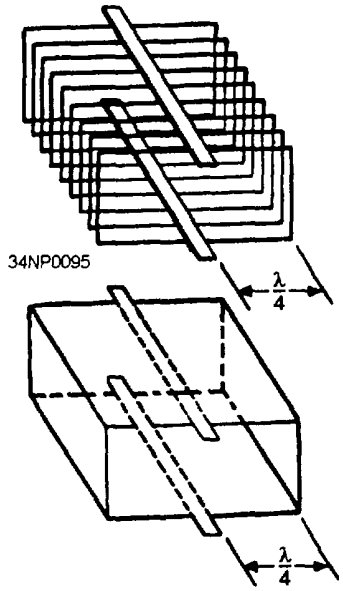

Figure 3-22.—Forming a waveguide by adding quarter-wave sections.

like a two-wire line that is completely shunted by quarter-wave sections. If it did, the use of a waveguide would be limited to a single-frequency wave length that was four times the length of the quarter-wave sections. In fact, waves of this length cannot pass efficiently through waveguides. Only a small range of frequencies of somewhat shorter wavelength (higher frequency) can pass efficiently.

As shown in figure 3-23, the widest dimension of a waveguide is called the “a” dimension and determines the range of operating frequencies. The narrowest dimension determines the power-handling capability of the waveguide and is called the “b” dimension.

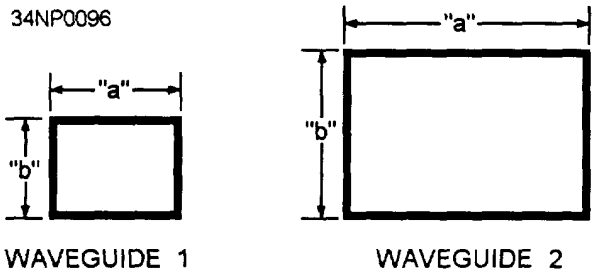

Figure 3-23.—Labeling waveguide dimensions,

NOTE: This method of labeling waveguides is not standard in all texts, Different methods may be used in other texts on microwave principles, but this method is in accordance with Navy Military Standards (MIL-STDS).

In theory, a waveguide could function at an infinite number of frequencies higher than the designed frequency; however, in practice, an upper frequency limit is caused by modes of operation, which will be discussed later.

If the frequency of a signal is decreased so much that two quarter-wavelengths are longer than the wide dimension of a waveguide, energy will no longer pass through the waveguide. This is the lower frequency limit, or CUTOFF FREQUENCY of a given waveguide. In practical applications, the wide dimension of a waveguide is usually 0.7 wavelength at the operating frequency. This allows the waveguide to handle a small range of frequencies both above and below the operating frequency. The “b” dimension is governed by the breakdown potential of the dielectric, which is usually air. Dimensions ranging from 0.2 to 0.5 wavelength are common for the “b” sides of a waveguide.

ENERGY PROPAGATION IN WAVEGUIDES

Since energy is transferred through waveguides by electromagnetic fields, you need a basic understanding of field theory. Both electric (E FIELD) and magnetic fields (H FIELD) are present in waveguides, and the interaction of these fields causes energy to travel through the waveguide. This action is best understood by first looking at the properties of the two individual fields.

E Field

An electric field exists when a difference of potential causes a stress in the dielectric between two points. The simplest electric field is one that forms between the plates of a capacitor when one plate is made positive compared to the other, as shown in view A of figure 3-24. The stress created in the dielectric is an electric field.

Electric fields are represented by arrows that point from the positive toward the negative potential. The number of arrows shows the relative strength of the field. In view B, for example, evenly spaced arrows indicate the field is evenly distributed. For ease of explanation, the electric field is abbreviated E field, and the lines of stress are called E lines.

H Field

The magnetic field in a waveguide is made up of magnetic lines of force that are caused by current flow through the conductive material of the waveguide. Magnetic lines of force, called H lines, are continuous closed loops, as shown in figure 3-25. All of the H lines associated with current are collectively called a magnetic field or H field. The strength of the H field, indicated by the number of H lines in a given area, varies directly with the amount of current.

Although H lines encircle a single, straight wire, they behave differently when the wire is formed into a coil, as shown in figure 3-26. In a coil the individual H lines tend to form around each turn of wire. Since

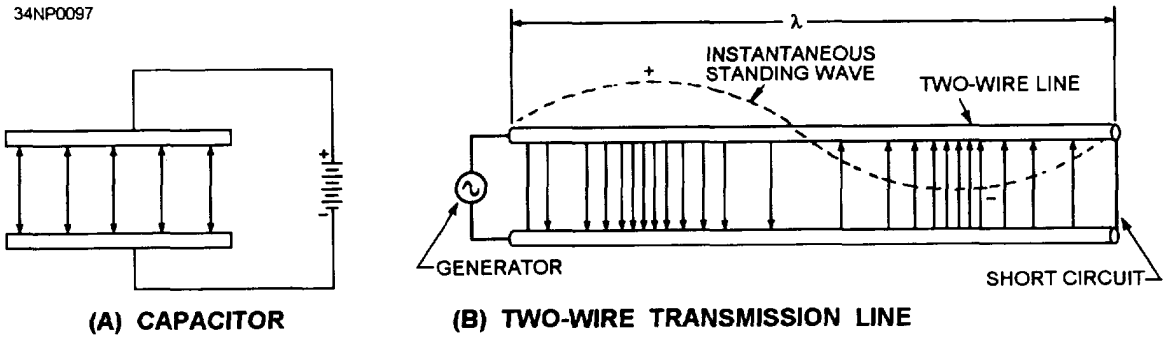

Figure 3-24.—Simple electric fields.

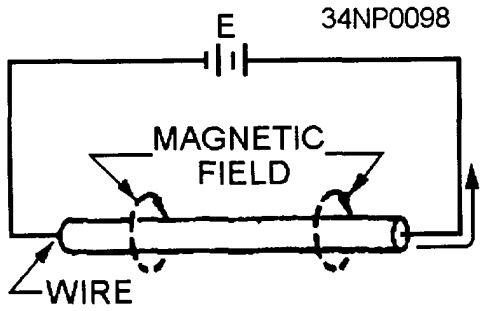

Figure 3-25.—Magnetic field on a single wire.

the H lines take opposite directions between adjacent turns, the field between the turns is canceled. Inside and outside the coil, where the direction of each H field is the same, the fields join and form continuous H lines around the entire coil. A similar action takes place in a waveguide.

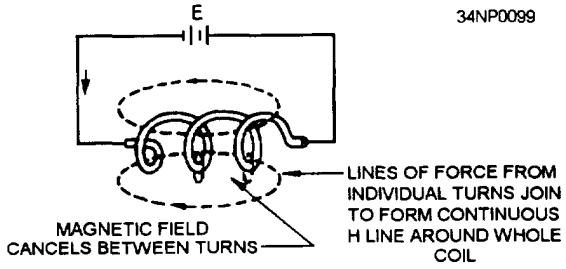

Figure 3-26.—Magnetic field on a coil.

BOUNDARY CONDITIONS IN A WAVEGUIDE

The travel of energy down a waveguide is similar, but not identical, to the travel of electromagnetic waves in free space. The difference is that the energy in a waveguide is confined to the physical limits of the guide. Two conditions, known as BOUNDARY CONDITIONS, must be satisfied for energy to travel through a waveguide.

The first boundary condition (illustrated in fig. 3-27, view A can be stated as follows:

For an electric field to exist at the surface of a conductor, it must be perpendicular to the conductor.

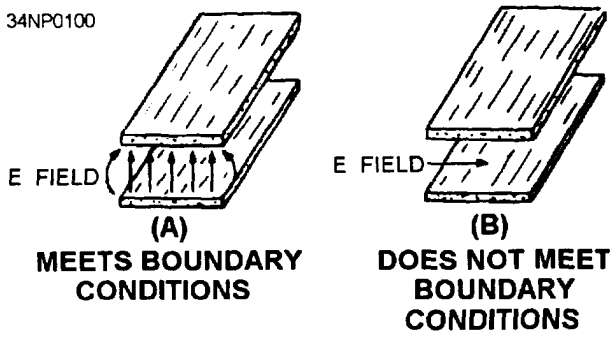

Figure 3-27.—E field boundary condition.

The opposite of this boundary condition, shown in view B, is also true. An electric field CANNOT exist parallel to a perfect conductor.

The second boundary condition, which is illustrated in figure 3-28, can be stated as follows:

For a varying magnetic field to exist, it must form closed loops in parallel with the conductors and be perpendicular to the electric field.

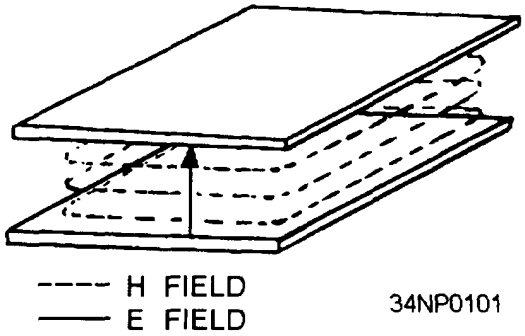

Figure 3-28.—H field boundary condition.

Since an E field causes a current flow that in turn produces an H field, both fields always exist at the same time in a waveguide. If a system satisfies one of these boundary conditions, it must also satisfy the other since neither field can exist alone.

WAVEFRONTS WITHIN A WAVEGUIDE

Electromagnetic energy transmitted into space consists of electric and magnetic fields that are at right angles (90 degrees) to each other and at right angles to the direction of propagation. A simple analogy to establish this relationship is by use of the right-hand rule for electromagnetic energy, based on the POYNTING VECTOR. It indicates that a screw (right-hand thread) with its axis perpendicular to the electric and magnetic fields will advance in the direction of propagation if the E field is rotated to the right (toward the H field). This rule is illustrated in figure 3-29.

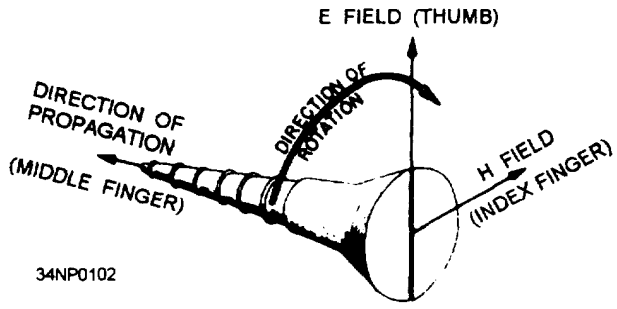

Figure 3-29.—The Poynting vector.

The combined electric and magnetic fields form a wavefront that can be represented by alternate negative and positive peaks at half-wavelength intervals, as illustrated in figure 3-30. Angle $\varnothing$ is the direction of travel of the wave with respect to some reference axis.

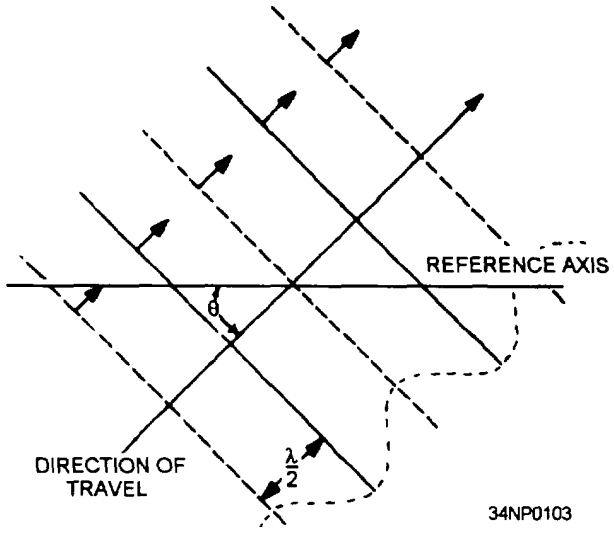

Figure 3-30.—Wavefronts in space.

The reflection of a single wavefront off the "b" wall of a waveguide is shown in figure 3-31. The wavefront is shown in view A as small particles, In views B and C particle 1 strikes the wall and is bounced back from the wall without losing velocity. If the wall is perfectly flat, the angle at which it the wall, known as the angle of incidence (θ), is the same as the angle of reflection $(\varnothing)$. An instant after particle 1 strikes the wall, particle 2 strikes the wall, as shown

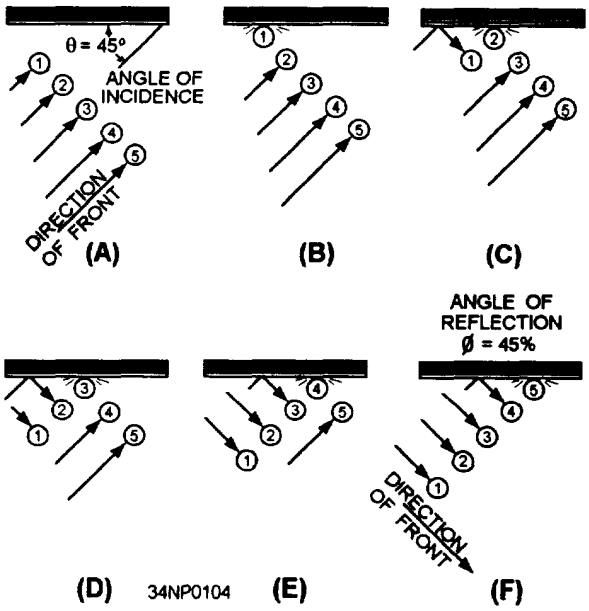

Figure 3-31.—Reflection of a single wavefront.

in view C, and reflects in the same manner. Because all the particles are traveling at the same velocity, particles 1 and 2 do not change their relative position with respect to each other. Therefore, the reflected wave has the same shape as the original. The remaining particles as shown in views D, E, and F reflect in the same manner. This process results in a reflected wavefront identical in shape, but opposite in polarity, to the incident wave.

Figure 3-32, views A and B, each illustrate the direction of propagation of two different electromagnetic wavefronts of different frequencies being radiated into a waveguide by a probe. Note that only the direction of propagation is indicated by the lines and arrowheads. The wavefronts are at right angles to the direction of propagation. The angle of incidence (θ) and the angle of reflection $(\varnothing)$ of the wavefronts vary in size with the frequency of the input energy, but the angles of reflection are equal to each other in a waveguide. The CUTOFF FREQUENCY in a waveguide is a frequency that would cause angles of incidence and reflection to be perpendicular to the walls of the guide. At any frequency below the cutoff frequency, the wavefronts will be reflected back and forth across the guide (setting up standing waves) and no energy will be conducted down the waveguide.

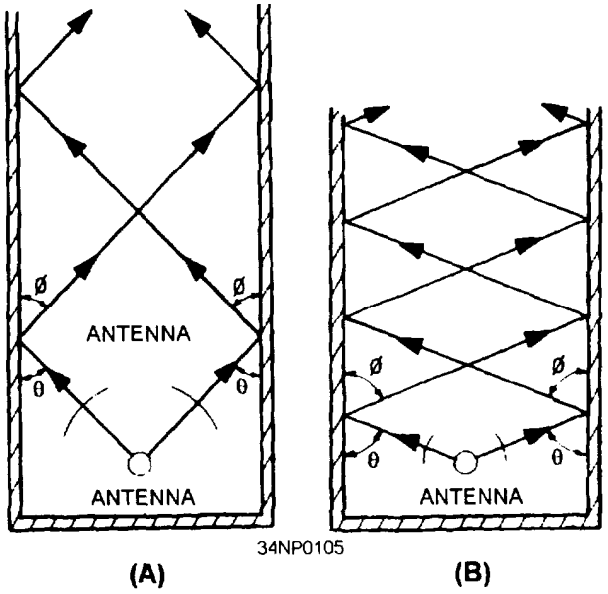

Figure 3-32.—Different frequencies in a waveguide.

The velocity of propagation of a wave along a waveguide is less than its velocity through free space (speed of light). This lower velocity is caused by the zigzag path taken by the wavefront. The forward-progress velocity of the wavefront in a waveguide is called GROUP VELOCITY and is somewhat slower than the speed of light.

The group velocity of energy in a waveguide is determined by the reflection angle of the wavefronts off the "b" walls. The reflection angle is determined by the frequency of the input energy. This basic principle is illustrated in figure 3-33. As frequency is decreased. the reflection angle increases, causing the group velocity to decrease. The opposite is also true; increasing frequency increases the group velocity.

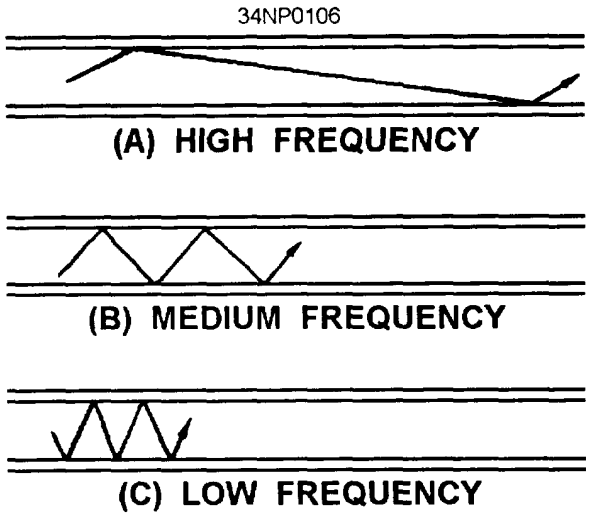

Figure 3-33.—Reflection angle at various frequencies.

WAVEGUIDE MODES OF OPERATION

The waveguide analyzed in the previous paragraphs yields an electric field configuration known as the half-sine electric distribution. This configuration, called a MODE OF OPERATION, is shown in figure 3-34. Recall that the strength of the field is indicated by the spacing of the lines; that is, the closer the lines, the stronger the field. The regions of maximum voltage in this field move continuously down the waveguide in a sine-wave pattern. To meet boundary conditions. the field must always be zero at the "b" walls.

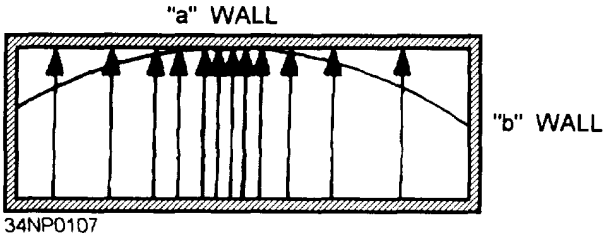

Figure 3-34.—Half-sine E field distribution.

The half-sine field is only one of many field configurations, or modes, that can exist in a rectangular waveguide. A full-sine field can also exist in a rectangular waveguide because, as shown in figure 3-35, the field is zero at the “b” walls.

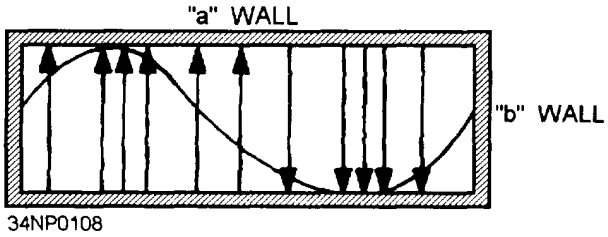

Figure 3-35.—Full-sine E field distribution.

The magnetic field in a rectangular waveguide is in the form of closed loops parallel to the surface of the conductors. The strength of the magnetic field is proportional to the electric field. Figure 3-36 illustrates the magnetic field pattern associated with a half-sine electric field distribution. The magnitude of the magnetic field varies in a sine-wave pattern down the center of the waveguide in “time phase” with the electric field. TIME PHASE means that the peak H lines and peak E lines occur at the same instant in time, although not necessarily at the same point along the length of the waveguide.

The dominant mode is the most efficient mode. Waveguides are normally designed so that only the dominant mode will be used. To operate in the dominant mode, a waveguide must have an “a” (wide) dimension of at least one half-wavelength of the frequency to be propagated. The “a” dimension of the waveguide must be kept near the minimum allowable value to ensure that only the dominant mode will exist. In practice, this dimension is usually 0.7 wavelength.

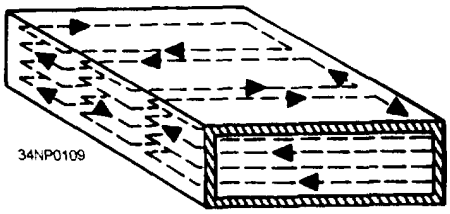

Figure 3-36.—Magnetic field caused by a half-sine E field.

Of the possible modes of operation available for a given waveguide, the dominant mode has the lowest cutoff frequency. The high-frequency limit of a rectangular waveguide is a frequency at which its “a” dimension becomes large enough to allow operation in a mode higher than that for which the waveguide has been designed.

Circular waveguides are used in specific areas of radar and communications systems, such as rotating joints used at the mechanical point where the antennas rotate. Figure 3-37 illustrates the dominant mode of a circular waveguide. The cutoff wavelength of a circular guide is 1.71 times the diameter of the waveguide. Since the “a” dimension of a rectangular waveguide is approximately one half-wavelength at the cutoff frequency, the diameter of an equivalent circular waveguide must be 2/1.71, or approximately

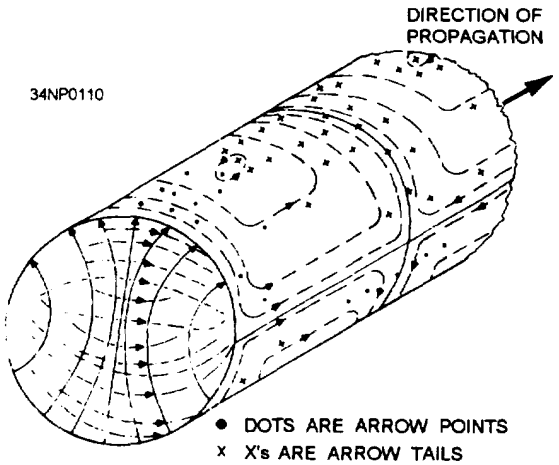

Figure 3-37.—Dominant mode in a circular waveguide.

1.17 times the "a" dimension of a rectangular waveguide.

MODE NUMBERING SYSTEMS

So far, only the most basic types of E and H field arrangements have been shown. More complicated arrangements are often necessary to make possible coupling, isolation, or other types of operation. The field arrangements of the various modes of operation are divided into two categories: TRANSVERSE ELECTRIC (TE) and TRANSVERSE MAGNETIC (TM).

In the transverse electric (TE) mode, the entire electric field is in the transverse plane, which is perpendicular to the waveguide, (direction of energy travel). Part of the magnetic field is parallel to the length axis.

In the transverse magnetic (TM) mode, the entire magnetic field is in the transverse plane and has no portion parallel to the length axis.

Since there are several TE and TM modes, subscripts are used to complete the description of the field pattern. In rectangular waveguides, the first subscript indicates the number of half-wave patterns in the "a" dimension, and the second subscript indicates the number of half-wave patterns in the "b" dimension.

The dominant mode for rectangular waveguides is shown in figure 3-38. It is designated as the TE mode because the E fields are perpendicular to the "a" walls. The first subscript is 1, since there is only one half-wave pattern across the "a" dimension. There are no E-field patterns across the "b" dimension, so the second subscript is 0. The complete mode description of the dominant mode in rectangular waveguides is $TE_{1,0}$. Subsequent description of waveguide operation in this text will assume the dominant ($TE_{1,0}$) mode unless otherwise noted.

A similar system is used to identify the modes of circular waveguides. The general classification of TE and TM is true for both circular and rectangular waveguides. In circular waveguides the subscripts have a different meaning. The first subscript indicates the number of fill-wave patterns around the circumference of the waveguide. The second subscript indicates the number of half-wave patterns across the diameter.

In the circular waveguide in figure 3-39, the E field is perpendicular to the length of the waveguide with no E lines parallel to the direction of propagation. Thus, it must be classified as operating in the TE mode. If you follow the E line pattern in a counterclockwise direction starting at the top, the E lines go from zero, through maximum positive (tail of arrows), back to zero, through maximum negative (head of arrows), and then back to zero again. This is one full wave, so the first subscript is 1. Along the diameter, the E lines go from zero through maximum and back to zero, making a half-wave variation. The second subscript, therefore, is also 1. $TE_{1,1}$ is the complete mode description of the dominant mode in circular waveguides. Several modes are possible in both circular and rectangular waveguides. Figure 3-40 illustrates several different modes that can be used to verify the mode numbering system.

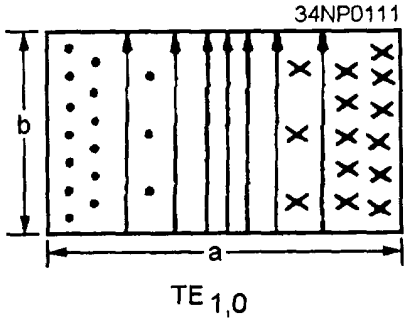

Figure 3-38.—Dominant mode in a rectangular waveguide.

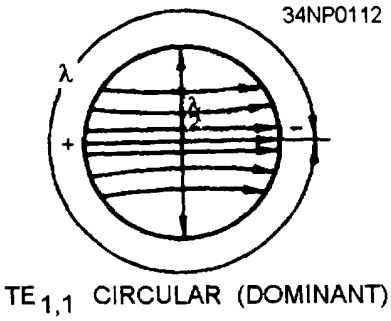

Figure 3-39.—Counting wavelengths in a circular waveguide.

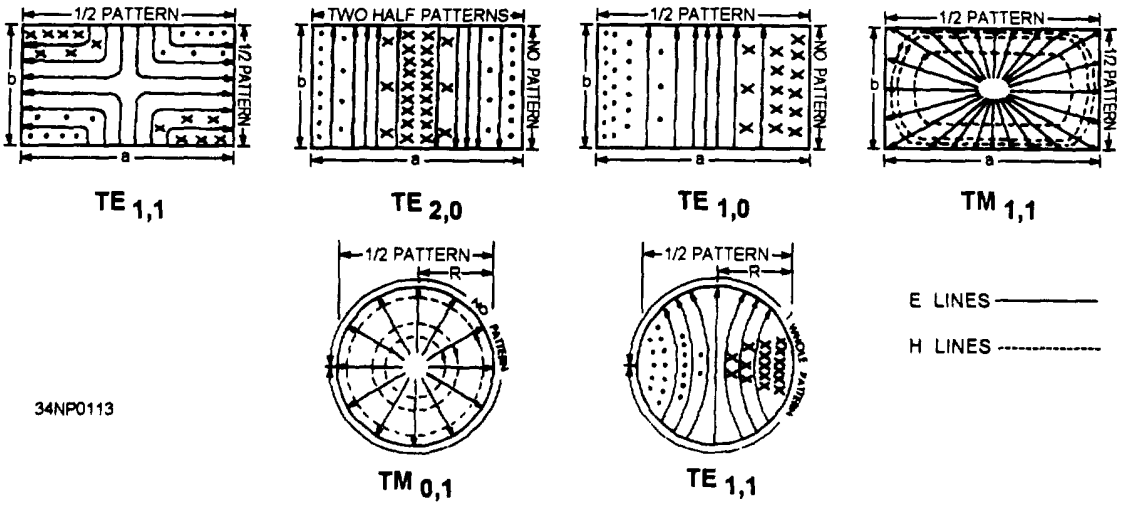

Figure 3-40.—Various modes of operation for rectangular and circular waveguides.

WAVEGUIDE INPUT/OUTPUT METHODS

A waveguide, as explained earlier in this topic, operates differently from an ordinary transmission line. Therefore, special devices must be used to put energy into a waveguide at one end and remove it from the other end.

The three devices used to injector remove energy from waveguides are PROBES, LOOPS, and SLOTS. Slots may also be called APERTURES or WINDOWS.

When a small probe is inserted into a waveguide and supplied with microwave energy, it acts as a quarter-wave antenna. Current flows in the probe and sets up an E field such as the one shown in figure 3-41, view A. The E lines detach themselves from the probe. When the probe is located at the point of highest efficiency, the E lines set up an E field of considerable intensity.

The most efficient place to locate the probe is in the center of the “a” wall, parallel to the “b” wall, and one quarter-wavelength from the shorted end of the waveguide, as shown in figure 3-41, views B and C. This is the point at which the E field is maximum in the dominant mode. Therefore, energy transfer (coupling) is maximum at this point. Note that the quarter-wavelength spacing is at the frequency required to propagate the dominant mode.

In many applications a lesser degree of energy transfer, called loose coupling, is desirable. The amount of energy transfer can be reduced by decreasing the length of the probe, by moving it out of the center of the E field, or by shielding it. Where the degree of coupling must be varied frequently, the probe is made retractable so the length can be easily changed.

The size and shape of the probe determines its frequency, bandwidth, and power-handling capability. As the diameter of a probe increases, the bandwidth increases. A probe similar in shape to a door knob is capable of handling much higher power and a larger bandwidth than a conventional probe. The greater power-handling capability is directly related to the increased surface area. Two examples of broad-bandwidth probes are illustrated in figure 3-41, view D. Removal of energy from a waveguide is simply a reversal of the injection process using the same type of probe.

Another way of injecting energy into a waveguide is by setting up an H field in the waveguide. This can be accomplished by inserting a small loop that carries a high current into the waveguide, as shown in figure 3-42, view A. A magnetic field builds up around the loop and expands to fit the waveguide, as shown in view B. If the frequency of the current in the loop is within the bandwidth of the waveguide, energy will be transferred to the waveguide.

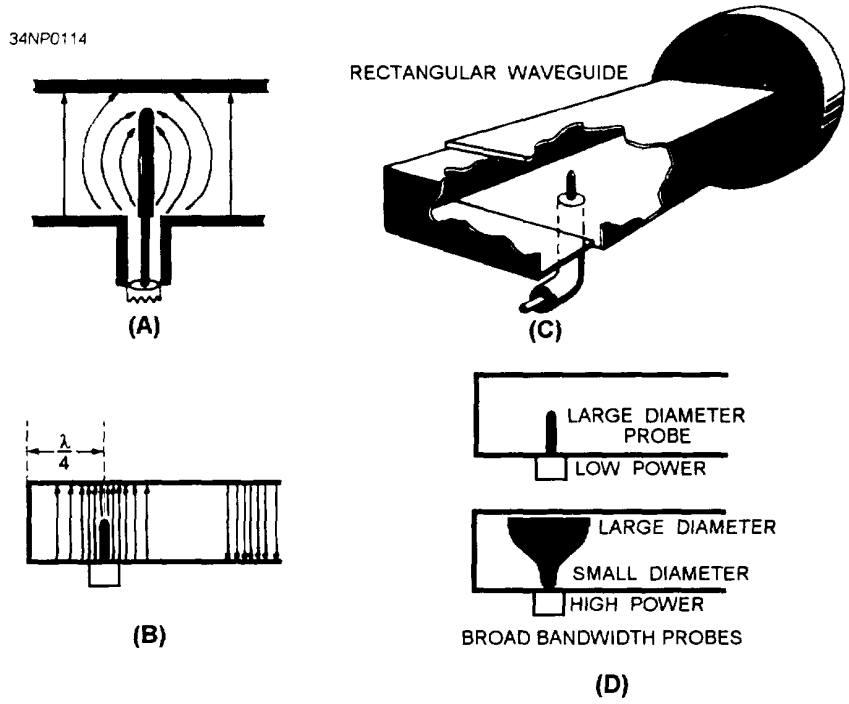

Figure 3-41.—Probe coupling in a rectangular waveguide.

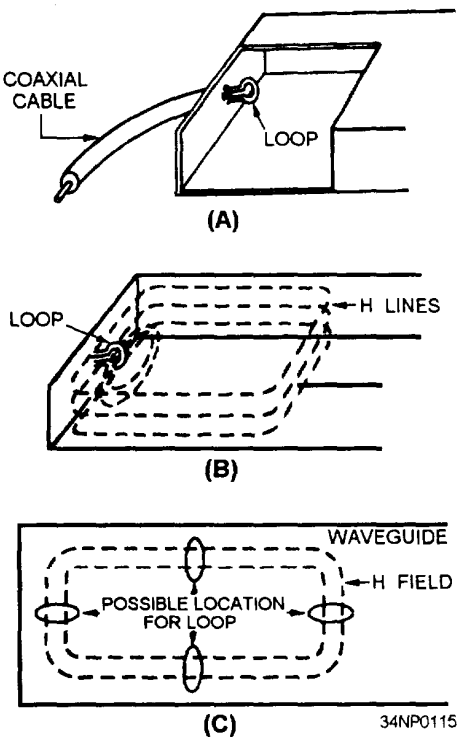

Figure 3-42.—Loop coupling in a rectangular waveguide.

For the most efficient coupling to the waveguide, the loop is inserted at one of several points where the magnetic field will be of greatest strength. Four of those points are shown in figure 3-42, view C.

When less efficient coupling is desired, you can rotate or move the loop until it encircles a smaller number of H lines. When the diameter of the loop is increased, its power-handling capability also increases. The bandwidth can be increased by increasing the size of the wire used to make the loop.

When a loop is introduced into a waveguide in which an H field is present, a current is induced in the loop. When this condition exists, energy is removed from the waveguide.

Slots or apertures are sometimes used when very loose (inefficient) coupling is desired, as shown in figure 3-43. In this method energy enters through a small slot in the waveguide and the E field expands into the waveguide. The E lines expand first across the slot and then across the interior of the waveguide.

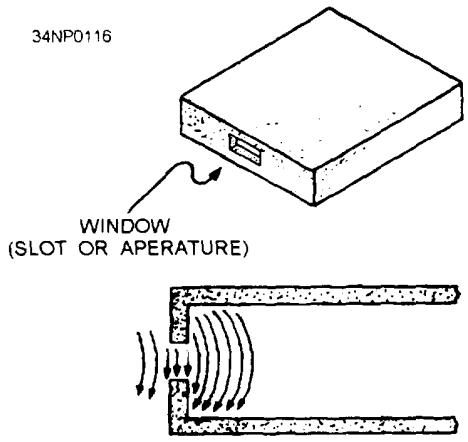

Figure 3-43.—Slot coupling in a waveguide.

Minimum reflections occur when energy is injected or removed if the size of the slot is properly proportioned to the frequency of the energy.

After learning how energy is coupled into and out of a waveguide with slots, you might think that leaving the end open is the most simple way of injecting or removing energy in a waveguide. This is not the case, however, because when energy leaves a waveguide, fields form around the end of the waveguide. These fields cause an impedance mismatch which, in turn, causes the development of standing waves and a drastic loss in efficiency. Various methods of impedance matching and terminating waveguides will be covered in the next section.

WAVEGUIDE IMPEDANCE MATCHING

Waveguide transmission systems are not always perfectly impedance matched to their load devices. The standing waves that result from a mismatch cause a power loss, a reduction in power-handling capability, and an increase in frequency sensitivity. Impedance-changing devices are therefore placed in the waveguide to match the waveguide to the load. These devices are placed near the source of the standing waves.

Figure 3-44 illustrates three devices, called irises, that are used to introduce inductance or capacitance into a waveguide. An iris is nothing more than a metal plate that contains an opening through which the waves may pass. The iris is located in the transverse plane of either the magnetic or electric field.

An inductive iris and its equivalent circuit are illustrated in figure 3-44, view A. The iris places a shunt inductive reactance across the waveguide that is directly proportional to the size of the opening. Notice that the inductive iris is in the magnetic plane. The shunt capacitive reactance, illustrated in view B, basically acts the same way. Again, the reactance is directly proportional to the size of the opening, but the iris is placed in the electric plane. The iris, illustrated in view C, has portions in both the magnetic

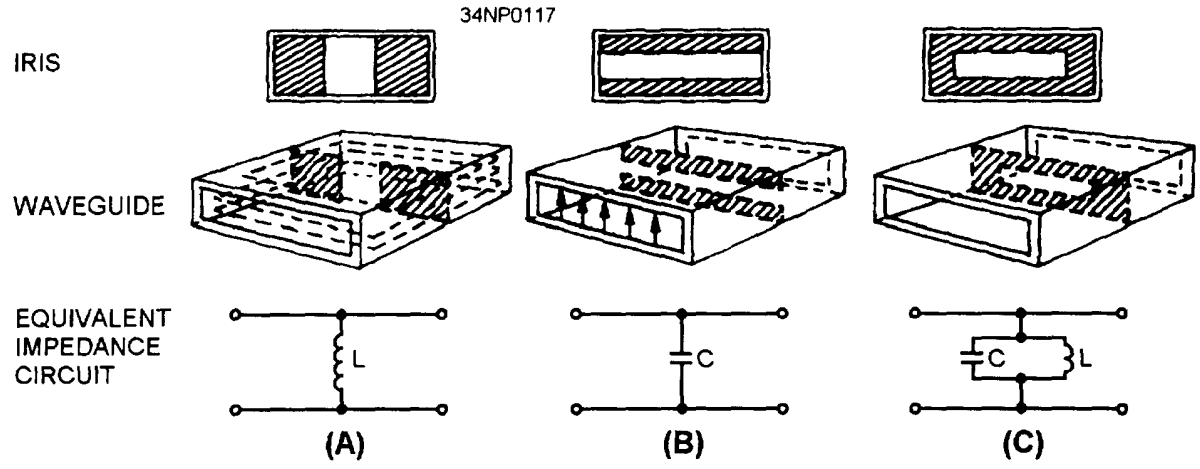

Figure 3-44.—Waveguide irises.

and electric transverse planes and forms an equivalent parallel-LC circuit across the waveguide. At the resonant frequency, the iris acts as a high shunt resistance. Above or below resonance, the iris acts as a capacitive or inductive reactance.

POSTS and SCREWS made from conductive material can be used for impedance-changing devices in waveguides. Views A and B of figure 3-45, illustrate two basic methods of using posts and screws. A post or screw that only partially penetrates into the waveguide acts as a shunt capacitive reactance. When the post or screw extends completely through the waveguide, making contact with the top and bottom walls, it acts as an inductive reactance. Note that when screws are used, the amount of reactance can be varied.

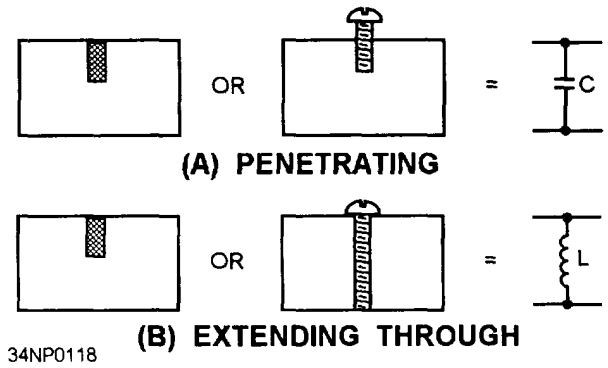

Figure 3-45.—Conducting posts and screws.

WAVEGUIDE TERMINATIONS

Electromagnetic energy is often passed through a waveguide to transfer the energy from a source into space. As previously mentioned, the impedance of a waveguide does not match the impedance of space, and without proper impedance matching standing waves cause a large decrease in the efficiency of the waveguide.

Any abrupt change in impedance causes standing waves, but when the change in impedance at the end of a waveguide is gradual, almost no standing waves are formed. Gradual changes in impedance can be obtained by terminating the waveguide with a funnel-shaped HORN, such as the three types illustrated in figure 3-46. The type of horn used depends upon the frequency and the desired radiation pattern.

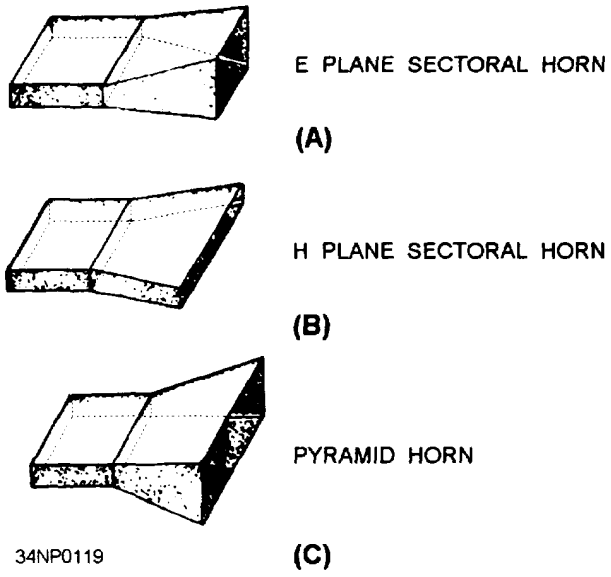

Figure 3-46.—Waveguide horns.

As you may have noticed, horns are really simple antennas. They have several advantages over other impedance-matching devices, such as their large bandwidth and simple construction.

A waveguide may also be terminated in a resistive load that is matched to the characteristic impedance of the waveguide. The resistive load is most often called a DUMMY LOAD, because its only purpose is to absorb all the energy in a waveguide without causing standing waves.

There is no place on a waveguide to connect a fixed termination resistor; therefore, several special arrangements are used to terminate waveguides. One method is to fill the end of the waveguide with a graphite and sand mixture, as illustrated in figure 3-47, view A. When the fields enter the mixture, they induce a current flow in the mixture that dissipates the energy as heat. Another method (view B) is to use a high-resistance rod placed at the center of the E field. The E field causes current to flow in the rod, and the high resistance of the rod dissipates the energy as a power loss, again in the form of heat.

Still another method for terminating a waveguide is the use of a wedge of highly resistive material, as shown in view C of figure 3-47. The plane of the wedge is placed perpendicular to the magnetic lines

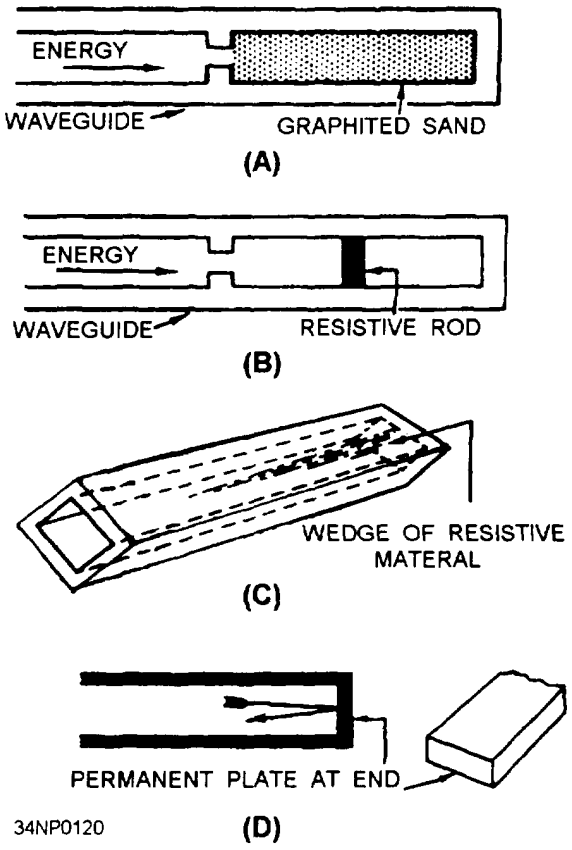

Figure 3-47.—Terminating waveguides.

of force. When the H lines cut through the wedge, current flows in the wedge and causes a power loss. As with the other methods, this loss is in the form of heat. Since very little energy reaches the end of the waveguide, reflections are minimum.

All of the terminations discussed so far are designed to radiate or absorb the energy without reflections. In many instances, however, all of the energy must be reflected from the end of the waveguide. The best way to accomplish this is to permanently weld a metal plate at the end of the waveguide, as shown in view D of figure 3-47.

WAVEGUIDE PLUMBING

Since waveguides are really only hollow metal pipes, the installation and the physical handling of waveguides have many similarities to ordinary plumbing. In light of this fact, the bending, twisting, joining, and installation of waveguides is commonly called waveguide plumbing. Naturally, waveguides are different in design from pipes that are designed to carry liquids or other substances. The design of a waveguide is determined by the frequency and power level of the electromagnetic energy it will carry. The following paragraphs explain the physical factors involved in the design of waveguides.

Waveguide Bends

The size, shape, and dielectric material of a waveguide must be constant throughout its length for energy to move from one end to the other without reflections. Any abrupt change in its size or shape can cause reflections and a loss in overall efficiency. When such a change is necessary, the bends, twists, and joints of the waveguides must meet certain conditions to prevent reflections.

Waveguides maybe bent in several ways that do not cause reflections. One way is the gradual bend shown in figure 3-48. This gradual bend is known as an E bend because it distorts the E fields. The E bend must have a radius greater than two wavelengths to prevent reflections.

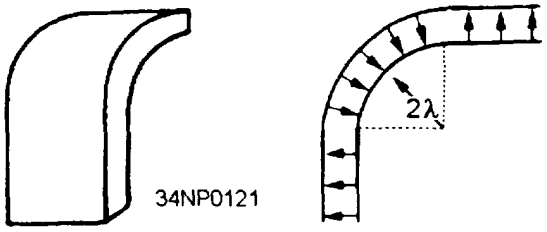

Figure 3-48.—Gradual E bend.

Another common bend is the gradual H bend (fig. 3-49). It is called an H bend because the H fields are distorted when a waveguide is bent in this manner. Again, the radius of the bend must be greater than two wavelengths to prevent reflections. Neither the E bend in the “a” dimension nor the H bend in the “b” dimension changes the normal mode of operation.

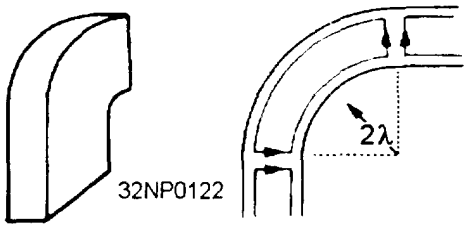

Figure 3-49.—Gradual H bend.

A sharp bend in either dimension may be used if it meets certain requirements. Notice the two 45-degree bends in figure 3-50; the bends are 1/4λ apart. The reflections that occur at the 45-degree bends cancel each other, leaving the fields as though no reflections have occurred.

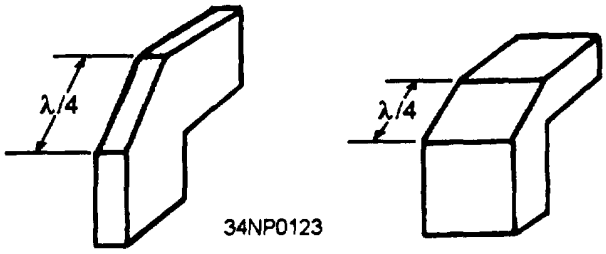

Figure 3-50.—Sharp bends.

Sometimes the electromagnetic fields must be rotated so that they are in the proper phase to match the phase of the load. This may be accomplished by twisting the waveguide as shown in figure 3-51. The twist must be gradual and greater than 2λ.

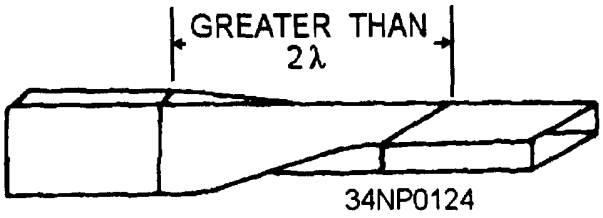

Figure 3-51.—Waveguide twist.

The flexible waveguide (fig. 3-52) allows special bends, which some equipment applications might require. It consists of a specially wound ribbon of conductive material, the most commonly used is brass, with the inner surface plated with chromium. Power losses are greater in the flexible waveguide because the inner surfaces are not perfectly smooth. Therefore, it is only used in short sections where no other reasonable solution is available.

Waveguide Joints

Since an entire waveguide system cannot possibly be molded into one piece, the waveguide must be

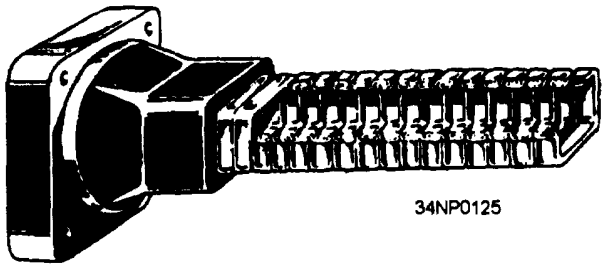

Figure 3-52.—Flexible waveguide.

constructed in sections and the sections connected with joints. The three basic types of waveguide joints are the PERMANENT, the SEMIPERMANENT, and the ROTATING JOINTS. Since the permanent joint is a factory-welded joint that requires no maintenance, only the semipermanent and rotating joints will be discussed.

Sections of waveguide must be taken apart for maintenance and repair. A semipermanent joint, called a CHOKE JOINT, is most commonly used for this purpose. The choke joint provides good electromagnetic continuity between the sections of the waveguide with very little power loss.

A cross-sectional view of a choke joint is shown in figure 3-53. The pressure gasket shown between the two metal surfaces forms an airtight seal. Notice in view B that the slot is exactly 1/4λ from the "a" wall of the waveguide. The slot is also 1/4λ deep, as shown in view A, and because it is shorted at point 1, a high impedance results at point 2. Point 3 is 1/4λ from point 2. The high impedance at point 2 results in a low impedance, or short, at point 3. This effect creates a good electrical connection between the two sections that permits energy to pass with very little reflection or loss.

Whenever a stationary rectangular waveguide is to be connected to a rotating antenna, a rotating joint must be used. A circular waveguide is normally used in a rotating joint. Rotating a rectangular waveguide would cause field pattern distortion. The rotating section of the joint, illustrated in figure 3-54, uses a choke joint to complete the electrical connection with the stationary section. The circular waveguide is designed so that it will operate in the $TM_{0,1}$ mode.

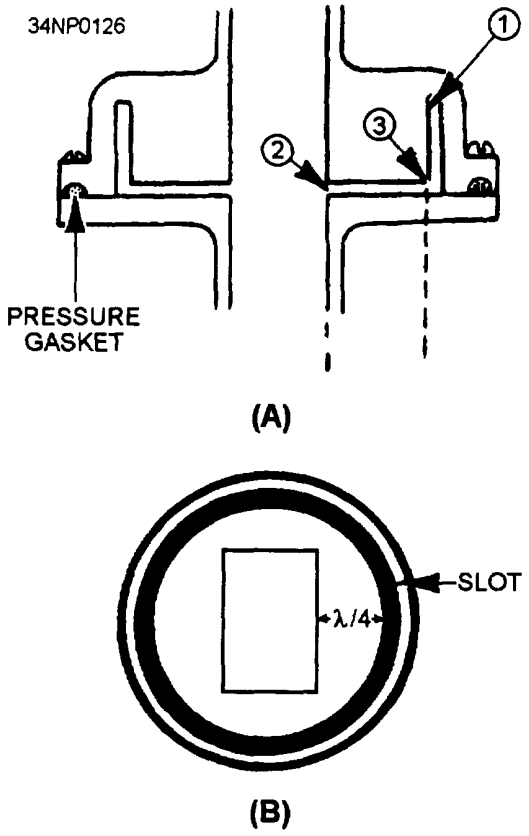

Figure 3-53.—Choke joint.

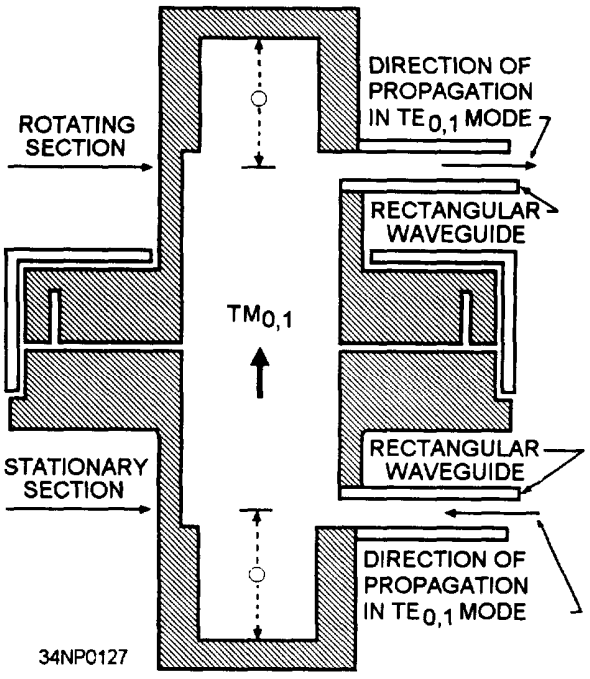

Figure 3-54.—Rotating joint.

The rectangular sections are attached as shown in the illustration to prevent the circular waveguide from operating in the wrong mode. Distance "O" is $3/4\lambda$ so that a high impedance will be presented to any unwanted modes. This is the most common design used for rotating joints, but other types may be used in specific applications.

WAVEGUIDE MAINTENANCE

The installation of a waveguide system presents problems that are not normally encountered when dealing with other types of transmission lines. These problems often fall within the technician's area of responsibility. A brief discussion of waveguide handling, installation, and maintenance will help prepare you for this maintenance responsibility, Detailed information concerning waveguide maintenance in a particular system may be found in the technical manuals for the system.

Since a waveguide naturally has a low loss ratio, most losses in a waveguide system are caused by other factors. Improperly connected joints or damaged inner surfaces can decrease the efficiency of a system to the point that it will not work at all. Therefore, you must take great care when working with waveguides to prevent physical damage. Since waveguides are made from a soft, conductive material, such as copper or aluminum, they are very easy to dent or deform. Even the slightest damage to the inner surface of a waveguide will cause standing waves and, often, internal arcing. Internal arcing causes further damage to the waveguide in an action that is often self-sustaining until the waveguide is damaged beyond use. Part of your job as a technician will be to inspect the waveguide system for physical damage. The previously mentioned dents are only one type of physical damage that can decrease the efficiency of the system. Another problem occurs because waveguides are made from a conductive material such as copper while the structures of most ships are made from steel. When two dissimilar metals, such as copper and steel, are in direct contact, an electrical action called ELECTROLYSIS takes place that causes very rapid corrosion of the metals. Waveguides can be completely destroyed by electrolytic corrosion in a relatively short period of time if they are not isolated from direct contact with other metals. Any inspection

of a waveguide system should include a detailed inspection of all support points to ensure that electrolytic corrosion is not taking place. Any waveguide that is exposed to the weather should be painted and all joints sealed. Proper painting prevents natural corrosion, and sealing the joints prevents moisture from entering the waveguide.

Moisture can be one of the worst enemies of a waveguide system. As previously discussed, the dielectric in waveguides is air, which is an excellent dielectric as long as it is free of moisture. Wet air, however, is a very poor dielectric and can cause serious internal arcing in a waveguide system. For this reason, care is taken to ensure that waveguide systems are pressurized with air that is dry. Checking the pressure and moisture content of the waveguide air may be one of your daily system maintenance duties.

More detailed waveguide installation and maintenance information can be found in the technical manuals that apply to your particular system. Another good source is the *Electronics Installation and Maintenance Handbooks (EIMB)* published by Naval Sea Systems Command. *Installation Standards (EIMB) Handbook,* NAVSEA 0967-LP-000-0110, is the volume that deals with waveguide installation and maintenance.

WAVEGUIDE DEVICES

The discussion of waveguides, up to this point, has been concerned only with the transfer of energy from one point to another. Many waveguide devices have been developed, however, that modify the energy in some fashion during the transmission. Some devices do nothing more than change the direction of the energy. Others have been designed to change the basic characteristics or power level of the electromagnetic energy.

This section will explain the basic operating principles of some of the more common waveguide devices, such as DIRECTIONAL COUPLERS, CAVITY RESONATORS, and HYBRID JUNCTIONS.

Directional Couplers

The directional coupler is a device that provides a method of sampling energy from within a waveguide for measurement or use in another circuit. Most couplers sample energy traveling in one direction only. However, directional couplers can be constructed that sample energy in both directions. These are called BIDIRECTIONAL couplers and are widely used in radar and communications systems.

Directional couplers may be constructed in many ways. The coupler illustrated in figure 3-55 is constructed from an enclosed waveguide section of the same dimensions as the waveguide in which the energy is to be sampled. The "b" wall of this enclosed section is mounted to the "b" wall of the waveguide from which the sample will be taken. There are two holes in the "b" wall between the sections of the coupler. These two holes are $1/4\lambda$ apart. The upper section of the directional coupler has a wedge of energy-absorbing material at one end and a pickup probe connected to an output jack at the other end. The absorbent material absorbs the energy not directed at the probe and a portion of the overall energy that enters the section.

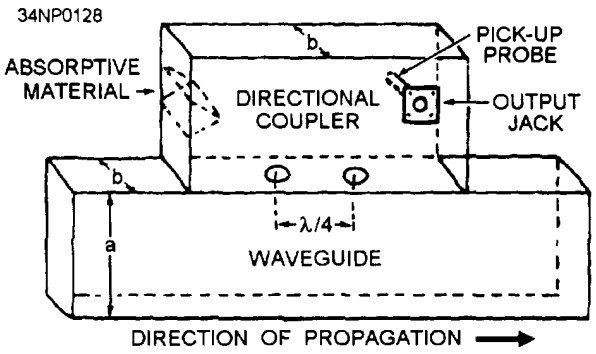

Figure 3-55.—Directional coupler.

Figure 3-56 illustrates two portions of the incident wavefront in a waveguide. The waves travel down the waveguide in the direction indicated and enter the coupler section through both holes. Since both portions of the wave travel the same distance, they are in phase when they arrive at the pickup probe. Because the waves are in phase, they add together and provide a sample of the energy traveling down the waveguide. The sample taken is only a small portion of the energy that is traveling down the waveguide. The magnitude of the sample, however, is proportional to the magnitude of the energy in the waveguide. The absorbent material is designed to ensure that the ratio

between the sample energy and the energy in the waveguide is constant. Otherwise, the sample would contain no useful information. The ratio is usually stamped on the coupler in the form of an attenuation factor.

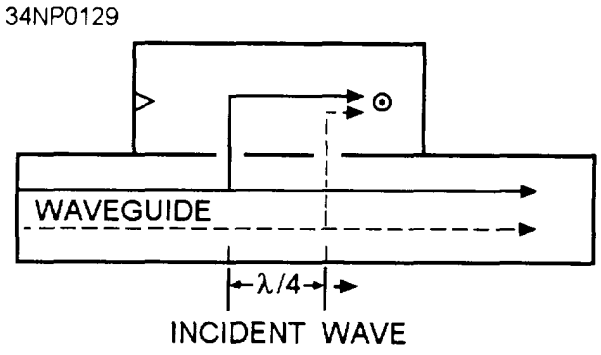

Figure 3-56.—Incident wave in a directional coupler designed to sample incident waves.

The effect of a directional coupler on any reflected energy is illustrated in figure 3-57. Note that these two waves do not travel the same distance to the pickup probe. The wave represented by the dotted line travels $1/2\lambda$ further and arrives at the probe 180 degrees out of phase with the wave, represented by the solid line. Because the waves are 180 degrees out of phase at the probe, they cancel each other and no energy is induced into the pickup probe. When the reflected energy arrives at the absorbent material, it adds and is absorbed by the material.

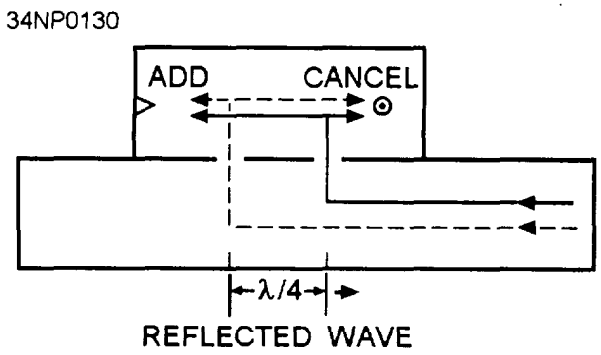

Figure 3-57.—Reflected wave in a directional coupler.

A directional coupler designed to sample reflected energy is shown in figure 3-58. The absorbent material and the probe are in opposite positions from the directional coupler designed to sample the incident energy. This positioning causes the two portions of the reflected energy to arrive at the probe in phase, providing a sample of the reflected energy. The transmitted energy is absorbed by the absorbent material.

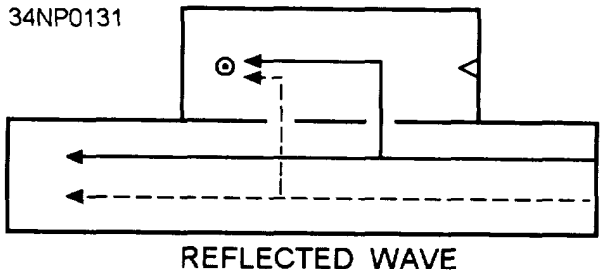

Figure 3-58.—Directional coupler designed to sample retlected energy.

A simple bidirectional coupler for sampling both transmitted and reflected energy can be constructed by mounting two directional couplers on opposite sides of a waveguide, as shown in figure 3-59.

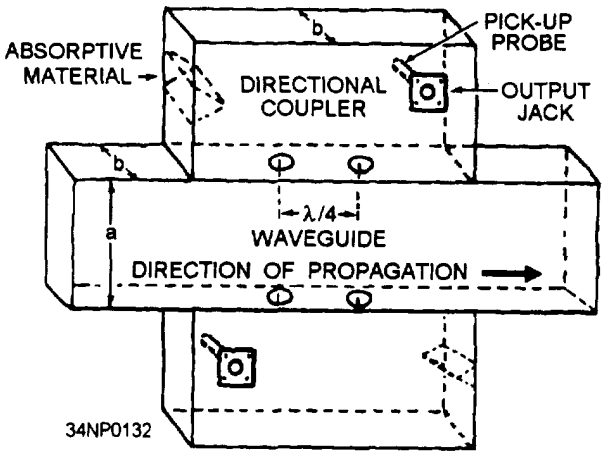

Figure 3-59.—Bidirectional coupler.

Cavity Resonators

By definition, a resonant cavity is any space completely enclosed by conducting walls that can contain oscillating electromagnetic fields and possess resonant properties. The cavity has many advantages

and uses at microwave frequencies. Resonant cavities have a very high Q and can be built to handle relatively large amounts of power. Cavities with a Q value in excess of 30,000 are not uncommon. The high Q gives these devices a narrow bandpass and allows very accurate tuning. Simple, rugged construction is an additional advantage.

Although cavity resonators, built for different frequency ranges and applications, have a variety of shapes, the basic principles of operation are the same for all.

One example of a cavity resonator is the rectangular box shown in figure 3-60, view A. It may be thought of as a section of rectangular waveguide closed at both ends by conducting plates. The frequency at which the resonant mode occurs is $1/2\lambda$ of the distance between the end plates. The magnetic field patterns in the rectangular cavity are shown in view B.

There are two variables that determine the primary frequency of any resonant cavity. The first variable is PHYSICAL SIZE. In general, the smaller the cavity, the higher its resonant frequency. The second controlling factor is the SHAPE of the cavity. Figure 3-61 illustrates several cavity shapes that are commonly used. Remember from the previously stated definition of a resonant cavity that any completely enclosed conductive surface, regardless of its shape, can act as a cavity resonator.

Energy can be inserted or removed from a cavity by the same methods that are used to couple energy into and out of waveguides. The operating principles of probes, loops, and slots are the same whether used in a cavity or a waveguide. Therefore, any of the three methods can be used with cavities to inject or remove energy.

The resonant frequency of a cavity can be varied by changing any of the three parameters: cavity volume, cavity capacitance, or cavity inductance. Changing the frequencies of a cavity is known as TUNING. The mechanical methods of tuning a cavity may vary with the application, but all methods use the same electrical principles.

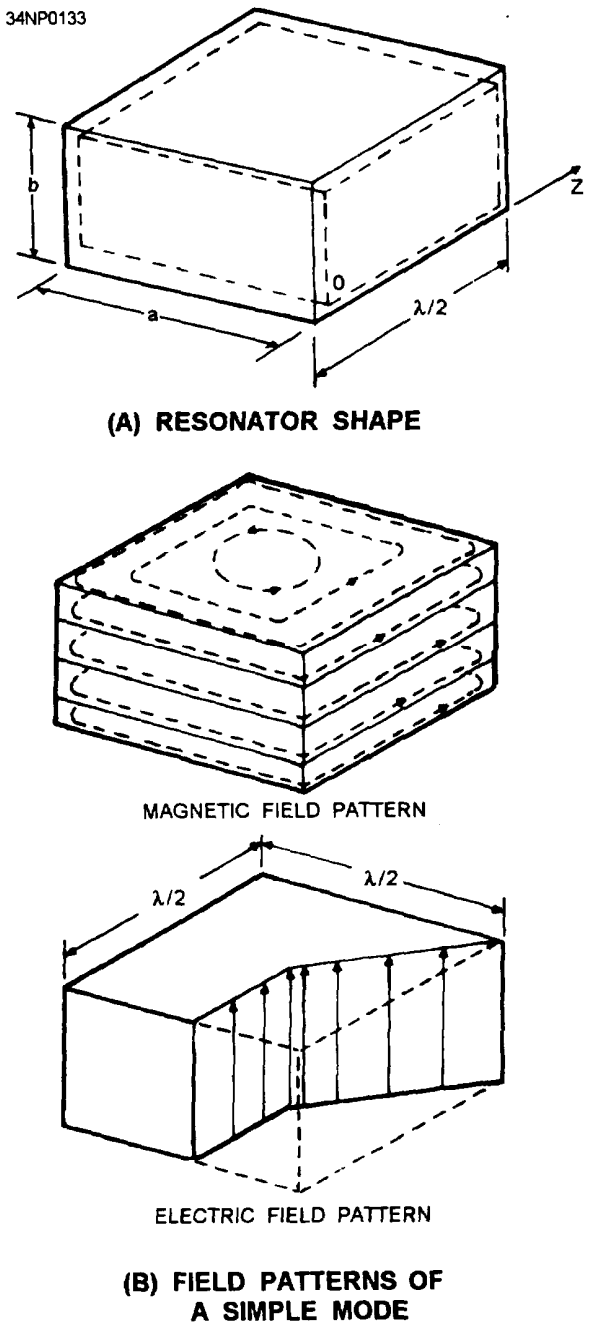

Figure 3-60.—Rectangular waveguide cavity resonator.

Waveguide Junctions

You may have assumed that when energy traveling down a waveguide reaches a junction it simply divides and follows the junction. This is not strictly true.

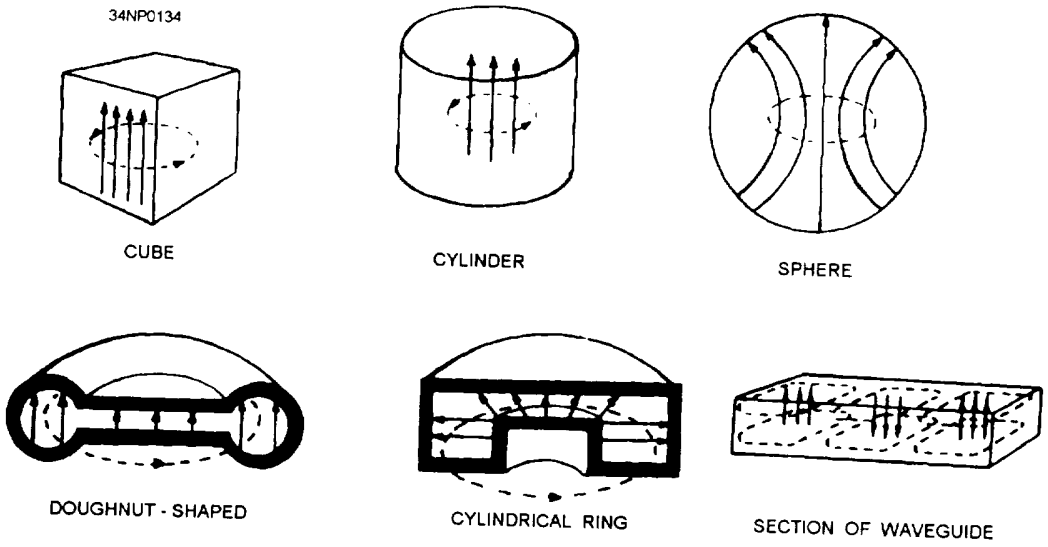

Figure 3-61.—Types of cavities.

Different types of junctions affect the energy in different ways. Since waveguide junctions are used extensively in most systems, you need to understand the basic operating principles of those most commonly used.

The T JUNCTION is the most simple of the commonly used waveguide junctions. T junctions are divided into two basic types, the E TYPE and the H TYPE. HYBRID JUNCTIONS are more complicated developments of the basic T junctions. The MAGIC-T and the HYBRID RING are the two most commonly used hybrid junctions.

E-TYPE T JUNCTION.— An E-type T junction is illustrated in figure 3-62, view A.

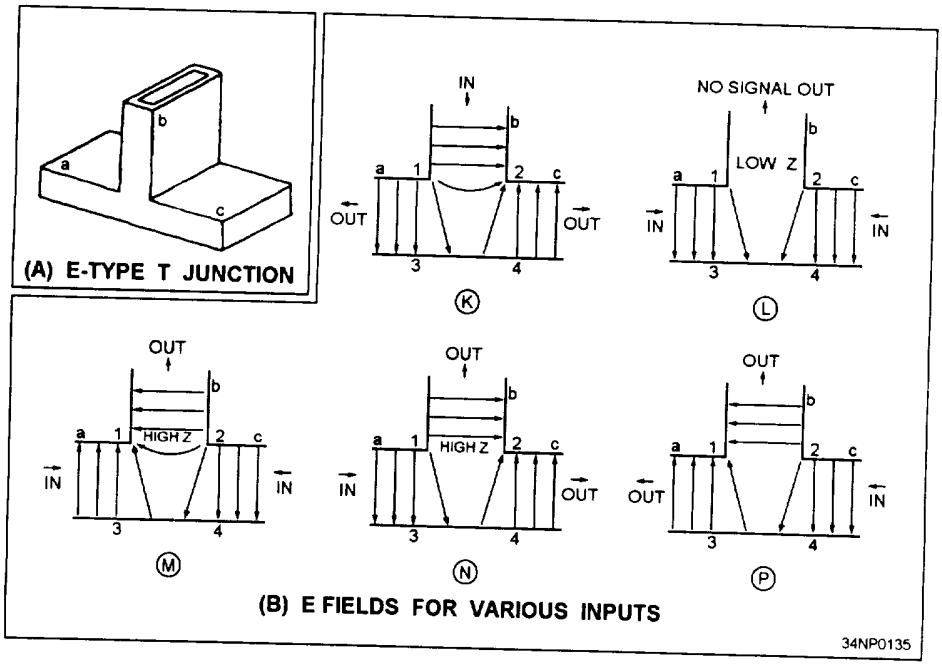

Figure 3-62.—E fields in an E-type T junction.

It is called an E-type T junction because the junction arm extends from the main waveguide in the same direction as the E field in the waveguide.

Figure 3-62, view B, illustrates cross-sectional views of the E-type T junction with inputs fed into the various arms. For simplicity, the magnetic lines that are always present with an electric field have been omitted. In view K, the input is fed into arm b and the outputs are taken from the a and c arms. When the E field arrives between points 1 and 2, point 1 becomes positive and point 2 becomes negative. The positive charge at point 1 then induces a negative charge on the wall at point 3. The negative charge at point 2 induces a positive charge at point 4. These charges cause the fields to form 180 degrees out of phase in the main waveguide; therefore, the outputs will be 180 degrees out of phase with each other. In view L, two in-phase inputs of equal amplitude are fed into the a and c arms. The signals at points 1 and 2 have the same phase and amplitude. No difference of potential exists across the entrance to the b arm, and no energy will be coupled out. However, when the two signals fed into the a and c arms are 180 degrees out of phase, as shown in view M, points 1 and 2 have a difference of potential. This difference of potential induces an E field from point 1 to point 2 in the b arm, and energy is coupled out of this arm. Views N and P illustrate two methods of obtaining two outputs with only one input.

H-TYPE T JUNCTION.— An H-type T junction is illustrated in figure 3-63, view A. It is called an H-type T junction because the long axis of the "b" arm is parallel to the plane of the magnetic lines of force in the waveguide. Again, for simplicity, only the E lines are shown in this figure. Each X indicates an E line moving away from the observer. Each dot indicates an E line moving toward the observer.

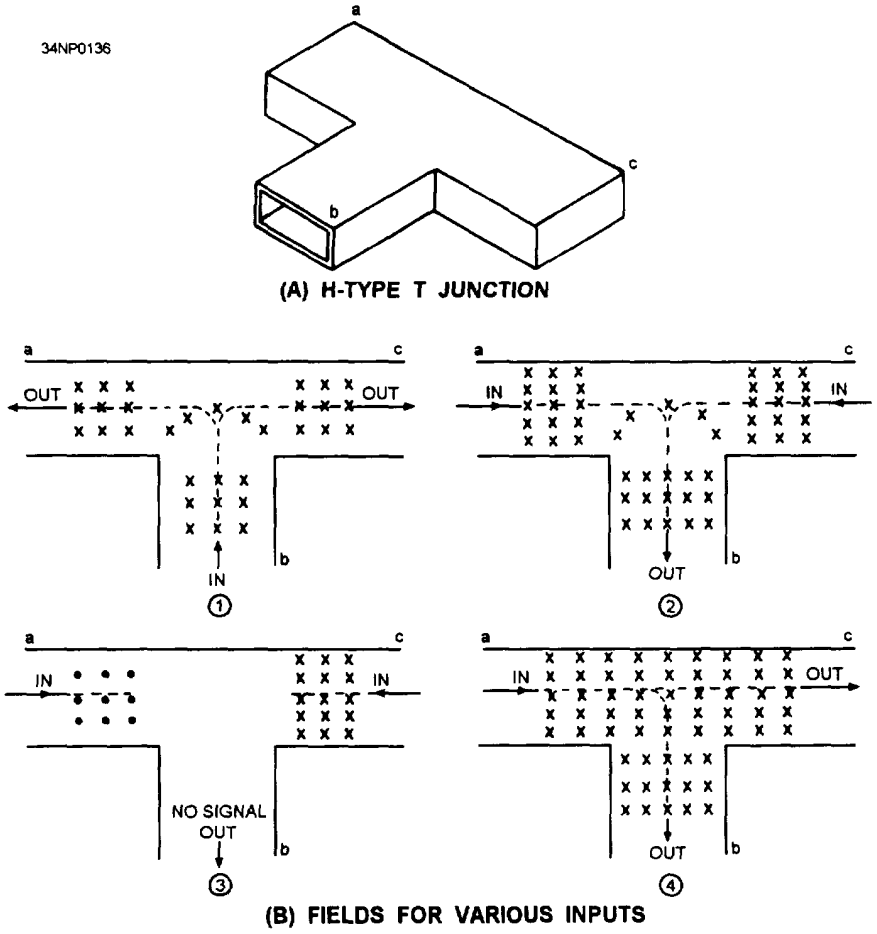

Figure 3-63.—E field in an H-type T junction.

In view 1 of figure 3-63, view B, the signal is fed into arm b and in-phase outputs are obtained from the a and c arms. In view 2, in-phase signals are fed into arms a and c and the output signal is obtained from the b arm because the fields add at the junction and induce E lines into the b arm. If 180-degree-out-of-phase signals are fed into arms a and c, as shown in view 3, no output is obtained from the b arm because the opposing fields cancel at the junction. If a signal is fed into the a arm, as shown in view 4 , outputs will be obtained from the b and c arms. The reverse is also true. If a signal is fed into the c arm, outputs will be obtained from the a and b arms.

MAGIC-T HYBRID JUNCTION.— A simplified version of the magic-T hybrid junction is shown in figure 3-64. The magic-T is a combination of the H-type and E-type T junctions. The most common application of this type of junction is as the mixer section for microwave radar receivers.

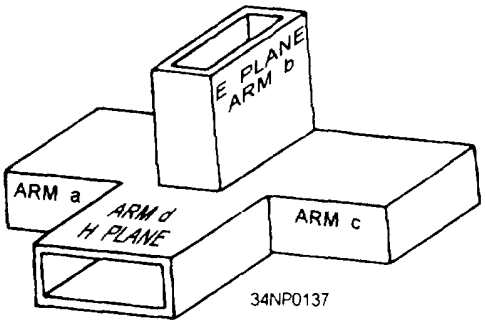

Figure 3-64.—Magic-T hybrid junction.

If a signal is fed into the b arm of the magic-T, it will divide into two out-of-phase components. As shown in figure 3-65, view A, these two components will move into the a and c arms. The signal entering the b arm will not enter the d arm because of the zero potential existing at the entrance of the d arm. The potential must be zero at this point to satisfy the boundary conditions of the b arm. This absence of potential is illustrated in views B and C where the magnitude of the E field in the b arm is indicated by the length of the arrows. Since the E lines are at maximum in the center of the b arm and minimum at the edge where the d arm entrance is located, no potential difference exists across the mouth of the d arm.

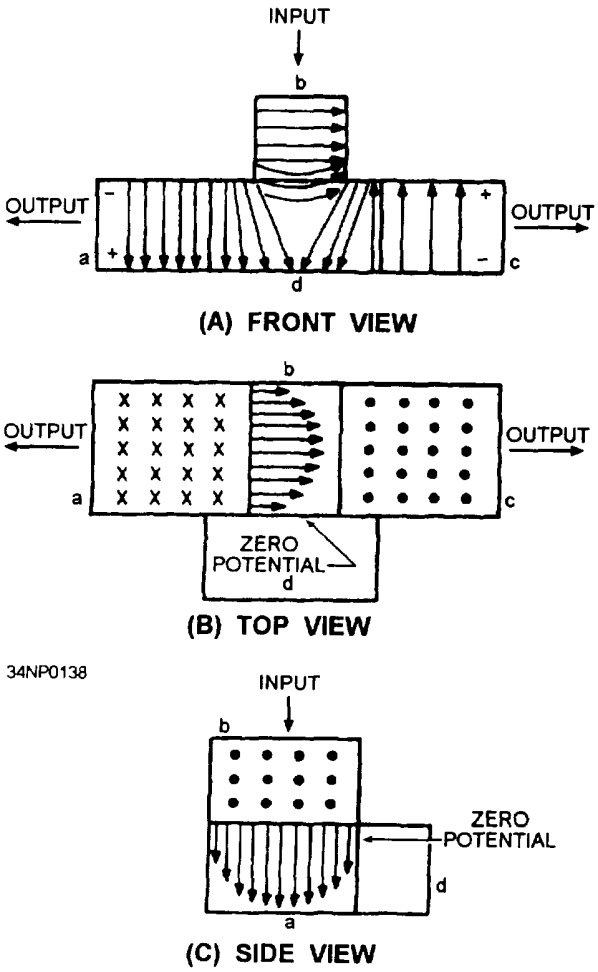

Figure 3-65.—Magic-T with input to arm b.

In summary, when an input is applied to arm b of the magic-T hybrid junction, the output signals from arms a and c are 180 degrees out of phase with each other, and no output occurs at the d arm.

The action that occurs when a signal is fed into the d arm of the magic-T is illustrated in figure 3-66. As with the H-type T junction, the signal entering the d arm divides and moves down the a and c arms as outputs that are in phase with each other and with the input. The shape of the E fields in motion is shown by the numbered curved slices. As the E field moves down the d arm, points 2 and 3 are at an equal potential. The energy divides equally into arms a and c, and the E fields in both arms become identical in shape. Since the potentials on both sides of the b arm are equal, no potential difference exists at the entrance to the b arm, resulting in no output.

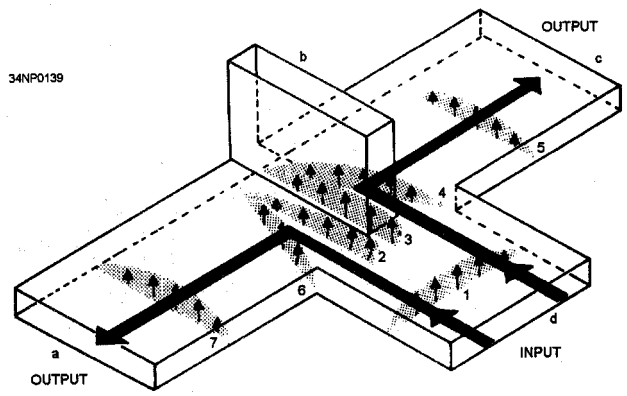

Figure 3-66.—Magic-T with input to arm d.

When an input signal is fed into the a arm as shown in figure 3-67, a portion of the energy is coupled into the b arm as it would be in an E-type T junction. An equal portion of the signal is coupled through the d arm because of the action of the H-type junction. The c arm has two fields across it that are out of phase with each other. Therefore, the fields cancel, resulting in no output at the c arm. The reverse of this action takes place if a signal is fed into the c arm, resulting in outputs at the b and d arms and no output at the a arm.

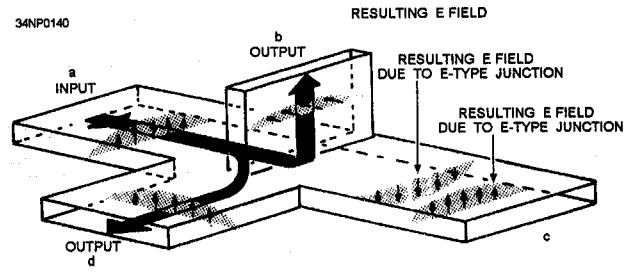

Figure 3-67.—Magic-T with input to arm a.

Unfortunately, when a signal is applied to any arm of a magic-T, the flow of energy in the output arms is affected by reflections. Reflections are caused by impedance mismatching at the junctions. These reflections are the cause of the two major disadvantages of the magic-T. First, the reflections represent a power loss since all the energy fed into the junction does not reach the load that the arms feed. Second, the reflections produce standing waves that can result in internal arcing. Thus, the maximum power a magic-T can handle is greatly reduced.

Reflections can be reduced by using some means of impedance matching that does not destroy the shape of the junctions. One method is shown in figure 3-68. A post is used to match the H plane, and an iris is used to match the E plane. Even though this method reduces reflections, it lowers the power-handling capability even further.

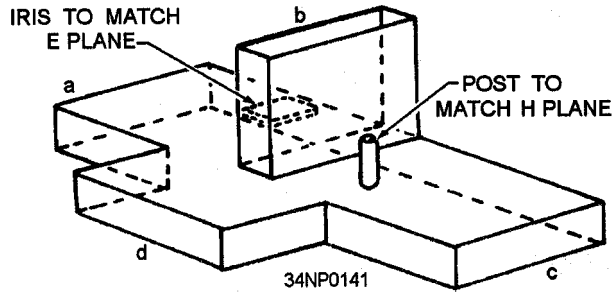

Figure 3-68.—Magic-T impedance matching.

HYBRID RING.— A type of hybrid junction that overcomes the power limitation of the magic-T is the hybrid ring, also called a RAT RACE. The hybrid ring, illustrated in figure 3-69, view A, is actually a modification of the magic-T. It is constructed of rectangular waveguides molded into a circular pattern. The arms are joined to the circular waveguide to form E-type T junctions. View B shows, in wavelengths, the dimensions required for a hybrid ring to operate properly.

The hybrid ring is used primarily in high-powered radar and communications systems to perform two functions. During the transmit period, the hybrid ring couples microwave energy from the transmitter to the antenna and allows no energy to reach the receiver. During the receive cycle, the hybrid ring couples energy from the antenna to the receiver and allows no energy to reach the transmitter. Any device that performs both of these functions is called a DUPLEXER. A duplexer permits a system to use the same antenna for both transmitting and receiving.

SUMMARY

This concludes our discussion on transmission lines and waveguides. In this volume you have been given a basic introduction on wave propagation from the time it leaves the transmitter to the point of reception. In volume 8 you will be introduced to a variety of electronic support systems.

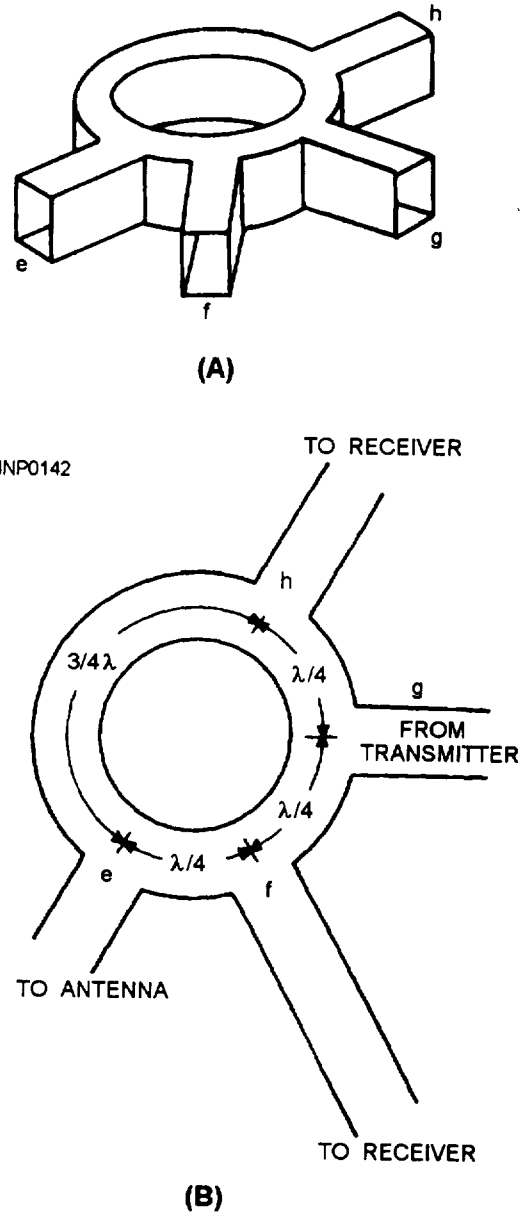

Figure 3-69.—Hybrid ring with wavelength measurements.

APPENDIX I

GLOSSARY

ABSORPTION—(1) Absorbing light waves. Does not allow any reflection or refraction; (2) Atmospheric absorption of rf energy with no reflection or refraction (adversely affects long-distance communications).

ACOUSTICS—The science of sound.

AMPLITUDE—The portion of a cycle measured from a reference line to a maximum value above (or to a maximum value below) the line.

ANGLE OF INCIDENCE—The angle between the incident wave and the normal.

ANGLE OF REFLECTION—The angle between the reflected wave and the normal.

ANGLE OF REFRACTION—The angle between the normal and the path of a wave through the second medium.

ANGSTROM UNIT—The unit used to define the wavelength of light waves.

ANISOTROPIC—The property of a radiator to emit strong radiation in one direction.

ANTENNA—A conductor or set of conductors used either to radiate rf energy into space or to collect rf energy from space.

APERTURE—See SLOT.

ARRAY OF ARRAYS—See COMBINATION ARRAY.

BAY—Part of an antenna array.

BEARING—An angular measurement that indicates the direction of an object in degrees from true north. Also called azimuth.

BEVERAGE ANTENNA—A horizontal, longwire antenna designed for reception and transmission of low-frequency, vertically polarized ground waves. Also known as WAVE ANTENNA.

BIDIRECTIONAL ARRAY—An array that radiates in opposite directions along the line of maximum radiation.

BROADSIDE ARRAY—An array in which the direction of maximum radiation is perpendicular to the plane containing the elements.

BOUNDARY CONDITIONS—The two conditions that the E-field and H-field within a waveguide must meet before energy will travel down the waveguide. The E-field must be perpendicular to the walls and the H-field must be in closed loops, parallel to the walls, and perpendicular to the E-field.

CAVITY RESONATOR—A space totally enclosed by a metallic conductor and supplied with energy in such a way that it becomes a source of electromagnetic oscillations. The size and shape of the enclosure determine the resonant frequency.

CENTER-FEED METHOD—Connecting the center of an antenna to a transmission line, which is then connected to the final (output) stage of the transmitter. Also known as CURRENT-FEED METHOD.

CHARACTERISTIC IMPEDANCE—The ratio of voltage to current at any given point on a transmission line. Represented by a value of impedance.

CHOKE JOINT—A joint between two sections of waveguide that provides a good electrical connection without power losses or reflections.

COAXIAL LINE—A type of transmission line that contains two concentric conductors.

COLLINEAR ARRAY—An array with all the elements in a straight line. Maximum radiation is perpendicular to the axis of the elements.

COMBINATION ARRAY—An array system that uses the characteristics of more than one array. Also known as ARRAY OF ARRAYS.

COMPLEX WAAE—A wave produced by combining two or more pure tones at the same time.

CONDUCTANCE—The opposite of resistance in transmission lines. The minute amount of resistance that is present in the insulator of a transmission line.

CONNECTED ARRAY—see DRIVEN ARRAY

COPPER LOSS—Power loss in copper conductors caused by the internal resistance of the conductors to current flow. Also know as I^2R LOSS.

CORNER-REFLECTOR ANTENNA—A half-wave antenna with a reflector consisting of two flat metal surfaces meeting at an angle behind the radiator.

COUNTERPOISE—A network of wire that is connected to a quarter-wave antenna at one end and provides the equivalent of an additional ¼ wavelength.

COUPLING DEVICE—A coupling coil that connects the transmitter to the feeder.

CREST (TOP)—The peak of the positive alternation (maximum value above the line) of a wave.

CRITICAL ANGLE—The maximum angle at which radio waves can be transmitted and still be refracted back to earth.

CRITICAL FREQUENCY—The maximum frequency at which a radio wave can be transmitted vertically and still be refracted back to earth.

CURRENT-FEED METHOD—See CENTER-FEED METHOD.

CURRENT STANDING-WAVE RATIO (ISWR)—The ratio of maximum to minimum current along a transmission line.

CUTOFF FREQUENCY—The frequency at which the attenuation of a waveguide increases sharply and below which a traveling wave in a given mode cannot be maintained. A frequency with a half wavelength that is greater than the wide dimension of a waveguide.

CYCLE—One complete alternation of a sine wave that has a maximum value above and a maximum value below the reference line.

DAMPING—Reduction of energy by absorption.

DENSITY—(1) The compactness of a substance; (2) Mass per unit volume.

DETECTOR—The device that responds to a wave or disturbance.

DIELECTRIC HEATING—The heating of an insulating material by placing it in a high frequency electric field.

DIELECTRIC LOSSES—The losses resulting from the heating effect on the dielectric material between conductors.

DIELECTRIC CONSTANT—The ratio of a given dielectric to the dielectric value of a vacuum.

DIFFRACTION—The bending of the paths of waves when the waves meet some form of obstruction.

DIPOLE—A common type of half-wave antenna made from a straight piece of wire cut in half. Each half operates at a quarter wavelength of the output.

DIRECTIONAL.—Radiation that varies with direction.

DIRECTIONAL COUPLER—A device that samples the energy traveling in a waveguide for use in another circuit.

DIRECTOR—The parasitic element of an array that reinforces energy coming from the driver toward itself.

DIRECTIVITY—The property of an array that causes more radiation to take place in certain directions than in others.

DISTRIBUTED CONSTANTS—The constants of inductance, capacitance, and resistance in a transmission line. The constants are spread along the entire length of the line and cannot be distinguished separately.

DOMINANT MODE—The easiest mode to produce in a waveguide, and also, the most efficient mode in terms of energy transfer.

DOPPLER EFFECT—The apparent change in frequency or pitch when a sound source moves either toward or away from a listener.

DOUBLET—Another name for the dipole antenna.

DRIVEN ARRAY—An array in which all of the elements are driven. Also known as CONNECTED ARRAY

DRIVEN ELEMENT—An element of an antenna (transmitting or receiving) that is connected directly to the transmission line.

DUMMY LOAD—A device used at the end of a transmission line or waveguide to convert transmitted energy into heat so no energy is radiated outward or reflected back.

E-FIELD—Electric field that exists when a difference in electrical potential causes a stress in the dielectric between two points. Also known as ELECTRIC FIELD.

E-TYPE T-JUNCTION—A waveguide junction in which the junction arm extends from the main waveguide in the same direction as the E-field in the waveguide.

ECHO—The reflection of the original sound wave as it bounces off a distant surface.

ELECTROMAGNETIC FIELD—The combination of an electric (E) field and a magnetic (H) field.

ELECTROMAGNETIC INTERFERENCE—Man-made or natural interference that degrades the quality of reception of radio waves.

ELECTROMAGNETIC RADIATION—The radiation of radio waves into space.

ELECTRIC FIELD—See E-FIELD.

ELEMENT—A part of an antenna that can be either an active radiator or a parasitic radiator.

END-FEED METHOD—Connecting one end of an antenna through a capacitor to the final output stage of a transmitter. Also known as VOLTAGE-FEED METHOD.

END-FIRE ARRAY—An array in which the direction of radiation is parallel to the axis of the array.

ELEVATION ANGLE—The angle between the line of sight to an object and the horizontal plane.

FADING—Variations in signal strength by atmospheric conditions.

FEEDER—A transmission line that carries energy to the antenna.

FLAT LINE—A transmission line that has no standing waves. This line requires no special tuning device to transfer maximum power.

FLEXIBLE COAXIAL LINE— coaxial line made with a flexible inner conductor insulated from the outer conductor by a solid, continuous insulating material.

FOLDED DIPOLE—An ordinary half-wave antenna (dipole) that has one or more additional conductors connected across the ends parallel to each other.

FOUR-ELEMENT ARRAY—An array with three parasitic elements and one driven element.

FREE-SPACE LOSS—The loss of energy of a radio wave because of the spreading of the wavefront as it travels from the transmitter.

FREQUENCY—The number of cycles that occur in one second. Usually expressed in Hertz.

FREQUENCY DIVERSITY—Transmitting (and receiving) of radio waves on two different frequencies simultaneously.

FRONT-TO-BACK RATIO—The ratio of the energy radiated in the principal direction to the energy radiated in the opposite direction.

FUNDAMENTAL FREQUENCY—The basic frequency or first harmonic frequency.

GAIN—The ratio between the amount of energy propagated from an antenna that is directional to the energy from the same antenna that would be propagated if the antenna were not directional.

GENERATOR END—See INPUT END

GROUND PLANE—The portion of a groundplane antenna that acts as ground.

GROUND-PLANE ANTENNA—A type of antenna that uses a ground plane as a simulated ground to produce low-angle radiation.

GROUND REFLECTION LOSS—The loss of rf energy each time a radio wave is reflected from the earth's surface.

GROUND SCREEN—A series of conductors buried below the surface of the earth and arranged in a radial pattern. Used to reduce losses in the ground.

GROUND WAVES—Radio waves that travel near the surface of the earth.

GROUP VELOCITY—The forward progress velocity of a wave front in a waveguide.

H-FIELD—Any space or region in which a magnetic force is exerted. The magnetic field may be produced by a current-carrying coil or conductor, by a permanent magnet, or by the earth itself. Also known as MAGNETIC FIELD.

H-TYPE T-JUNCTION—A waveguide junction in which the junction arm is parallel to the magnetic lines of force in the main waveguide.

HALF-WAVE DIPOLE ANTENNA—An antenna consisting of two rods (¼ wavelength h) in a straight line, that radiates electromagnetic energy.

HARMONIC—A frequency that is a whole number multiple of a smaller base frquency.

HERTZ ANTENNA—A half-wave antenna installed some distance above ground and positioned either vertically or horizontally.

HORN—A funnel-shaped section of waveguide used as a termination device and as a radiating antenna.

HORIZONTAL AXIS—On a graph, the straight line axis plotted from left to right.

HORIZONTAL PATTERN—The part of a radiation pattern that is radiated in all directions along the horizontal plane.

HORIZONTALLY POLARIZED—Waves that are radiated with their E-field component parallel to the earth's surface.

HYBRID JUNCTION—A waveguide junction that combines two or more basic T-junctions.

HYBRID RING—A hybrid-waveguide junction that combines a series of E-type T-junctions in a ring configuration.

I^2R LOSS—See COPPER LOSS.

INCIDENT WAVE—(1) The wave that strikes the surface of a medium; (2) The wave that travels from the sending end to the receiving end of a transmission line.

INDUCTION FIELD—The electromagnetic field produced about an antenna when current and voltage are present on the same antenna.

INDUCTION LOSSES—The losses that occur when the electromagnetic field around a conductor cuts through a nearby metallic object and induces a current into that object.

INPUT END—The end of a two-wire transmission line that is connected to a source. Also known as a GENERATOR END or a TRANSMITTER END.

INPUT IMPEDANCE—The impedance presented to the transmitter by the transmission line and its load.

INTERFERENCE—Any disturbance that produces an undesirable response or degrades a wave.

IONOSPHERE—The most important region of the atmosphere extending from 31 miles to 250 miles above the earth. Contains four cloud-like layers that affect radio waves.

IONOSPHERIC STORMS—Disturbances in the earth's magnetic field that make communications practical only at lower frequencies.

IONIZATION—The process of upsetting electrical neutrality.

IRIS—A metal plate with an opening through which electromagnetic waves may pass. Used as an impedance matching device in waveguides.

ISOTROPIC RADIATION—The radiation of energy equally in all directions.

LEAKAGE CURRENT—The small amount of current that flows between the conductors of a transmission line through the dielectric.

LOAD END—See OUTPUT END.

LOAD ISOLATOR—A passive attenuator in which the loss in one direction is much greater than that in the opposite direction. An example is a ferrite isolator for waveguides that allow energy to travel in only one direction.

LOADING—See LUMPED-IMPEDANCE TUNING.

LOBE—An area of a radiation pattern plotted on a polar-coordinate graph that represents maximum radiation.

LONG-WIRE ANTENNA—An antenna that is a wavelength or more long at its operating frequency.

LONGITUDINAL WAVES—Waves in which the disturbance (back and forth motion) takes place in the direction of propagation. Sometimes called compression waves.

LOOP—(1) The curves of a standing wave or antenna that represent amplitude of current or voltage; (2) A curved conductor that connects the ends of a coaxial cable or other transmission line and projects into a waveguide or resonant cavity for the purpose of injecting or extracting energy.

LOWEST USABLE FREQUENCY—The minimum operating frequency that can be used for communications between two points.

LUMPED CONSTANTS—The properties of inductance, capacitance, and resistance in a transmission line.

LUMPED-IMPEDANCE TUNING—The insertion of an inductor or capacitor in series with an antenna to lengthen or shorten the antenna electrically. Also known as LOADING.

LOOSE COUPLING—Inefficient coupling of energy from one circuit to another that is desirable in some applications. Also called weak coupling.

MAGIC-T JUNCTION—A combination of the H-type and E-type T-junctions.

MAGNETIC FIELD—See H-FIELD.

MAJOR LOBE—The lobe in which the greatest amount of radiation occurs.

MARCONI ANTENNA—A quarter-wave antenna oriented perpendicular to the earth and operated with one end grounded. Also known as QUARTER-WAVE ANTENNA.

MAXIMUM USABLE FREQUENCY—Maximum frequency that can be used for communications between two locations for a given time of day and a given angle of incidence.

MEDIUM—The substance through which a wave travels from one point to the next. Air, water, wood, etc., are examples of a medium.

METALLIC INSULATOR—A shorted quarter-wave section of transmission line.

MICROWAVE REGION—The portion of the electromagnetic spectrum from 1,000 megahertz to 100,000 megahertz.

MINOR LOBE—The lobe in which the radiation intensity is less than a major lobe.

MULTIELEMENT ARRAY—An array consisting of one or more arrays and classified as to directivity.

MULTIELEMENT PARASITIC ARRAY—An array that contains two or more parasitic elements and a driven element.

MULTIPATH—The multiple paths a radio wave may follow between transmitter and receiver.

NEGATIVE ALTERNATION—The portion of a sine wave below the reference line.

NODE—The fixed minimum points of voltage or current on a standing wave or antenna.

NONDIRECTIONAL—See OMNIDIRECTIONAL,

NONRESONANT LINE—A transmission line that has no standing waves of current or voltage.

NORMAL—The imaginary line perpendicular to the point at which the incident wave strikes the reflecting surface. Also called the perpendicular.

NULL—On a polar-coordinate graph, the area that represents minimum or 0 radiation.

OMNIDIRECTIONAL—Transmitting in all directions. Also known as NONDIRECTIONAL.

OPEN-ENDED LINE—A transmission line that has an infinitely large terminating impedance.

OPTIMUM WORKING FREQUENCY—The most practical operating frequency that can be used with the least amount of problems; roughly 85 percent of the maximum usable frequency.

ORIGIN—The point on a graph where the vertical and horizontal axes cross each other.

OUTPUT END—The end of a transmission line that is opposite the source. Also known as RECEIVING END.

OUTPUT IMPEDANCE—The impedance presented to the load by the transmission line and its source.

PARALLEL RESONANT CIRCUIT—A circuit that acts as a high impedance at resonance.

PARALLEL-WIRE—A type of transmission line consisting of two parallel wires.

PARASITIC ARRAY—An array that has one or more parasitic elements.

PARASITIC ELEMENT—The passive element of an antenna array that is connected to neither the transmission line nor the driven element.

PERIOD—The amount of time required for completion of one full cycle.

PHASE SHIFTER—A device used to change the phase relationship between two ac signals.

PLANE OF POLARIZATION—The plane (vertical or horizontal) with respect to the earth in which the E-field propagates.

POSITIVE ALTERNATION—The portion of a sine wave above the reference line.

POWER GAIN—The ratio of the radiated power of an antenna compared to the output power of a standard antenna. A measure of antenna efficiency usually expressed in decibels. Also referred to as POWER RATIO.

POWER LOSS—The heat loss in a conductor as current flows through it.

POWER RATIO—See POWER GAIN.

POWER STANDING—WAVE RATIO (PSWR)—The ratio of the square of the maximum and minimum voltages of a transmission line.

PROPAGATION—Waves traveling through a medium.

PROBE—A metal rod that projects into, but is insulated from, a waveguide or resonant cavity and used to inject or extract energy.

QUARTER-WAVE ANTENNA—See MARCONI ANTENNA.

RADIATION FIELD—The electromagnetic field that detaches itself from an antenna and travels through space.

RADIATION LOSSES—The losses that occur when magnetic lines of force about a conductor are projected into space as radiation and are not returned to the conductor as the cycle alternates.

RADIATION PATTERN—A plot of the radiated energy from an antenna.

RADIATION RESISTANCE—The resistance, which if inserted in place of an antenna, would consume the same amount of power as that radiated by the antenna.

RADIO FREQUENCIES—Electromagnetic frequencies that fall between 3 kilohertz and 300 gigahertz and are used for radio communications.

RADIO HORIZON—The boundary beyond the natural horizon in which radio waves cannot be propagated over the earth's surface.

RADIO WAVE—(1) A form of radiant energy that can neither be seen nor felt; (2) An electromagnetic wave generated by a transmitter.

RAREFIED WAVE—A longitudinal wave that has been expanded or rarefied (made less dense) as it moves away from the source.

RECEIVER—The object that responds to a wave or disturbance. Same as detector.

RECEIVING ANTENNA—The device used to pick up an rf signal from space.

RECEIVING END—See OUTPUT END.

RECIPROCITY—The ability of an antenna to both transmit and receive electromagnetic energy with equal efficiency.

REFLECTED WAVE—(1) The wave that reflects back from a medium; (2) Waves traveling from the load back to the generator on a transmission line; (3) The wave moving back to the sending end of a transmission line after reflection has occurred.

REFLECTION WAVES—Waves that are neither transmitted nor absorbed, but are reflected from the surface of the medium they encounter.

REFLECTOR—The parasitic element of an array that causes maximum energy radiation in a direction toward the driven element.

REFRACTION—The changing of direction as a wave leaves one medium and enters another medium of a different density.

REFRACTIVE INDEX—The ratio of the phase velocity of a wave in free space to the phase velocity of the wave in a given substance (dielectric).

RERADIATION—The reception and retransmission of radio waves caused by turbulence in the troposphere.

RESONANCE—The condition produced when the frequency of vibrations are the same as the natural frequency (of a cavity), The vibrations reinforce each other.

RESONANT LINE—A transmission line that has standing waves of current and voltage.

RHOMBIC ANTENNA—A diamond-shaped antenna used widely for long-distance, high-frequency transmission and reception.

RIGID COAXIAL LINE—A coxial line consisting of a central, insulated wire (inner conductor) mounted inside a tubular outer conductor.

ROTATING JOINT—A joint that permits one section of a transmission line or waveguide to rotate continuously with respect to another while passing energy through the joint. Also called a rotary coupler.

SCATTER ANGLE—The angle at which the receiving antenna must be aimed to capture the scattered energy of tropospheric scatter.

SELF-INDUCTION—The phenomenon caused by the expanding and collapsing fields of an electron that encircles other electrons and retards the movement of the encircled electrons.

SERIES RESONANT CIRCUIT—A circuit that acts as a low impedance at resonance.

SHIELDED PAIR—A line consisting of parallel conductors separated from each other and surrounded by a solid dielectric.

SHORT-CIRCUITED LINE—A transmission line that has a terminating impedance equal to 0.

SKIN EFFECT—The tendency for alternating current to concentrate in the surface layer of a conductor. The effect increases with frequency and serves to increase the effective resistance of the conductor.

SKIP DISTANCE—The distance from a transmitter to the point where the sky wave is first returned to earth.

SKIP ZONE—A zone of silence between the point where the ground wave becomes too weak for reception and the point where the sky wave is first returned to earth.

SKY WAVES—Radio waves reflected back to earth from the ionosphere.

SLOT—Narrow opening in a waveguide wall used to couple energy in or out of the waveguide. Also called an APERTURE or a WINDOW.

SOURCE—(1) The object that produces waves or disturbance; (2) The name given to the end of a two-wire transmission line that is connected to a source.

SPACE DIVERSITY—Reception of radio waves by two or more antennas spaced some distance apart,

SPACE WAVE—A radio wave that travels directly from the transmitter to the receiver and remains in the troposphere.

SPECTRUM—(1) The entire range of electromagnetic waves; (2) VISIBLE. The range of electromagnetic waves that stimulate the sense of sight;

(3) ELECTROMAGNETIC. The entire range of electromagnetic waves arranged in order of their frequencies.

SPORADIC E LAYER—Irregular cloud-like patches of unusually high ionization. Often forms at heights near the normal E-layer.

SPREADER—Insulator used with transmission lines and antennas to keep the parallel wires separated.

STANDING WAVE—The distribution of voltage and current formed by the incident and reflected waves, which have minimum and maximum points on a resultant wave that appears to stand still.

STANDING-WAVE RATIO (SWR)—The ratio of the maximum to the minimum amplitudes of corresponding components of a field, voltage, or current along a transmission line or waveguide in the direction of propagation measured at a given frequency. Measures the perfection of the termination of the line.

STRATOSPHERE—Located between the troposphere and the ionosphere. Has little effect on radio waves.

STUB—Short section of a transmission line used to match the impedance of a transmission line to an antenna. Can also be used to produce desired phase relationships between connected elements of an antenna.

SUDDEN IONOSPHERIC DISTURBANCE—An irregular ionospheric disturbance that can totally blank out hf radio communications.

SURFACE WAVE—A radio wave that travels along the contours of the earth, thereby being highly attenuated.

TEMPERATURE INVERSION—The condition in which warm air is formed above a layer of cool air that is near the earth's surface.

THREE-ELEMENT ARRAY—An array with two parasitic elements (reflector and director) and a driven element.

TRANSMISSION LINE—A device designed to guide electrical energy from one point to another.

TRANSMITTING ANTENNA—The device used to send the transmitted signal energy into space.

TRANSMISSION MEDIUMS—The various types of lines and waveguides used as transmission lines.

TRANSMITTER END—See INPUT END.

TRANSVERSE WAVE MOTION—The up and down motion of a wave as the wave moves outward.

TRANSVERSE ELECTRIC MODE—The entire electric field in a waveguide is perpendicular to the wide dimension and the magnetic field is parallel to the length. Also called the TE mode.

TRANSVERSE MAGNETIC MODE—The entire magnetic field in a waveguide is perpendicular to the wide dimension ("a" wall) and some portion of the electric field is parallel to the length. Also called the TM mode.

TROPOSPHERE—The portion of the atmosphere closest to the earth's surface, where all weather phenomena take place.

TROPOSPHERIC SCATTER—The propagation of radio waves in the troposphere by means of scatter.

TROUGH (BOTTOM)—The peak of the negative alternation (maximum value below the line).

TUNED LINE—Another name for the resonant line. This line uses tuning devices to eliminate the reactance and to transfer maximum power from the source to the line.

TURNSTILE ANTENNA—A type of antenna used in vhf communications that is omnidirectional

and consists of two horizontal half-wave antennas mounted at right angles to each other in the same horizontal plane.

TWISTED PAIR—A line consisting of two insulated wires twisted together to form a flexible line without the use of spacers.

TWO-WIRE OPEN LINE—A parallel line consisting of two wires that are generally spaced from 2 to 6 inches apart by insulating spacers.

TWO-WIRE RIBBON (TWIN LEAD)—A parallel line similar to a two-wire open line except that uniform spacing is assured by embedding the two wires in a low-loss dielectric.

UNIDIRECTIONAL ARRAY—An array that radiates in only one general direction.

UNTUNED LINE—Another name for the flat or nonresonant line.

V ANTENNA—A bidirectional antenna, shaped like a V, which is widely used for communications.

VELOCITY—The rate at which a disturbance travels through a medium.

VERTICAL AXIS—On a graph, the straight line axis oriented from bottom to top.

VERTICAL PATTERN—The part of a radiation pattern that is radiated in the vertical plane.

VERTICAL PLANE—An imaginary plane that is perpendicular to the horizontal plane.

VERTICALLY POLARIZED—Waves radiated with the E-field component perpendicular to the earth's surface.

VOLTAGE-FEED METHOD—See END-FEED METHOD.

VOLTAGE STANDING-WAVE RATIO (VSWR)—The ratio of maximum to minimum voltage of a transmission line.

WAVE ANTENNA—See BEVERAGE ANTENNA.

WAVE MOTION—A recurring disturbance advancing through space with or without the use of a physical medium.

WAVE TRAIN—A continuous series of waves with the same amplitude and wavelength.

WAVEFRONT—A small section of an expanding sphere of electromagnetic radiation, perpendicular to the direction of travel of the energy.

WAVEGUIDE—A rectangular, circular, or elliptical metal pipe designed to transport electro-magnetic waves through its interior.

WAVEGUIDE MODE OF OPERATION—Particular field configuration in a waveguide that satisfies the boundary conditions. Usually divided into two broad types: the transverse electric (TE) and the transverse magnetic (TM).

WAVEGUIDE POSTS—A rod of conductive material used as impedance-changing devices in waveguides.

WAVEGUIDE SCREW—A screw that projects into a waveguide for the purpose of changing the impedance.

WAVELENGTH—(1) The distance in space occupied by 1 cycle of a radio wave at any given instant; (2) The distance a disturbance travels during one period of vibration.

WINDOW—See Slot.

YAGI ANTENNA—A multielement parasitic array. Elements lie in the same plane as those of the end-fire array.

Assignment Questions

Information: The text pages that you are to study are provided at the beginning of the assignment questions.

ASSIGNMENT 1

Textbook Assignment: "Wave Propagation," chapter 1, pages 1-1 through 1-14.

1-1. Which of the following factors can affect atmospheric conditions?

1. Geographic height
2. Geographic location
3. Changes in time
4. All of the above

1-2. In what portion of the atmosphere does the majority of weather phenomena take place?

1. Ionosphere
2. Stratosphere
3. Troposphere
4. Hydrosphere

1-3. Because the stratosphere is a relatively calm region with little or no temperature change, it will have almost no effect on radio wave propagation.

1. True
2. False

1-4. Variations in the ionosphere resulting from changes in the sun's activity are known as

1. regular variations
2. irregular variations
3. both 1 and 2 above
4. seasons

1-5. The regular variations in the ionosphere can be separated into how many classes?

1. One
2. Two
3. Three
4. Four

1-6. In ionization, when an electron is knocked free from a neutral gas atom, what is the overall charge of the atom?

1. Negative
2. Positive
3. Neutral
4. Inverted

1-7. The frequency of ultraviolet light passing through the atmosphere has what relationship to the ionospheric layer it ionizes?

1. It is inversely proportional
2. It is directly proportional
3. It is inversely proportional during the day and directly proportional at night
4. It is directly proportional during the day and inversely proportional at night

1-8. What term best describes the process that returns positive ions to their original neutral state?

1. Refraction
2. Recombination
3. Ionization
4. Polarization

1-9. At what approximate time of day is the density of the ionospheric layers at its lowest level?

1. Just before sunrise
2. Mid-morning
3. Afternoon
4. Sunset

1-10. How many distinct layers make up the ionosphere?

1. One
2. Two
3. Three
4. Four

1-11. At what frequencies does the combination of the earth's surface and the D layer act as a waveguide?

1. Vlf
2. Lf
3. Mf
4. Hf

1-12. The D layer loses its absorptive qualities at frequencies above what level?

1. 30 MHz
2. 20 MHz
3. 10 MHz
4. 3 MHz

1-13. What is the approximate range of the E layer above the earth's surface?

1. 30–54 miles
2. 55–90 miles
3. 91–130 miles
4. 131–160 miles

1-14. Frequencies above what level pass through the E layer unaffected?

1. 50 MHz
2. 100 MHz
3. 150 MHz
4. 200 MHz

1-15. During daylight hours, the F layer will divide into how many separate layers?

1. Five
2. Two
3. Three
4. Four

1-16. Most high-frequency, long-range communications occur in what layer(s) of the ionosphere?

1. D
2. E
3. F
4. H

1-17. Which of the following is NOT a factor for radio wave refraction?

1. Ionization density of the layer
2. Frequency of the radio wave
3. Angle of incidence
4. Transmitter power

1-18. For any given ionized layer, the critical frequency is just below the escape point.

1. True
2. False

1-19. The critical angle for radio wave propagation depends on what two factors?

1. Angle of incidence and layer density only
2. Layer density and wavelength only
3. Angle of incidence and wavelength only
4. Wavelength and antenna height only

1-20. What term best describes the area located between the transmitting antenna and the point where the sky wave first returns to the earth?

1. Ground wave
2. Skip zone
3. Skip distance
4. Ace area

1-21. Which of the following factors will affect the outer limits of the skip zone?

1. Frequency
2. Sunspot activity
3. Angle of transmission
4. All of the above

1-22. Radio waves reflecting from the earth's surface or the ionosphere, 180 degrees out of phase, have what effect, if any, at the receiving station?

1. The signal will be weak or faded
2. The signal will be stronger
3. The signal will be garbled
4. None

1-23. For ionospheric reflection to occur, the ionized layer must not be thicker than how many wavelengths of the transmitted frequency?

1. One
2. Two
3. Three
4. Four

1-24. The ability of radio waves to turn sharp corners and bend around obstacles is known as

1. reflection
2. refraction
3. diffraction
4. waveshaping

1-25. Which of the following definitions best describes a shadow zone?

1. The area of complete coverage at vlf frequencies
2. The area within the diameter of an obstruction
3. The area ranging the height of the obstruction
4. The area on the opposite side of the obstruction, in line-of-site from the transmitter to the receiver

1-26. What type of fading occurs for the longest amount of time?

1. Phase shift
2. Absorption
3. Multipath
4. Diffraction

1-27. Which of the following are examples of multipath radio wave transmissions?

1. Groundwaves
2. Ionospheric refractions
3. Reflection from the earth's surface
4. All of the above

1-28. Fading on the majority of the ionospheric circuits is a result of what particular type of fading?

1. Selective
2. Absorption
3. Multipath
4. Weather

IN ANSWERING QUESTIONS 1-29 AND 1-30, SELECT FROM THE FOLLOWING LIST THE DEFINITION OF THE INDICATED TERM.

A. Two or more receiving antennas spaced apart to produce a usable signal

B. Two or more receiving antennas of varying heights located together

C. The use of two separate transmitters and receivers on different frequencies transmitting the same information

D. The use of two separate transmitters and receivers on the same frequency transmitting the same information

1-29. Space diversity.

1. A
2. B
3. C
4. D

1-30. Frequency diversity.

1. A
2. B
3. C
4. D

1-31. A wide band of frequencies is transmitted and selective fading occurs. Which of the following statements best describes the effect of the fading on the signal?

1. It affects various frequencies
2. It can cause changes in phase and amplitude
3. It can cause severe distortion and limit total signal strength
4. All of the above

1-32. Which ionospheric layer is most dense during the winter?

1. E
2. D
3. F2
4. F1

1-33. During the 27-day sunspot cycle, which ionospheric layer experiences the greatest fluctuations in density?

1. D
2. E
3. F1
4. F2

IN ANSWERING QUESTIONS 1-34 THROUGH 1-38, SELECT FROM THE FOLLOWING LIST THE DEFINITION OF THE INDICATED TERM.

A. Depends on the angle of the sun; refracts hf waves during the day, up to 20 MHz, to distances of 1200 miles; greatly reduced at night

B. Reflects vlf waves for long-range communications; refracts lf and mf for short-range communications; has little effect on vhf and above; gone at night

C. Density depends on the angle of the sun; its main effect is absorption of hf waves passing through to the F2 layer

D. Provides long-range hf communications; very variable; height and density change with time of day, season, and sunspot activity

E. Structure and density depend on the time of day and the angle of the sun; consists of one layer at night and two layers during the day

1-34. D layer.

1. A
2. B
3. C
4. D

1-35. E layer.

1. A
2. B
3. C
4. E

1-36. F layer.

1. B
2. C
3. D
4. E

1-37. F1 layer.

1. A
2. B
3. C
4. D

1-38. F2 layer.

1. A
2. C
3. D
4. E

1-39. During periods of maximum sunspot activity within the eleven-year cycle, critical frequencies for all layers increase.

1. True
2. False

1-40. Which of the following problems is NOT a negative side effect of the sporadic E layer?

1. Causes increased multipath problems
2. Provides additional absorption
3. Blanks out more favorable layers
4. Increased static in line of sight communications

1-41. When sudden ionospheric disturbances (SID) occurs, which ionospheric layer is affected the most?

1. D
2. E
3. F1
4. F2

1-42. What effect do ionospheric storms have on (a) the range of frequencies and (b) the working frequency used for communications?

1. (a) Increase (b) increase
2. (a) Decrease (b) decrease
3. (a) Increase (b) decrease
4. (a) Decrease (b) increase

1-43. What form of precipitation has the greatest absorption effect on RF energy?

1. Fog
2. Snow
3. Rain
4. Hail

1-44. The duct effect produced by temperature inversion allows for long-distance communications over what frequency band?

1. Vlf
2. Lf
3. Hf
4. Vhf

1-45. Which of the following factors affect(s) the amount of ground reflection loss when a radio wave is reflected from the earth's surface?

1. Angle of incidence
2. Ground irregularities
3. Electrical conductivity at the point of reflection
4. All of the above

1-46. As an RF wave increases in distance, the wavefront spreads out, reducing the amount of energy available within any given unit of area. This action produces what type of energy loss?

1. Absorption
2. Ground reflection
3. Freespace
4. Spread

1-47. Radio waves above the MUF will experience what effect when refracted from the ionosphere?

1. They will fall short of the desired location
2. They will overshoot the desired location
3. They will be absorbed by lower layers
4. They will experience multipath fading

1-48. Variations in the ionosphere may change a preexisting muf. This is especially true because of the volatility of which of the following layers?

1. F1
2. F2
3. D
4. E

1-49. Radio waves that are propagated below the LUF are affected by what problem(s)?

1. Increased absorption
2. Higher levels of atmospheric noise
3. Higher rate of refraction
4. All of the above

1-50. The frequency that will avoid the problems of multipath fading, absorption, noise, and rapid changes in the ionosphere is known by what term?

1. LUF
2. MUF
3. FOT
4. LOS

ASSIGNMENT 2

Textbook Assignment: "Antennas," chapter 2, pages 2-1 through 2-32.

2-1. Electromagnetic radiation from an antenna is made up of what two components?

1. E and H fields
2. Ground and sky waves
3. Vertical and horizontal wavefronts
4. Reflected and refracted energy

2-2. What determines the size of a transmitting antenna?

1. Transmitter power
2. Available space
3. Operating frequency
4. Distance to be transmitted

2-3. Most practical transmitting antennas are divided into two classifications, Hertz and Marconi.

1. T
2. F

2-4. Hertz antennas are designed to operate at what wavelength in relationship to their operating frequency?

1. Quarter-wave
2. Half-wave
3. Three quarter-wave
4. Full-wave

2-5. Marconi antennas are used for operating frequencies below what level?

1. 10 MHz
2. 6 MHz
3. 4 MHz
4. 2 MHz

2-6. All antennas regardless of their shape or size have how many basic characteristics?

1. 1
2. 2
3. 3
4. 4

2-7. The ability to use the same antenna for both transmitting and receiving is known by what term?

1. Gain
2. Reciprocity
3. Directivity
4. Polarization

2-8. The ability of an antenna or array to focus energy in one or more specific directions is represented by a measurement of what antenna property?

1. Signal Strength
2. Reciprocity
3. Directivity
4. Polarization

2-9. The gain of a transmitting antenna is 9 dB, what will the gain be for the same antenna used for receiving?

1. 9 dB
2. 6 dB
3. 4 dB
4. 3 dB

2-10. Which, if any, of the following components of a radiated electromagnetic field determines its direction of polarization?

1. H lines
2. E lines
3. Angle of Propagation
4. None of the above

2-11. Over long distances the polarization of a radiated wave changes, at what frequencies will this change be the most dramatic?

1. VLF
2. LF
3. MF
4. HF

2-12. A transmitting antenna at ground level should be polarized in what manner to achieve best signal strength?

1. Horizontally
2. Vertically
3. Circularly
4. Linearly

2-13. What term describes the distance a wave travels during the period of one cycle?

1. Wavelength
2. Frequency
3. Travel time
4. Radiation rate

IN ANSWERING QUESTIONS 2-14 AND 2-15, REFER TO FIGURE 2-4 OF THE TEXT.

2-14. The points of high current and voltage are best described by which of the following terms?

1. Peaks
2. Crescents
3. Loops
4. Highs

2-15. The points of minimum voltage and minimum current are represented by which of the following terms?

1. Lows
2. Valleys
3. Descents
4. Nodes

2-16. An antenna at resonance will transmit at maximum efficiency; an antenna that is not at resonance will lose power in which of the following ways?

1. Skin effect loss
2. Heat loss
3. Ground absorption
4. Wave scattering

2-17. An antenna that radiates energy in all directions is said to have what type of radiation pattern?

1. Isotropic
2. Anisotropic
3. Bysotropic
4. Circumstropic

2-18. An antenna that radiates energy more strongly in one direction than another is said to have what type of radiation pattern?

1. Isotropic
2. Anisotropic
3. Bysotropic
4. Circumstropic

2-19. When viewing a radiation pattern graph, you can expect the areas of maximum and minimum radiation be identified by which of the following terms?

1. High and low probes
2. Maximum and minimum points
3. Major and minor lobes
4. Positive and negative lobes

2-20. If an antenna is too short for the wavelength being used, what electrical compensation must be introduced for the antenna to achieve resonance?

1. Lumped resistance
2. Lumped capacitive reactance
3. Lumped inductive reactance
4. More power

2-21. If an antenna is too long for the wavelength being used, what electrical compensation must be introduced for the antenna to achieve resonance?

1. Lumped resistance
2. Lumped capacitive reactance
3. Lumped inductive reactance
4. Less power

2-22. A ground screen is a series of conductors buried 1 or 2 feet below the surface in a radial pattern and is usually of what length in comparison to the wavelength being used?

1. One-quarter wavelength
2. One-half wavelength
3. Three-quarter wavelength
4. Full wavelength

2-23. When would a counterpoise be used?

1. When easy access to the antenna base is necessary
2. When the surface below is solid rock
3. When the surface below is sandy ground
4. All the above

2-24. Capacitive top-loading helps to increase which of the following antenna characteristics?

1. Bandwidth
2. Power-handling
3. Directivity
4. Radiation efficiency

2-25. What is the most limiting characteristic of the Yagi antenna?

1. Power-handling
2. Narrow bandwidth
3. Physical size
4. Lack of directivity

2-26. In general, log-periodic antennas have which of the following characteristics?

1. Medium power handling capabilities
2. High gain
3. Extremely broad bandwidth
4. All the above

2-27. A typical vertical monopole log periodic antenna designed to cover a frequency range of 2 to 30 MHz will require approximately how many acres of land for its ground plane system?

1. 1 acre
2. 2 acres
3. 3 acres
4. 4 acres

2-28. A sector log-periodic array can act as an antenna for a minimum of what number of transmit or receive systems?

1. 1
2. 2
3. 3
4. 4

2-29. The most distinct advantage of the rotatable log-periodic antenna is its ability to perform what function?

1. Rotate 360 degrees
2. Rotate from horizontal to vertical and back
3. Ability to handle high transmitter power
4. Ability to produce high antenna gain

2-30. What is the average power handling capability of an Inverted Cone antenna?

1. 20 kw
2. 30 kw
3. 40 kw
4. 50 kw

2-31. What determines the gain and directivity of a Rhombic antenna?

1. Transmitter power
2. Antenna height
3. Radiated wave interaction
4. Transmitted frequency

2-32. Most Whip antennas require some kind of a tuning system to improve bandwidth and power handling capabilities.

1. T
2. F

2-33. Why are UHF and VHF antennas on board ship installed as high as possible?

1. To prevent radiation hazard to personnel
2. To prevent radiation hazard to ordinance
3. To increase power handling capabilities
4. To prevent unwanted directivity in the radiation pattern from mast structures

2-34. The central feed section for both the biconical and center-fed dipole are protected by what type of covering?

1. SCOTCHCOAT
2. RTV
3. Laminated fiberglass
4. Rubber shield

2-35. The adjustable stub on the AS-390/SRC uhf antenna is used to adjust what antenna characteristic?

1. The counterpoise angle
2. The input impedance
3. The radiation angle
4. The feed point

2-36. The OE-82B/WSC-I(V) antenna group uses what type of polarization?

1. Vertical
2. Horizontal
3. Right-hand circular
4. Left-hand circular

2-37. The AN/WSC-5 (V) shore station antenna consists of what number of OE-82A/WSC-1 (V) assemblies?

1. 1
2. 2
3. 3
4. 4

2-38. What does the acronym LPI stand for?

1. Low power interference
2. Low probability of intercept
3. Low phase intercept
4. Last pass intercept

2-39. The reflectors for the AN/WSC-6 (V) are mounted on three-axis pedestals and provide auto tracking using what scanning technique?

1. Conical
2. Peripheral
3. Vertical
4. Horizontal

2-40. Antenna tuning is accomplished using what piece or pieces of equipment?

1. Couplers
2. Tuners
3. Multicouplers
4. All the above

2-41. Antenna multicouplers are used to match more than one transmitter or receiver to what number of antennas?

1. 1
2. 2
3. 3
4. 4

2-42. The AN/URA-38 antenna coupler is an automatic tuning system primarily used with which radio transmitter?

1. AN/WSC-3
2. AN/URT-23
3. AN/URC-80
4. AN/FRT-84

2-43. The AN/SRA-57 coupler group operates in which of the following frequency ranges?

1. 2- 6 Mhz
2. 4-12 Mhz
3. 10-30 Mhz
4. 40-60 Mhz

2-44. How many channels are provided with the AN/SRA-12 multicoupler?

1. 4
2. 5
3. 6
4. 7

2-45. What type of radar would use a truncated paraboloid reflector that has been rotated 90 degrees?

1. A surface search
2. An air search
3. A navigation
4. A height-finder

2-46. Of the following methods, which is NOT used to feed a cylindrical paraboloid reflector?

1. A linear array of dipoles
2. A slit in the side of a waveguide
3. A thin waveguide radiator
4. A quarter-wave stub

2-47. The elements of a broadside array are spaced one-half wavelength apart and are spaced how many wavelengths away from the reflector?

1. One-eighth
2. One-quarter
3. One-half
4. Three-quarter

2-48. What is the advantage, if any, to offsetting a feedhorn radiator for a parabolic dish?

1. A broader beam angle
2. The elimination of shadows
3. A narrower beam angle
4. No advantage

2-49. What is the range in nautical miles of the AN/GPN-27 radar?

1. 55
2. 75
3. 105
4. 155

2-50. What is the purpose of the jackscrew on the AS-3263/SPS-49(V) antenna?

1. To adjust the beam width
2. To vary the antenna feed horn focal distance
3. To adjust the beam elevation angle
4. To lockdown the antenna for PM

2-51. The OE-172/SPS-55 antenna normally operates in the linearly polarized mode, for what reason would you use the circular polarized mode?

1. To compensate for the ships pitch and roll
2. To prevent jamming
3. To reduce return echoes from precipitation
4. To achieve over the horizon coverage

2-52. Which of the following is NOT a mode of operation for the AN/SPN-35A radar set?

1. Final
2. Dual
3. Surveillance
4. Simultaneous

2-53. The two primary safety concerns associated with rf fields are rf burns and injuries caused by dielectric heating.

1. T
2. F

2-54. When a person is standing in an rf field, power in excess of what level will cause a noticeable rise in body temperature?

1. 5 milliwatts
2. 10 milliwatts
3. 15 milliwatts
4. 20 milliwatts

2-55. When working aloft, what safety precaution(s) must be followed?

1. Tag out the antenna at the switchboard to prevent it from becoming operational
2. Secure motor safety switches for rotating antennas
3. Wear the proper oxygen breathing apparatus when working near a stack
4. All the above

ASSIGNMENT 3

Textbook Assignment: "Transmission Lines and Waveguides," chapter 3, pages 3-1 through 3-32.

3-1. A transmission line is designed to perform which of the following functions?

1. Disperse energy in all directions
2. Detune a transmitter to match the load
3. Guide electrical energy from point to point
4. Replace the antenna in a communications system

3-2. The conductance value of a transmission line represents which of the following values?

1. Expected value of current flow through the insulation
2. Expected value of voltage supplied by the transmitter
3. Value of the lump and distributed constants of the line divided by impedance
4. Value of the lumped constants of the line as seen by the source and the load

3-3. Distributed constants in a transmission line are distributed in which of the following ways?

1. Between ground and any single point on the line
2. Along the length of the line
3. According to the thickness of the line
4. According to the cross-sectional area of the line

3-4. Leakage current in a two-wire transmission line is the current that flows through what component?

1. The resistor
2. The inductor
3. The insulator
4. The conductor

3-5. Conductance is the reciprocal of what electrical property?

1. Inductance
2. Resistance
3. Capacitance
4. Reciprocity

3-6. A transmission line that has current flowing through it has which of the following fields about it?

1. Electric only
2. Magnetic only
3. Both electric and magnetic
4. Capacitive

3-7. A measurement of the voltage to current ratio (E_{in}/I_{out}) at the input end of a transmission line is called the

1. input-gain rate
2. voltage-gain ratio
3. output impedance
4. input impedance

3-8. The characteristic impedance (2.) of a transmission line is calculated by using which of the following ratios?

1. R_{source} to R_{load} of the line
2. I_{max} to I_{min} at every point along the line
3. E to I at every point along the line
4. E_{in} to E_{out} of the line

3-9. Maximum transfer of energy from the source to the transmission line takes place when what impedance relationship exists between the source and the transmission line?

1. When the load impedance equals the source impedance
2. When the load impedance is twice the source impedance
3. When the load impedance is half the source impedance
4. When the load impedance is one-fourth the source impedance

3-10. Which of the following sets of terms represents a type of loss in a transmission line?

1. I^2R and induction only
2. Induction and dielectric only
3. Dielectric and radiation only
4. I^2R, induction, and dielectric

3-11. Skin effect is classified as which of the following types of loss?

1. Copper
2. Voltage
3. Induction
4. Dielectric

3-12. What transmission-line loss is caused by magnetic lines of force not returning to the conductor?

1. Copper
2. Radiation
3. Induction
4. Dielectric

3-13. When a dc voltage is applied to a transmission line and the load absorbs all the energy, what is the resulting relationship between current and voltage?

1. They are in phase with each other
2. They are equal to Z_o of the line
3. They are out of phase with each other
4. They are evenly distributed along the line

3-14. The initial waves that travel from the generator to the load of a transmission line are referred to as what type of waves?

1. Incident
2. Refracted
3. Reflected
4. Diffracted

3-15. Waves that travel from the output end to the input end of a transmission line are referred to as what type of waves?

1. Incident
2. Refracted
3. Reflected
4. Diffracted

3-16. The ratio of maximum voltage to minimum voltage on a transmission line is referred to as the

1. rswr
2. pswr
3. vswr
4. iswr

3-17. Which of the following ratios samples the magnetic field along a line?

1. Vswr
2. Pswr
3. Iswr
4. Rswr

3-18. Which of the following lines is NOT a transmission medium?

1. Load line
2. Coaxial line
3. Two-wire open line
4. Twisted-pair line

3-19. Electrical power lines are most often made of which of the following types of transmission lines?

1. Twin-lead line
2. Shielded-pair line
3. Two-wire open line
4. Two-wire ribbon line

3-20. Uniform capacitance throughout the length of the line is an advantage of which of the following transmission lines?

1. Coaxial line
2. Twisted pair
3. Shielded pair
4. Two-wire open line

3-21. What is the primary advantage of a rigid coaxial line?

1. Low radiation losses
2. Inexpensive construction
3. Low high-frequency losses
4. Easy maintenance

3-22. The most efficient transfer of electromagnetic energy can be provided by which of the following mediums?

1. Waveguides
2. Twin-lead flat lines
3. Single-conductor lines
4. Coaxial transmission lines

3-23. Copper I^2R losses are reduced by what physical property of waveguides?

1. Small surface area
2. Large surface area
3. Shape of the waveguides
4. Waveguide material being used

3-24. In a coaxial line, the current-carrying area of the inner conductor is restricted to a small surface layer because of which of the following properties?

1. Skin effect
2. Copper loss
3. Conductor density
4. Waveguide material being used

3-25. Which of the following dielectrics is used in waveguides?

1. Air
2. Mica
3. Insulating oil
4. Insulating foam

3-26. Which of the following characteristics of a waveguide cause its lower-frequency limitation?

1. I^2R loss
2. Physical size
3. Wall thickness
4. Dielectric loss

3-27. At very high frequencies, ordinary insulators in a two-wire transmission line display the characteristics of what electrical component?

1. An inductor
2. A resistor
3. A capacitor
4. A transformer

3-28. At high frequencies, which of the following devices works best as an insulator?

1. An open half-wave section
2. An open quarter-wave section
3. A shorted half-wave section
4. A shorted quarter-wave section

3-29. The range of operating frequencies is determined by which of the following waveguide dimensions?

1. The widest (height/width)
2. The narrowest (height/width)
3. The shortest (length)
4. The longest (length)

3-30. The cutoff frequency for a waveguide is controlled by the physical dimensions of the waveguide and is defined as the frequency at which two quarter wavelengths are

1. shorter than the "a" dimension
2. shorter than the "b" dimension
3. longer than the "a" dimension
4. longer than the "b" dimension

3-31. In practical applications, which of the following dimensions describes the wide dimension of the waveguide at the operating frequency?

1. 0.1 wavelength
2. 0.2 wavelength
3. 0.5 wavelength
4. 0.7 wavelength

3-32. Which of the following fields is/are present in waveguides?

1. E field only
2. H field only
3. E and H fields
4. Stationary fields

3-33. A difference in potential across a dielectric causes which of the following fields to develop?

1. Electric only
2. Magnetic only
3. Electromagnetic

3-34. H lines have which of the following distinctive characteristics?

1. They are continuous straight lines
2. They are generated by voltage
3. They form closed loops
4. They form only in the waveguide

3-35. For an electric field to exist at the surface of a conductor, the field must have what angular relationship to the conductor?

1. 0°
2. 30°
3. 45°
4. 90°

3-36. If the wall of a waveguide is perfectly flat, the angle of reflection is equal to which of the following angles?

1. Cutoff
2. Incidence
3. Refraction
4. Penetration

3-37. The cutoff frequency in a waveguide occurs at exactly what angle of reflection?

1. 10°
2. 30°
3. 45°
4. 90°

3-38. How does the group velocity of an electromagnetic field in a waveguide compare to the velocity of a wavefront through free space?

1. Group velocity is somewhat faster
2. Group velocity is somewhat slower
3. Group velocity is twice that of free velocity
4. Free velocity is twice that of group velocity

3-39. The group velocity of a wavefront in a waveguide may be increased by which of the following actions?

1. Decreasing the frequency of the input energy
2. Increasing the frequency of the input energy
3. Increasing the power of the input energy
4. Decreasing the power of the input energy

3-40. The various field configurations that can exist in a waveguide are referred to as

1. wavefronts
2. modes of operation
3. fields of operation
4. fields of distribution

3-41. The most efficient transfer of energy occurs in a waveguide in what mode?

1. Sine
2. Dominant
3. Transverse
4. Time-phase

3-42. How is the cutoff wavelength for a circular waveguide computed?

1. 1.17 times the radius of the waveguide
2. 1.17 times the diameter of the waveguide
3. 1.71 times the diameter of the waveguide
4. 1.71 times the radius of the waveguide

3-43. The field configuration in waveguides is divided into what two categories?

1. Half-sine and dominant
2. Transverse electric and transverse magnetic
3. Transverse electric and dominant
4. Transverse magnetic and half-sine

3-44. With a mode description of $TE_{1,0}$, what maximum number of half-wave patterns exist across the "a" dimension of a waveguide?

1. One
2. Two
3. Three
4. Four

3-45. With the mode description, $TE_{1,1}$, what maximum number of half-wave patterns exist across the diameter of a circular waveguide?

1. One
2. Two
3. Three
4. Four

3-46. Which of the following devices CANNOT be used to inject or remove energy from a waveguide?

1. A slot
2. A loop
3. A probe
4. A horn

3-47. Loose coupling is a method used to reduce the amount of energy being transferred from a waveguide. How is loose coupling achieved when using a probe?

1. By doubling the size of the probe
2. By increasing the length of the probe
3. By decreasing the length of the probe
4. By placing the probe directly in the center of the energy field

3-48. Increasing the size of the loop wire increases which of the following loop capabilities?

1. Efficiency
2. Bandwidth coverage
3. Power-handling capability
4. Each of the above

3-49. A waveguide that is not perfectly impedance matched to its load is not efficient. Which of the following conditions in a waveguide causes this inefficiency?

1. Sine waves
2. Dominant waves
3. Standing waves
4. Transverse waves

3-50. A waveguide iris that covers part of both the electric and magnetic planes acts as what type of equivalent circuit at the resonant frequency?

1. As an inductive reactance
2. As a shunt resistance
3. As a capacitive reactance
4. As a shorted 1/4 wave stub

3-51. A horn can be used as a waveguide termination device because it provides which of the following electrical functions?

1. A reflective load
2. An absorptive load
3. An abrupt change in impedance
4. A gradual change in impedance

3-52. For a waveguide to be terminated with a resistive load, that load must be matched to which of the following properties of the waveguide?

1. The bandwidth
2. The frequency

4. The characteristic impedance

3-53. A resistive device with the sole purpose of absorbing all the energy in a waveguide without causing reflections is a/an

1. iris
2. horn
3. antenna
4. dummy load

3-54. A resistive load most often dissipates energy in which of the following forms?

1. Heat
2. Light
3. Magnetic
4. Electrical

3-55. Reflections will be caused by an abrupt change in which of the following waveguide's physical characteristics?

1. Size and shape only
2. Size and dielectric material only
3. Dielectric material and shape only
4. Size, shape, and dielectric material

3-56. A waveguide bend that in the E and H plane must be greater than two wavelengths to prevent

1. cracking
2. reflections
3. energy gaps
4. electrolysis

3-57. A flexible waveguide is used in short sections because of the power-loss disadvantages. What is the cause of this power loss?

1. Walls are not smooth
2. E and H fields are not perpendicular
3. Cannot be terminated in its characteristic impedance
4. Wall size cannot be kept consistent

3-58. The choke joint is used for what purpose in a waveguide?

1. To reduce standing waves
2. To restrict the volume of electron flow
3. To prevent the field from rotating
4. To provide a joint that can be disassembled during maintenance

3-59. A circular waveguide is normally used in a rotating joint because rotating a rectangular waveguide would cause which of the following unwanted conditions?

1. Oscillation
2. Large power loss
3. Decrease in bandwidth
4. Field-pattern distortion

3-60. In your waveguide inspection, you should be alert for which of the following problems?

1. Corrosion
2. Damaged surfaces
3. Improperly sealed joints
4. Each of the above

3-61. What type of corrosion occurs when dissimilar metals are in contact with each other?

1. Contact
2. Metallic
3. Electrical
4. Electrolytic

3-62. Internal arcing in a waveguide is usually a symptom of which of the following conditions?

1. Change in mode
2. Electrolysis at a joint
3. Moisture in the waveguide
4. Gradual change in frequency

3-63. What is the primary purpose of a directional coupler?

1. To sample the energy in a waveguide
2. To change the phase of the energy in the waveguide
3. To change the direction of energy travel in the waveguide
4. To allow energy in the waveguide to travel in one direction only

3-64. What is the electrical distance between the two holes in a simple directional coupler?

1. 1/8 wavelength
2. 1/4 wavelength
3. 1/2 wavelength
4. 3/4 wavelength

3-65. Of the following characteristics, which is NOT required for a device to be considered a resonant cavity?

1. Be enclosed by conducting walls
2. Possess resonant properties
3. Contain oscillating electromagnetic fields
4. Be round or elliptical in shape

3-66. What property gives a resonant cavity a narrow bandpass and allows very accurate tuning?

1. Low Q
2. High Q
3. Inductive reactance
4. Capacitive reactance

3-67. What factor(s) determine(s) the primary frequency of a resonant cavity?

1. Size only
2. Shape only
3. Size and shape
4. Q of the cavity

3-68. Tuning is the process of changing what property of a resonant cavity?

1. The Q
2. The power
3. The cutoff frequency
4. The resonant frequency

3-69. What are the two basic types of waveguide T junctions?

1. H and T
2. H and E
3. Hybrid Ring and magic T
4. Q and magic T

3-70. A waveguide junction in which the arm area extends from the main waveguide in the same direction as the electric field is an example of what type junction?

1. E-type T
2. H-type T
3. H-type T junction
4. H-type junction

3-71. Low power handling capabilities and internal power losses are the primary disadvantages of which of the following junctions?

1. Magic T
2. Rat race
3. Duplexer
4. Hybrid ring

3-72. The hybrid ring is usually used as what type of device in radar systems?

1. Mixer
2. Detector
3. Duplexer
4. Impedance matcher

Reconfigurable Antennas

Abstract

Reconfigurable antennas change polarization, operating frequency, or far-field pattern in order to cope with changing system parameters. This paper reviews some of the past and current technology applicable to reconfigurable antennas, with several examples of implementations. Mechanically movable parts and arrays are discussed, as well as more-recent semiconductor-component and tunable-material technologies applicable to reconfigurable antennas.

Keywords: Reconfigurable antennas; reconfigurable arrays; antenna arrays; wideband antennas; reflector antennas; microstrip patch antennas

1. Introduction

To configure means to arrange or organize the parts of something to achieve a purpose. For instance, configuring a microstrip antenna consists of determining the patch shape, substrate parameters, type and location of the feed, etc., in order for the antenna to radiate at a desired frequency and polarization. If the desired operating characteristics of the antenna change, then the antenna must be reconfigured or rebuilt to meet the new specifications. Reconfigurable antennas change their performance characteristics by altering the current flow on an antenna, using mechanically movable parts, phase shifters, attenuators, diodes, tunable materials, or active materials. A reconfigurable antenna can be a single antenna or an array.

A reconfigurable antenna modifies the antenna's pattern, polarization, or frequency/bandwidth in some desirable fashion. For instance, a reconfigurable antenna might steer or place a null in an antenna's pattern, switch from right-hand circularly polarized to left-hand circularly polarized, or move the resonant frequency from 2 GHz to 2.4 GHz. In this way, a single antenna replaces two or more antennas, in order to achieve multiple goals. Arrays are the ultimate reconfigurable antenna, because they have many avenues for controlling the current across the aperture. A reconfigurable array may have reconfigurable elements, or a reconfigurable array may change the amplitude and phase of each element, the number of active elements, the elements' positions, or the polarization.

The idea of reconfiguring an antenna is relatively old. In the early 1930s, the nulls of a two-element array were steered by using a calibrated variable phase changer in order to determine the direction of arrival of a signal [1]. Bruce and Beck changed the size of the rhombic antenna in Figure 1 by stretching the wires with a motor and weights [2]. The element lengths of the rhombus were 184 m, and the interior angles were between 132° and 164°. Reconfiguring the antenna consisted of adjusting the distance of the major axis by more than 100 m. Changing the shape of the rhombic wire antenna steered the beam in elevation. The Multiple-Unit Steerable Antenna (MUSA) was a six-element array of rhombic antennas with phase shifters at five of the elements [3]. A linear phase shift steered the main beam. This concept was perfected and introduced for azimuth scanning with a 14-row by three-column array of polyrod antennas. This array had 13 rotary phase changers for beam steering [4]. The Wullenweber array was invented during WW II. It is a large direction-finding circular array with a narrow beam that scans 360° in azimuth by activating a small group of adjacent elements along the circle [5].

In 1979, "reconfigurability" was defined as "the ability to adjust beam shapes upon command" [6]. The authors used

 ISSN 1045-9243/2012/$26 ©2013 IEEE

a six-beam antenna to dynamically change the coverage area for a communications satellite. Several additional papers reported other reconfigurable space-based arrays. In the 1990s, a research group in England described their efforts to alter the reflecting surface of a parabolic-reflector antenna in order to control the radiation pattern [7]. From the mid-1990s until the present, reconfigurable-antenna projects have mostly involved microstrip antennas, and various semiconductor technologies applied to altering the current flow on the microstrip antenna. Bernhard wrote an excellent overview of reconfigurable antennas, with many examples [8].

This paper is an introduction/tutorial on reconfigurable-antenna technology. It begins with the oldest technology, mechanically movable parts and arrays, and then transitions to the more-recent semiconductor-component and tunable-material technologies. A detailed explanation of the technology with background information and examples are given. Some of the interesting material technologies, such as active materials, are promising for reconfigurable antennas with low loss at high frequencies.

2. Mechanically Movable Parts

The first reconfigurable antennas had mechanically movable parts (as in Figure 1). Large reflector antennas moved feeds to steer the main beam, or interchanged feed antennas to change frequency bands. An excellent example is the Arecibo spherical-reflector antenna, shown in Figure 2. A Gregorian dome and a carriage house with linear antennas are on either side of a curved track, called the azimuth arm. Electric motors move the Gregorian dome and carriage house many meters from vertical to 20° off vertical, in addition to rotating 360° in azimuth, in order to steer the main beam. Inside the Gregorian dome, the secondary and tertiary reflectors focus the radiation onto one of several receiving antennas, which can be moved into position using a large rotating platform. Hanging below the carriage house are various linear antennas, each tuned to a narrow band of frequencies. A second example is a beam-waveguide antenna. This type of Cassegrain reflector guides the signal by mirrors, from its normal focal point near the vertex, to a focal point below the structural support (Figure 3) [9]. The rotating reflector at the base of the antenna steers the signal to an appropriate feed. In this way, a single reflector antenna can cover a very broad frequency range.

It is also possible to place nulls in the antenna pattern by altering the reflector's surface. One approach to reconfiguring a reflector's surface is to move scattering plates near the surface to cause cancellation of interfering signals entering the sidelobes [10, 11]. Distorting a mesh-reflector's surface using electrostatic controls is another possible approach [7, 12]. The scattering from a small distorted part of the reflector is sufficient to place a null in a sidelobe.

3. Reconfigurable Arrays

Most reconfigurable arrays control the array pattern in order to steer the beam, place a null, modify the main beam shape, or change the sidelobe levels. There have been several applications that involve changing the polarization or frequency of operation, as well. The textbook approach to reconfiguring an array has adjustable amplitude and/or phase weights at each element. The literature on these arrays is vast, and will not be covered here. A digital beamformer significantly enhances the ability of the array to control the radiation pattern, since all the reconfiguring is done in software.

Beam control is possible by turning elements on and off in the array, as was mentioned earlier with a Wullenweber array.

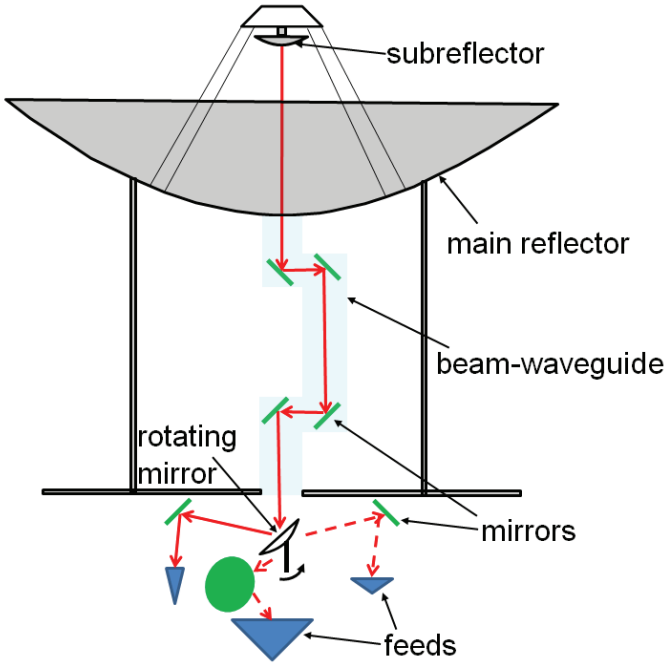

Figure 3. A diagram of a beam-waveguide antenna.

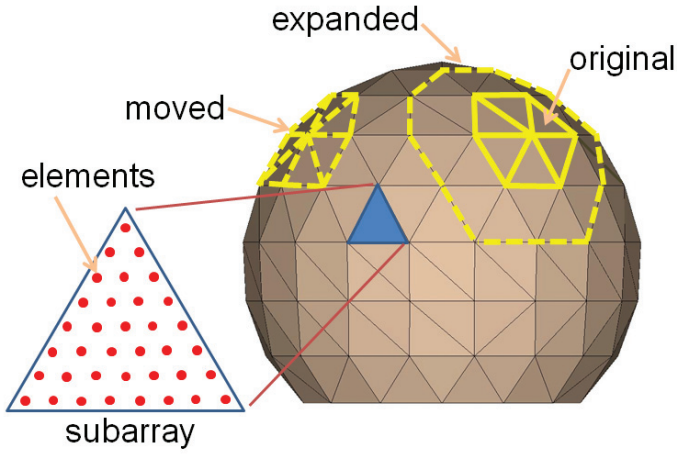

Figure 4. A phased array built on a geodesic dome. The yellow regions represent regions of activated subarrays.

Figure 4 shows this concept extended to a spherical array that was implemented on a geodesic dome. Each triangle on the dome was a subarray [13]. The active aperture was formed by combining the outputs from adjacent subarrays. Including more subarrays expanded the original active aperture (Figure 4). The active aperture could be moved to another location on the dome in order to point the main beam in a different direction. Other reconfigurable arrays that make use of switching an element on and off include dynamically thinning an array as one way to alter the sidelobe levels and nulls in order to reject interference [14], and time-modulated arrays that lower the average sidelobe levels by quickly switching elements on and off, with on times proportional to the desired amplitude of the element weight [15].

Another approach to reconfiguring an array is to physically move elements. Some very large reflector-antenna arrays use this concept. For instance, the Atacama Large Millimeter/sub-millimeter Array, or ALMA, will be a radio telescope composed of 66 12 m and 7 m parabolic dishes in Chile's Andes Mountains (Figure 5) [16]. The telescope will operate at frequencies from 31.25 GHz to 950 GHz. Array configurations from 250 m to 15 km will be possible. The ALMA antennas will be moved between flat concrete slabs by a special vehicle, as shown in Figure 5. A second example is the Very Large Array (VLA) radio telescope in New Mexico, built from 27 dish antennas that are 25 m in diameter [17]. Elements are placed in a Y shape, and can be changed by moving the elements along a railroad track (Figure 6). Four possible configurations, with aperture sizes of 36 km, 10 km, 3.6 km, or 1 km, are used. The array can operate between 73 MHz and 50 GHz.

The idea of moving elements to form a desired array aperture also extends to space. For instance, the TechSat 21 project investigated creating a large sparse antenna array by placing antenna elements on small spacecraft, and assembling the aperture with a formation of the satellites [18]. Beam formation was a function of the satellite constellation and the weighting of the signals.

4. RF Switches

An RF switch serves to open or close a current path on a reconfigurable antenna. A popular way to build a reconfigurable antenna is to connect various pieces of the antenna with RF switches. Opening and closing switches guides the current in a desirable path that changes the antenna's radiation properties, as well as its impedance.

RF switches may be mechanical or semiconductor. A switch is an open circuit when no actuation voltage is applied, and a low-impedance path for the RF signal when an actuation voltage is applied. The switch can be implemented in a series or shunt configuration. Some important characteristics of a switch are [19]:

- Characteristic impedance: if the switch is non-reflective, then it is matched to the transmission path; otherwise, it is reflective. The VSWR or return loss indicate the degree of matching.
- Bandwidth: some switches are low-pass filters (pass dc), while others are bandpass filters.
- Topology: is the switch normally on or off?
- Insertion loss and isolation: the ratio between the switch's output and input powers when the switch is on and off, respectively.
- Switching speed: the on time for a switch is defined by the time from when the control pulse reaches 50% of its level to the time that the RF signal is at 90% of its peak. The off time for a switch is defined by the time from when the control pulse reaches 50% of its level to the time that the RF signal is at 10% of its peak. Switching time is the larger of the on and off switch times.
- Expected life time: measured in number of switch actuations until failure.
- Power handling: measured in watts.

Below microwave frequencies, a low-pass switch acts like a resistor (R_{on}) when on, and a capacitor (C_{off}) when off. In contrast, a bandpass switch behaves like one capacitor when on, and a different capacitor when off. As the frequency increases, the ground inductance, bond-wire inductance, and transmission-line properties become significant factors, and complicate the circuit model. Parasitic resistances in the switch limit the upper-frequency bound. A switch figure-of-merit (FOM) is the cutoff frequency [20]:

$$f_c = \frac{1}{2\pi C_{off} R_{on}}. \qquad (1)$$

A rule of thumb for the highest operating frequency for the switch is approximately $f_c/10$ [21].

The switching speeds of semiconductor switches are of the order of nanoseconds, while the switching speeds of mechanical switches are of the order of milliseconds. System constraints may limit the type of switch used, based on required switching times.

Switches can be used to reconfigure microstrip-patch antennas in several different ways. For instance, Figure 7 shows a two-dimensional array of metal patches on a substrate [22]. The sides of adjacent patches are connected with RF switches, in order to configure a desirable patch antenna. Figure 8 is an example of a patch with slots that can be shorted, in order to switch between polarizations [23].

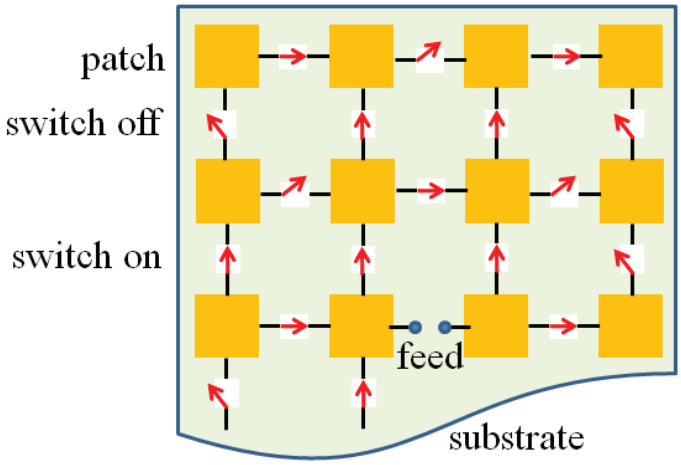

Figure 7. Reconfigurable microstrip patches.

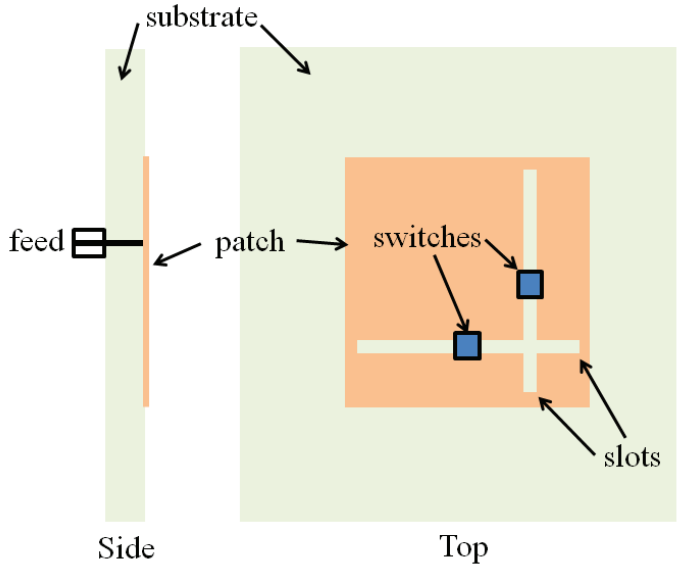

Figure 8. A reconfigurable slotted-patch antenna.

4.1 Semiconductor Switch

Figure 9 is a diagram of a field-effect transistor (FET) switch. Increasing the voltage at the gate increases the conducting channel's size beneath the gate, and allows current to flow between the source and drain. FET switches come in several varieties. Metal-semiconductor field-effect transistor (MESFET) and pseudomorphic high-electron-mobility transistor (PHEMT) switches are two variations, which are compared in Table 1. The authors in [24] suggested using FET switches in a configuration similar to Figure 7. The RF switch array was controlled with a light-emitting-diode backplane, which isolated the control circuitry from the RF paths in the antenna.

Another widely used microwave switch is the PIN diode [25]. It has heavily doped p-type and n-type regions (used for ohmic contacts), which are separated by a wide, lightly-doped intrinsic region (Figure 10). Forward biasing a PIN diode creates a very low resistance at high frequencies, while reverse biasing results in an open circuit. The PIN diode is current controlled, and can handle one or more amps of RF current. The authors in [23] suggested using PIN-diode switches for the configuration in Figure 8.

Table 1 compares the characteristics of FET and PIN-diode switches. Some notable differences between the two types of switches are [26, 27]:

- PIN diodes are current controlled, while FETs are voltage controlled. FETs require only a voltage signal for switching, instead of a dc current. This means that they have essentially zero dc power consumption, compared to the 10 mW or so it takes to turn on a PIN diode.
- PIN diodes have the ability to control large RF signal power while using much smaller levels of control power.
- PIN diodes are less susceptible to electrostatic-discharge (ESD) damage.
- The off-capacitance of PIN diodes is a function of reverse voltage: the more negative the voltage, the less capacitance.
- For FETs, the capacitance is not a strong function of reverse voltage.
- PIN diodes have a higher figure-of-merit than FETs. The useful upper-frequency-response limit of PIN diodes can be much higher, due to lower off-state capacitance (C_{off}) for a given on resistance (R_{on}).

Recently, a reconfigurable patch antenna was demonstrated in which the resonant frequency was altered between 2 GHz and 2.25 GHz, when the electrical length of a spiral-shaped slot in the patch was modified by a biased diode [28].

4.2 MEMS Switches

MEMS switches are tiny mechanical switches made on a substrate (silicon, quartz, glass) [29]. Unlike the PIN-diode and FET switches, a MEMS switch is mechanical. Figure 11 shows three types of MEMS switches in their on and off positions. The cantilever beam in Figures 11a and 11b is anchored to a post on the left, while the other end of the beam is suspended above the drain. An electrostatic force pulls the beam

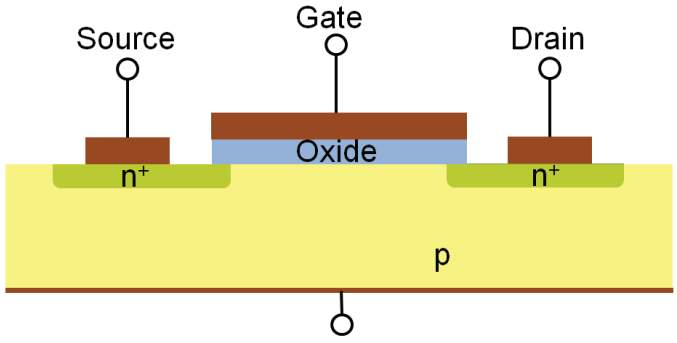

Figure 9. A diagram of a FET.

Table 1. A comparison of FET and PIN-diode switches [21].

	1 µm MESFET	0.25 µm PHEMT	Silicon PIN diode
Number of terminals	3	3	2
Typical on resistance	1.5 ohm-mm	1.2 ohm-mm	1.7 ohms
Typical off capacitance	0.40 pF/mm	0.32 pF/mm	0.05 pF
FOM (Eq. 1)	265 GHz	414 GHz	1872 GHz
Breakdown voltage	15 V	8 V	50 V
Lower frequency limit	dc	dc	10 MHz
Driver circuit complexity	low	low	high
Driver requirements	0 V on; –5 V off	+0.5 V on; –5 V off	5 to 10 mA on; 0 to –30 V off

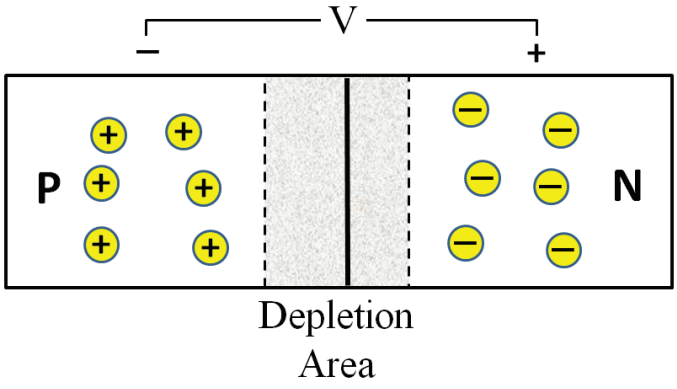

Figure 10. A diagram of a PIN diode.

down when a voltage is applied, and creates an electrical path between the beam and the drain. Figures 11c-11f show a MEMS membrane switch, which consists of a flexible, thin, metal membrane, anchored to posts at both ends. A potential applied to the bias electrode pulls the membrane down and closes the circuit. An ohmic contact is a metal-to-metal connection, while a capacitive contact has a dielectric between the two metal contacts. Ohmic switches have a higher bandwidth than capacitive switches. The capacitive MEMS switches handle higher peak power levels and tolerate environmental effects better than ohmic contacts. The figure-of-merit for MEMS switches was reported at 9000 GHz [20]. Switching speeds for electro-statically driven capacitor structures are 10 μs. Recently, MEMS switches with piezoelectric films have been developed, and have fast switching times (1-2 μs). The cantilever device travels 6 μm between the on and off states [30].

MEMS switches have low power consumption, low insertion loss, and high isolation, like mechanical switches, but are small, light weight, and low cost, like semiconductor switches [31]. On the other hand, MEMS switches have high losses at microwave and mm-wave frequencies, limited power-handling capability (~100 mW), and they may need expensive packaging to protect the movable MEMS bridges against the environment.

MEMS switches have been proposed for use in reconfigurable antennas since the late 1990s [29]. For example, two ultra-wideband monopoles with a reconfigurable band notch in the wireless-LAN frequency range (5.150 GHz to 5.825 GHz) are shown in Figure 12 [32]. The antenna was an elliptical patch, fed with a coplanar-waveguide line. The U-shaped slot was approximately $\lambda/2$ long, and had a frequency notch when the MEMS switch was open, but not when the MEMS switch was closed. When the switch was open at 5.8 GHz, the currents in the inner and outer side of the slot flowed in opposite directions and cancelled each other. When the MEMS switch was closed, the slot was shorted at its center point, so the total length of the slot was cut in half. Consequently, the slot no longer supported the resonating currents, and radiation occurred as if the slot was not present.

The second antenna in Figure 12 had two inverted-L-shaped open stubs that connected and disconnected the stubs from the elliptical patch via MEMS switches. Shorting the stubs to the patch created a rejection band. At the resonance frequency, the direction of the current on the stub flowed in the opposite direction to the current along the nearby edge of the radiator, so the radiated fields cancelled. When the stubs were not shorted, the antenna operated over the whole UWB range (3.1 GHz to 10.6 GHz) without any rejection band. The MEMS switches actuated through the RF signal path, without any dc bias lines that might have complicated the switch's fabrication and integration, while degrading the radiation performance due to RF leakage through the bias.

Reconfigurable antennas can also change the antenna's polarization. For instance, placing MEMS switches in the feeds of microstrip antennas provides the ability to switch from one linear polarization to the orthogonal linear polarization, or to circular polarization, as shown in Figure 13 [33].

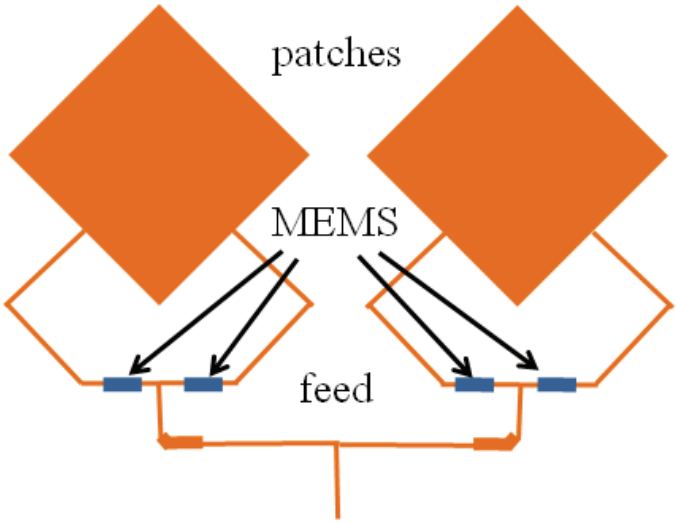

Figure 13. A reconfigurable antenna that changes polarization using MEMS.

MEMS structures are fabricated using a number of techniques, including etching trenches in the substrate, or building a multilayer structure on a planar substrate. Future research and development activities will need to address the cost and scalability of the MEMS process for large arrays. There are several important substrate properties that must be controlled, including surface roughness, permittivity, and dielectric loss. Recently, low-cost liquid-polymer substrates with $\varepsilon_r = 3$ and $\tan\delta = 0.002$ have been shown to be viable substrates for MEMS devices [34].

5. Varactors

Unlike the PIN diode, a varactor diode has a very thin depletion layer that acts like the insulating dielectric, and the P and N regions that act like the conducting plates (Figure 10). The capacitance is inversely proportional to the square root of the applied voltage, since the thickness of the depletion layer increases with the reverse bias. Varactors have a high-to-low capacitance ratio that is typically six over a voltage change of 0 V to 12 V.

Varactors are useful for tuning the antenna's frequency range. For instance, varactors were placed at the radiating edges of a microstrip-patch antenna in order to increase its very narrow bandwidth to a bandwidth of about 30% [35]. Strategically placing varactors along a slot antenna produced dual bands, with controllable first and second resonant frequencies [36]. A reconfigurable partially-reflecting-surface (PRS) antenna was built. It had a measured realized gain that varied from 10 dBi to 16.4 dBi over the tuning range of 5.2 GHz to 5.95 GHz, as the bias voltage was tuned from 6.49 V to 18.5 V [37]. The antenna had a partially-reflecting-surface material on the top surface, and a phase-agile surface below a microstrip patch. One phase-agile reflection cell was a microstrip-patch resonator, with varactor diodes that varied the resonant frequency of the patch antenna's reflection phase. The 13.5% tuning range extended the operating-frequency range by six times. The antenna's tuning bandwidth was limited by the varactor diode's tuning range for the phase-agile cells, and the antenna's efficiency was limited by the varactor diode's series resistance. A slotted-monopole antenna, modified with a varactor, could be tuned between 1.6 GHz and 2.3 GHz without a significant change in the antenna's efficiency [38]. Radiation pattern control has also been demonstrated using varactors [39].

6. Tunable Materials

Prospective devices with performance rivaling varactors will be based on materials that have tunable electrical, magnetic, and mechanical properties. For example, the propagation wavelength within the RF structure or impedance will be altered by permittivity (ε_r) or permeability (μ_r) changes, and the ability to tune the structure will be fundamentally related to the magnitudes of ε_r and μ_r [40]. Tunable mechanical strain alters either the effective length of the antenna, or modifies the impedance through capacitive coupling. Many concepts, such as tunable permeability, have been previously studied for microwave and millimeter-wave phase shifters [41]. Future tunable materials and devices will advance antenna technology through miniaturization and integration. A representative list of potential technologies for reconfigurable antennas is summarized in Table 2.

6.1 Tunable Conductivity

Conductivity in semiconductors can be tuned through changes in temperature, bias, or light. The conductivity of a semiconductor varies depending on the bandgap energy and the level of doping, and depending on defects in the material. Shining light with a photon energy greater than the bandgap on an intrinsic semiconductor increases the free-electron and hole-charge carriers, which in turn increases the semiconductor's conductivity. Solar cells are a good example.

Applying an electric field to a polymer electrolyte-silver-polyaniline composite alters the material from a state of low to high conductivity. Polymer composites with controllable resistance at microwave frequencies have stable, reproducible switching over more than 1000 test cycles [49].

Phase-change chalcogenides, such as $Ge_2Sb_2Te_5$ (proposed for non-volatile memory applications), also have tunable conductivity. Measurements have demonstrated that amorphous chalcogenides maintain low conductivity values into the GHz frequency range [50]. These become conducting upon recrystallization of the amorphous material. Resistivity changes of nearly three orders of magnitude are possible in small structures, by methods involving laser and Joule heating [51].

Table 2. Potential technologies with tunable dielectric, magnetic, and strain response for frequency-agile devices.

Method	Tunability (%)	Q	Stimulus	Frequency
Dielectric Thin Film [42]	30	45	Electric Field $E = 70$ kV/cm	1-20 GHz
Dielectric Bulk Ceramic [43]	16	>100	Electric Field $E = 15$ kV/cm	1-10 GHz
Magnetic Film [44]	15	$5 < Q < 11$	Magnetic Field 80 kA/m (1000 Oe)	0.3-5 GHz
Magnetic Bulk Ceramic [45]	3.4* (12)	<1700	Magnetic Field	7 GHz
Displacement Microstrip [46]	25* (625)	$40 < Q < 100$	Dielectric Translation (100 μm)	3-7 GHz
MEMS variable capacitor [47]	80	$100 < Q < 300$	Mechanical Displacement 1 μm	0.5-4 GHz
Varactor [48]	60	$30 < Q < 60$	Bias Voltage (20 V)	10 GHz

*Tunable frequency is proportional to the square root of the tunable permeability or permittivity, and the squares of the values are shown for comparison with the other methods (shown in parenthesis).

Silicon is a viable candidate for optically controlling conductivity. In [52], the authors reported on creating planar antennas on a silicon wafer by precisely forming plasma channels in the shape of the desired antenna. Varying the conductivity of silicon using an IR LED was reported for a reconfigurable patch antenna [53], and for a partially adaptive array with broadband monopoles [54].

6.2 Tunable Permittivity

A number of approaches have been explored to achieve economical solutions for a high ability to tune with low losses and fast response, for the purpose of controlling microwave filters and phased arrays. The relative "tunability" of the permittivity of a system is defined as

$$n_r = \frac{\varepsilon_r(0) - \varepsilon_r(E)}{\varepsilon_r(0)}, \qquad (2)$$

where $\varepsilon_r(0)$ and $\varepsilon_r(E)$ are the small-signal relative permittivities without bias and with a bias of strength E [V/cm], respectively. Tunabilities as high as 75% have been reported for $(Ba,Sr)TiO_3$ thin films at 1500 kV/cm [55]. A high electric field is required to generate a large tunability; however, the tuning voltage is low (< 25 V) because the films are in the nanometer-thickness range. A figure-of-merit for tunable dielectric devices has been established, which includes the device loss [56]:

$$K = \frac{Q(0)Q(V_{max})(n_r - 1)^2}{n_r}, \qquad (3)$$

where Q is the inverse of the device's loss; $Q(0)$ and $Q(V_{max})$ are at zero bias and at the maximum voltage, respectively; and n_r is the tunability from Equation (2). K factors as high as 500 have been reported for paraelectric $SrTiO_3$ thin films on $SrRuO_3$ conductors.

Dielectric materials with the highest tunability have paraelectric/ferroelectric transition temperatures that are below the operating temperature. The magnitude of the tunability is directly proportional to the dielectric permittivity, which approaches 1,000 for materials with the highest tunability [58]. The intrinsic dielectric loss increases with frequency, which may be a concern as the operating frequency increases into the mm-wave range [59].

The dielectric permittivities of thin films and bulk materials are altered through an externally applied electric field. Large changes in permittivity under a dc voltage bias have been demonstrated in epitaxial paraelectric $Ba_{0.5}Sr_{0.5}TiO_3$ ("BST") thin films that are deposited on single-crystal $LaAlO_3$ and MgO substrates [42]. The loss of the dielectric film is represented as an average Q value between the zero-field and high-electric-field bias. Bulk BST ceramics offer high tunability, and have higher Q values that BST films. Recent results have shown that high electric fields can be applied to bulk ceramics with nanometer-sized grains, corresponding to higher high overall tunability [43].

6.3 Tunable Permeability

Similar to the tunable response in dielectric materials, the magnetic permeability decreases with the application of a

static field. An early example of a 1.4 cm by 1.8 cm rectangular microstrip patch was printed on a 1.27 mm thick ferrite substrate (Trans-Tech G-113 YIG), and was fed with a coaxial probe near the edge of a long dimension [60]. The center design frequency was 4.6 GHz, which was tunable over a 40% bandwidth when it was magnetically biased in the plane of the substrate, and perpendicular to the resonant dimension. The polarization response of patch antennas on garnet single crystals has also been studied at 5 GHz for externally applied magnetic fields of 600 G. One advantage of higher permeability over high permittivity is that the effective patch dimensions can be reduced, without sacrificing bandwidth [61]. There are fundamental materials limitations for tunable magnetic materials, because the permeability and the highest operating frequency are inversely related [62]. Ferrites are a class of high-frequency magnetic materials with low eddy current and hysteretic losses [63].

Tunable magnetic structures have thin-film and bulk-ceramic forms. Conformal Permalloy films (120 nm thick) were deposited on CMOS structures, having lower conduction and hysteresis losses than bulk NiFe in the GHz frequency range [44]. In addition, eddy-current losses at high frequency were minimized through the inductor's design. Judicious patterning of the magnetic film raises the ferromagnetic resonance, and hence the operating frequency, of the tunable thin-film inductors; however, the magnetic-film technology will be limited to frequencies below 10 GHz, because of the limitation in the ferromagnetic resonance frequency. There are fundamental material limitations for tunable magnetic materials, because the magnitude of μ_r and the highest operating frequency are inversely related [62]. The magnetic response of ferrites is limited to below the K band [64]. Bulk-ceramic ferrite plugs were placed within the center of a dielectric resonator operating in the $TE01\delta$ mode [45]. The resonator was placed on top of a coil, which was used to apply the dc magnetic field. A high Q value was reported because of the low-loss dielectric resonator within the tunable structure.

6.4 Tunable Mechanical

Tunable mechanical materials are also known as active materials, and they change shape when exposed to an electric, magnetic, or thermal stimulus. Electrostrictive materials strain under an applied electric field. Magnetostrictive materials change shape due to an applied magnetic field. A magnetic field applied to a ferromagnetic material aligns the magnetic domains, and increases the length of the material in the direction of the magnetic field.

Shape-memory materials change shape due to a temperature change. Both alloys and polymers have been shown to exhibit this change. Shape-memory materials return to their original shape or size when deformed and subjected to an appropriate stimulus. The first shape-memory alloy, Nitinol (*Ni*ckel *Ti*tanium *N*aval *O*rdance *L*aboratory), was discovered in the early 1960s [65]. Today, copper-aluminum-nickel, copper-zinc-aluminum, nickel-titanium, and iron-manganese-silicon are other commonly used examples of alloys that when plastically deformed at a relatively low temperature, return to their original shape when subjected to a high temperature. Some shape-memory alloys, like Ni-Mn-Ga, respond to magnetic fields [66]. Shape-memory polymers (SMPs) are the polymer equivalent of shape-memory alloys. Light-induced shape-memory polymers are also available [67]. Lu and Kota outlined the use of shape-memory materials to adaptively deform reflector antennas from a parabolic to a spherical shape, or to tilt the reflector's surface [68].

The strain response of active materials is summarized in Table 3. Piezoelectric, electrostrictive, and Maxwell stress-based actuations are mechanical responses to an applied electric field. Piezoelectricity is generally limited to non-centrosymmetric crystal structures, and $Pb(Zr,Ti)O_3$ ("PZT") ceramics are commonly used for actuator applications. Exceptionally high piezoelectric coefficients have been discovered for $Pb(Mg,Nb)O_3$-$PbTiO_3$ ("PMN-PT") single crystals, which have strain values exceeding 1%. Electrostriction is possible in all materials, and the highest strains are found in PMN-PT ceramics and ferroelectric poly(vinylidene fluoride-trifluoroethylene) polymers. Maxwell stresses, created by the electrostatic attraction between oppositely charged conductor plates, cause very high strains in compliant polymers, such as silicone.

Only the strain parameters are shown in Table 2, and additional requirements must be considered for implementation of active materials into a tunable device. For example, the elastic modulus of high-strain polymers is low, and will limit the total force available to move a tunable structure. Piezoelectric materials have hysteretic strain behavior at high electric

Table 3. The strain responses of several types of active materials.

Actuation Mechanism	Piezoelectric	Electrostriction	Maxwell	Magnetostriction	Phase Change
Materials	PZT, PMN-PT single crystal	PMN-PT ceramics and PVDF	Silicone	Terfernol	Nitinol
% strain range	0.1 to 1.5	0.1 to 4	20	0.2	6
Reference	[69]	[70]	[71]	[72]	[72]

fields, which may limit reproducibility in the strain response. The time response and reversibility of the phase transition in Nitinol will limit its use for fast tuning systems.

Tunable micro-electromechanical system (MEMS) and microstrip structures take advantage of piezoelectric or electrostatic forces to move capacitor plates. Tunable microstrip configurations, based on translatable superstrates above ring resonators, offer high tunability and Q values [46]. A variable MEMS capacitor has been demonstrated. The capacitance changed from 1.2 pF to 0.25 pF as the voltage was altered from 15 V to 10 V. The Q factor was high, because the structure was fabricated from high-resistivity silicon [47].

There are several challenges in comparing tunable devices that have a range of impedance, Q, and tunability parameters. Figures-of-merit have incorporated all of these parameters and have been tailored to specific devices, such as phase shifters [40]. In addition, device-performance metrics, such as temperature stability, RF power, response time, and cost, must also be considered [48]. In Table 1, the device tunability is defined by different parameters, and depends on the physical mechanism. For example, the MEMS, dielectric devices, and varactors depend upon a permittivity or capacitance change. The magnetic devices depend upon a permeability or inductance change. The magnetic bulk-ceramic and displacement-microstrip methods that are listed in Table 3 are defined by tunable frequency: hence, these values are squared, to provide a meaningful comparison with the other methods. From Table 3, it is apparent that devices that are based on mechanical strain are promising candidates for tunable devices with high Q and high tunability. In addition, these devices are not limited in frequency, as in the case of tunable magnetic materials.

7. Conclusions

Reconfigurable antennas have been around since the 1930s. Initially, they were based on mechanical movement of a feed or other antenna part. Antenna arrays took reconfigurability to a new level with the electronic control of the antenna's pattern. Semiconductor and MEMS switches have been at the heart of most reconfigurable-antenna research since the late 1990s. More recently, materials research has introduced new approaches to reconfigurable antennas, via tunable constitutive parameters and even active materials that move in response to an electrical stimulus. The need for a single antenna to perform multiple missions will continue the drive for antennas that can reconfigure themselves based upon the current need.

Introducing the Feature Article Authors

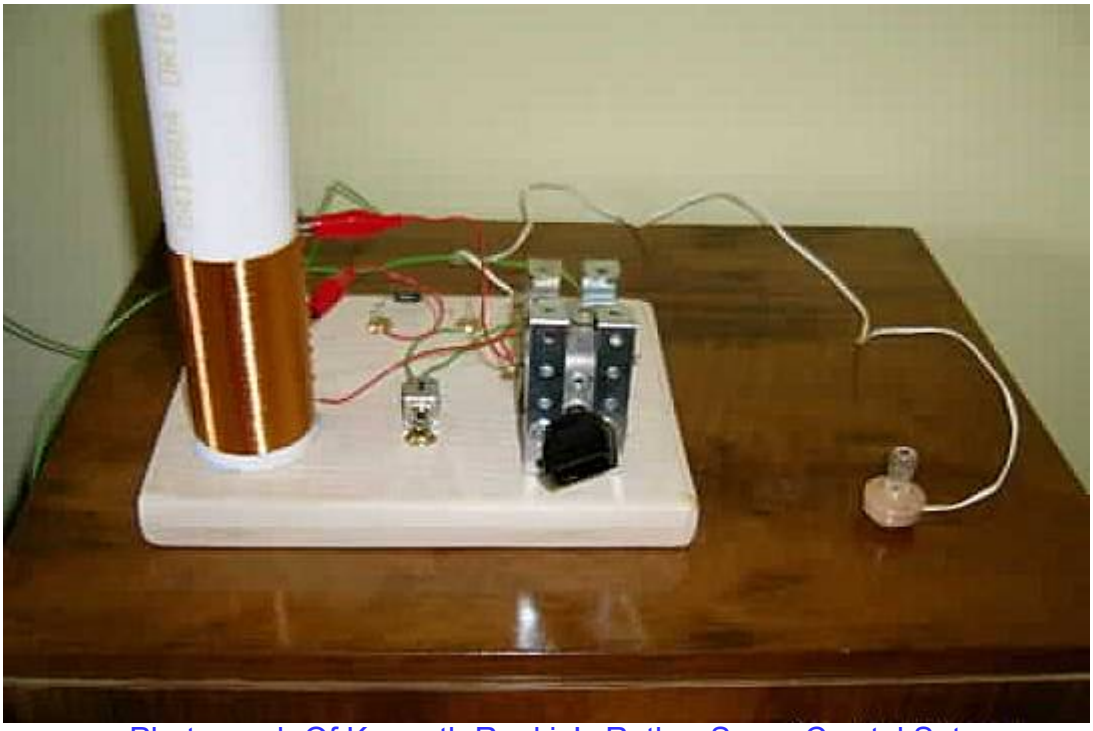
Randy L. Haupt received the BSEE from the USAF Academy (1978), the MS in Engineering Management from Western New England College (1982), the MSEE from Northeastern University (1983), and the PhD in Electrical Engineering from the University of Michigan (1987). He is a Professor and Department Head for the Electrical Engineering and Computer Science Department of the Colorado School of Mines, Golden, Colorado. He was an RF Staff Consultant at Ball Aerospace & Technologies, Corp. He was Senior Scientist and Department Head at the Applied Research Laboratory of Penn State, Professor and Department Head of ECE at Utah State, Professor and Chair of EE at the University of Nevada Reno, and Professor of EE at the USAF Academy. He was a project engineer for the OTH-B radar, and a research antenna engineer for Rome Air Development Center early in his career. He is coauthor of the books *Practical Genetic Algorithms, Second Edition* (Wiley, 2004); *Genetic Algorithms in Electromagnetics* (Wiley, 2007), and *Introduction to Adaptive Antennas* (SciTech, 2010), as well as author of *Antenna Arrays: A Computation Approach* (Wiley, 2010). Dr. Haupt was the Federal Engineer of the Year in 1993. He is a Fellow of the IEEE and of the Applied Computational Electromagnetics Society (ACES). He serves as Associate Editor for the "Ethically Speaking" column in the *IEEE Antennas and Propagation Magazine*.

Michael Lanagan received his BS in Ceramic Engineering from the University of Illinois in 1982, and his PhD from Penn State in 1987. He is presently Professor of Engineering Science and Mechanics. Before joining Penn State, Dr. Lanagan was at Argonne National Laboratory for twelve years. Prof. Lanagan's research interests are in two general areas. The first is the exploration of new materials and structures for energy-storage applications. The second research topic involves advanced materials and devices for enhanced magnetic-resonance imaging. He is an author of over 250 technical publications and 10 patents. His present interests also include synthesis, processing, and characterization of new materials for wireless communications and power electronics applications.

CRYSTAL SETS 4
A Crystal Set By Kenneth Rankin

CRYSTAL SETS 4: A CRYSTAL SET BUILT BY KENNETH RANKIN

MDS975.co.uk reader Roddie Rankin kindly sent in the details of a crystal set built by his son Kenneth for a school project which won him great praise and merit. The crystal set is so nicely made and the project so well written that I thought it deserved a special page of its own.



Photograph Of Kenneth Rankin's Rather Super Crystal Set

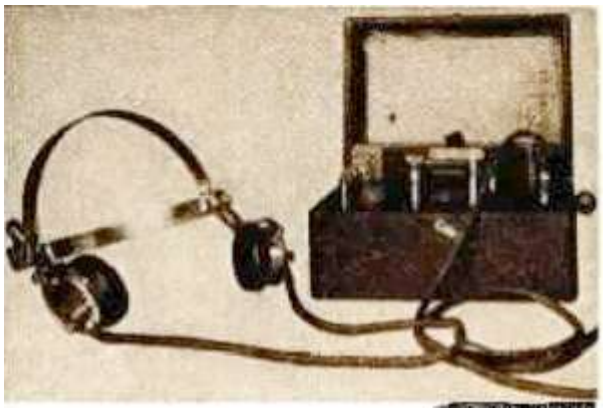
7 - Quiz

1 - WHAT IS A CRYSTAL SET?

Perhaps you think, like I did, that a crystal set is just a collection of lovely stones. In fact a crystal set is a very early, simple domestic radio. The photograph above shows the crystal set I built.

The crystal set does not have a battery. It runs completely from the radio waves it picks up in the air. It is absolutely free to run!

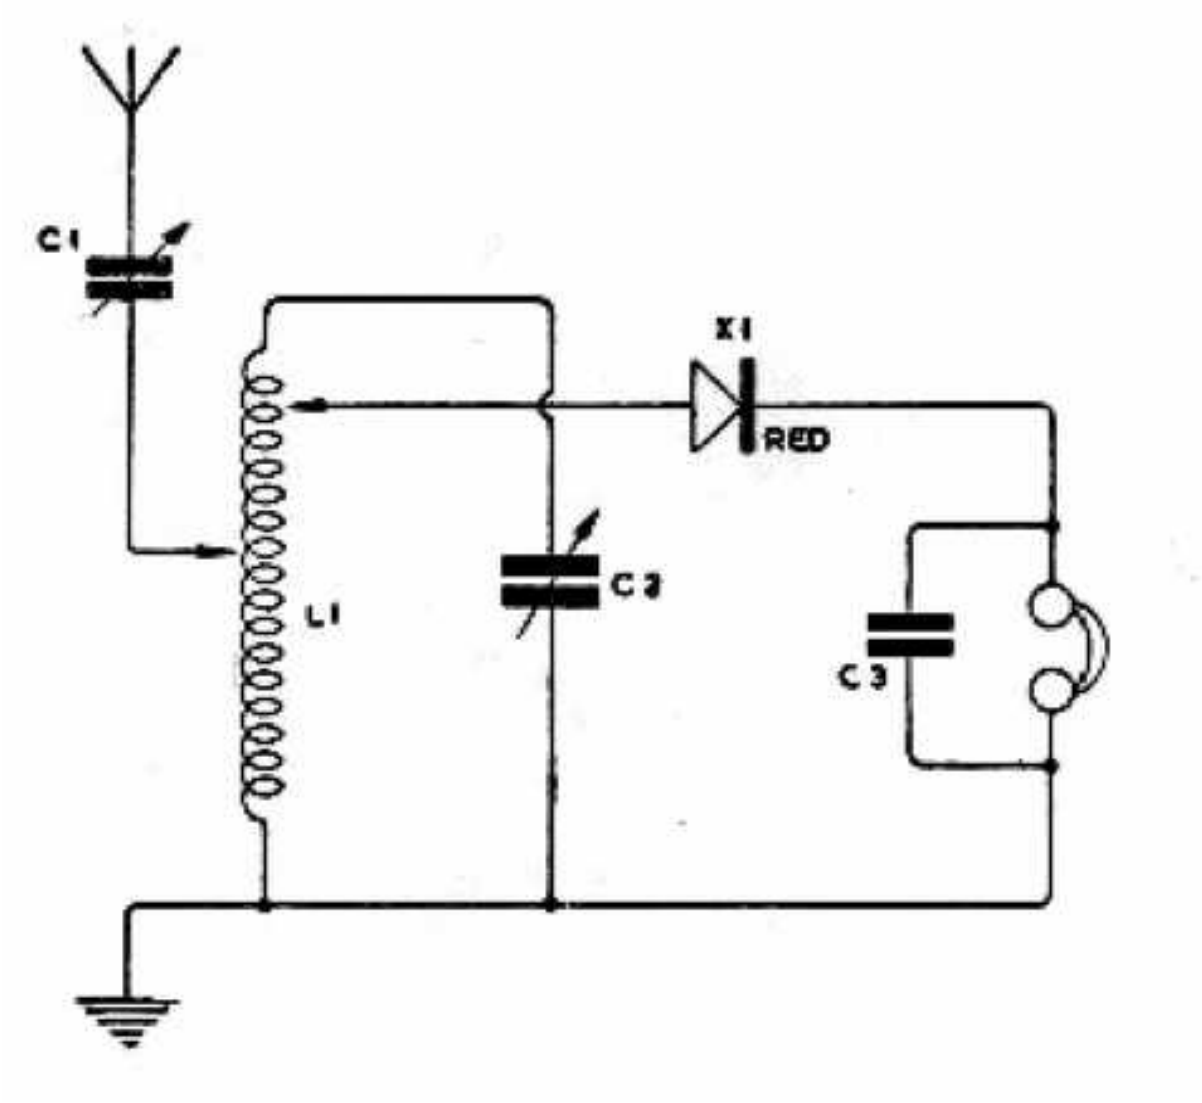
Please read on to find out more about this exciting invention!



The birth of domestic radio: A deluxe crystal set produced by Marconi for the reception of programmes from the first of the BBC's radio stations, 2LO in London.
[from Pageant Of The Century - Odhams Press]

2 - HOW A CRYSTAL SET WORKS

The diagram below shows the circuit diagram of the crystal set I have built. It consists of a coil (L1), a tuning capacitor (C2), a diode (X1), an aerial, a crystal earpiece and an earth. (Capacitors C1 and C3 are not essential.)



Circuit Diagram Of The Crystal Set

First the aerial picks up radio waves from radio stations all over the world. Then the required station needs to be selected, this is called tuning, and this is achieved with a Tuned Circuit. The Tuned Circuit in the crystal set consists of two items; a component called a variable capacitor and a coil of wire.

By adjusting the value of the capacitor and coil tuning is achieved. The coil taking unwanted signals of low frequency straight through to the earth, which gets rid of them, while the capacitor takes unwanted signals of high frequency straight through to the earth. The remaining signal, in between the high frequency and low frequency signals, is the signal of the required station which is not passed to earth by either the coil or the capacitor. This is the frequency to which the set is now tuned in.

You normally change the frequency to which a set is tuned in to by turning the knob on the tuning capacitor, thus receiving different stations by varying the capacitance of the variable capacitor. The number of turns on the coil can also be changed [called varying the inductance of the coil] and this will give different tuning ranges. A larger number of turns provided longer wavelengths [lower frequencies], while a smaller number of turns of wire provides shorter wavelengths [higher frequencies].

[It is also worth noting that the inductance of a coil can be increased by inserting a component called a Ferrite Rod into the centre of the coil.]

Once tuned into the required station this remaining signal goes to earth by travelling through the diode and earpiece. The diode takes the sound signal out of the radio signal [called demodulation], and passes it to the earpiece. The sound signal travels through the crystal in the earpiece which vibrates the air in the earpiece giving us the sound of the radio station to which you are tuned.

3 - THE HISTORY OF THE CRYSTAL SET

The history of crystal sets begins with the first broadcast stations being opened. This happened in England in 1922. The simplest form of receiver for these broadcasts was the crystal set.

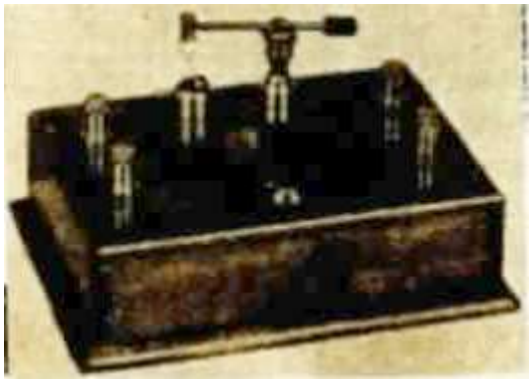
In those early sets they had "cat's whiskers" instead of diodes. A cat's whisker was a fine piece of wire which was adjusted to make a suitable contact with a crystal. The crystal would be made of a substance such as coke or galena. An example from 1923 is shown in the picture below. Notice how well made these instruments were.

There were several limitations to the crystal set: it needed a big aerial, an earth connection, the clumsy cat's whisker, and the weak signal could only be listened to by one person at a time with headphones. Very quickly the crystal set began to be replaced by valve radios with loudspeakers, powered by battery (see the picture from 1923).

In World War II, crystal sets were used by prisoners of war in prison camps to listen to news from home. As they were often badly treated it was hard to get all the right parts to build the set.

By this time crystal sets were no longer used in the home. Instead radios like the attractive 1937 model in the picture were being used.

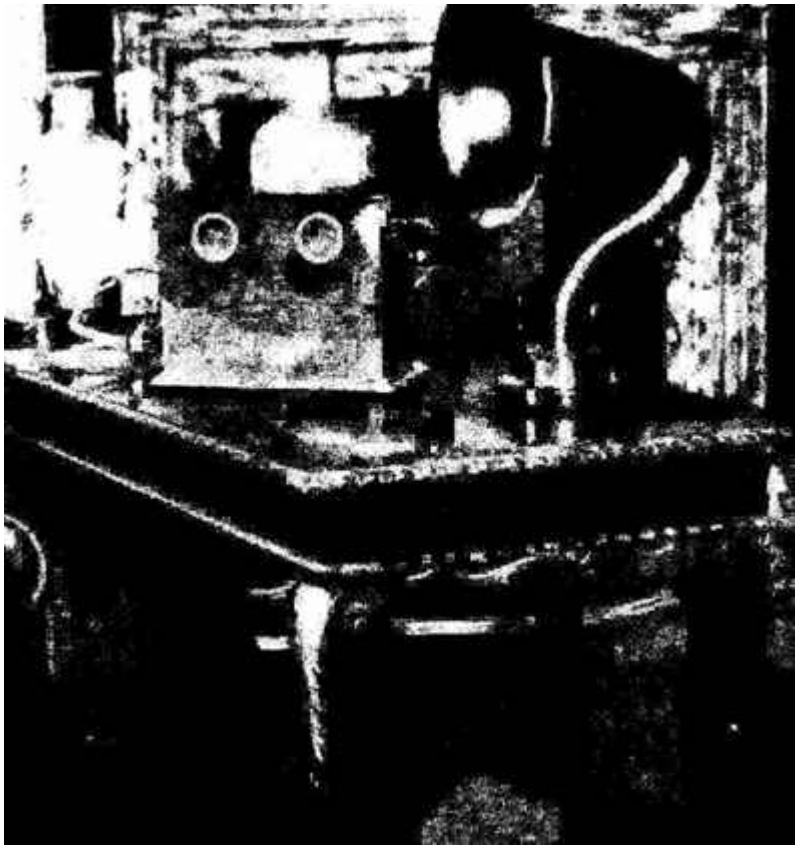
Nowadays people only use crystal sets as a hobby. There are various different kits available on the market (see websites in the references below).



Photograph Of A Crystal Set From 1923

[from Pageant Of The Century - Odhams Press]

Crystal sets were primitive instruments used for 'listening in', and were fitted with the now famous cats whisker. Listening was done though a pair of headphones which meant that only one person could listen at a time.



Photograph Of a 1923 Radio

[from Pageant Of The Century - Odhams Press]

Later valve amplification could be added to radios which allowed them to power a loudspeaker so that everyone in a room could listen in.

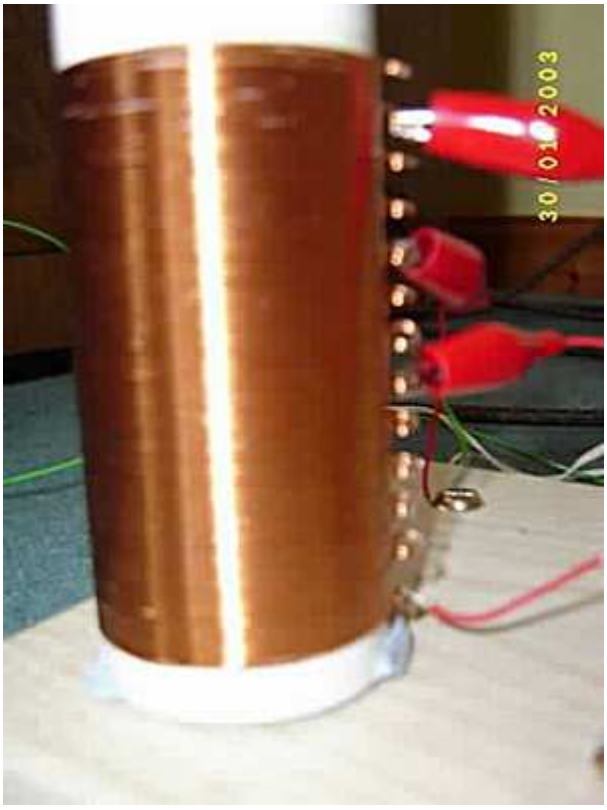
4 - HOW I BUILT MY CRYSTAL SET

The crystal set is a fun and easy thing to build.

The first thing I had to do was put up an aerial and earth. For the aerial I drilled a hole in the ceiling and fed wire through the hole. Then I went into the attic and took the wire to the other end of the attic, fastening it to rafters as I went. When I got to the other side I fed the wire out of an air vent to the outside of the house. I then went outside tied wire to a nearby tree and joined it up to the wire coming out of the air vent. This gave me an aerial of about 25 metres.

Next the earth. For this I drilled another hole in the ceiling and fed another wire through and out of an air vent at the other side of the house (see previous paragraph). I attached this wire to the metal frame of my swing. This is a good earth because its poles stick deep into the ground.

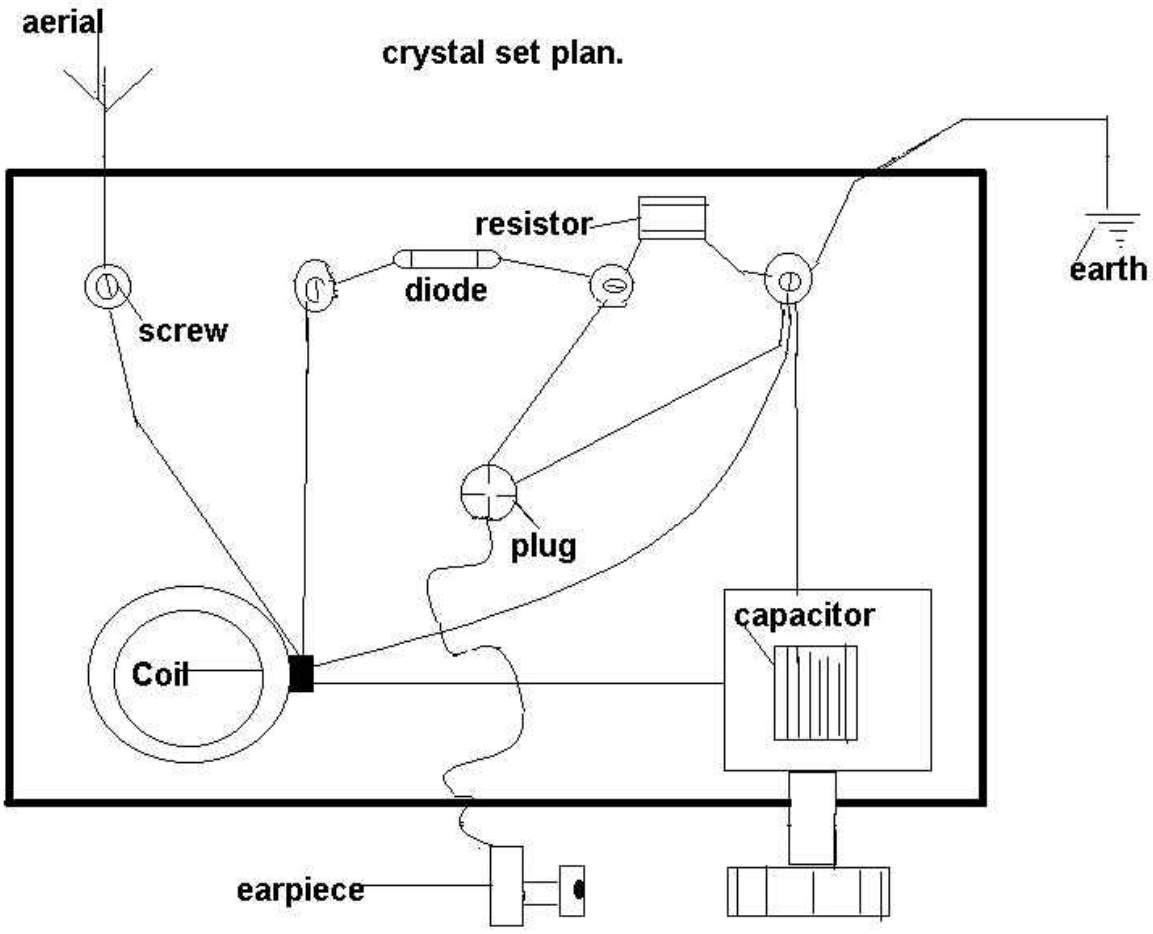
The coil used enamelled copper wire wound on to a piece of plastic pipe with a diameter of 5 cm. There were 120 turns of wire. Every 10 turns I made a loop on which a crocodile clip could be fixed. See the picture below:



Photograph Of The Coil Showing The Tapping Points & Crocodile Clips

The Tuning Capacitor - Being Carefully Adjusted

For the crystal set itself, I first had to plan what I would be using and where the pieces would be placed (see picture and the plan drawing). I was using the circuit shown above. I built the crystal set on a wooden board about 20cm by 15cm. I drilled 4 holes 4cm apart. I put screws with cup washers in each hole and fastened the wires of the parts of the crystal set and the aerial and earth wires under the cup washers. I fastened the capacitor to the board using Meccano brackets and screws. The coil was fixed to the board using glue. The earpiece plugged into a socket which was fastened to the board using a thunderbolt shaped piece of Meccano.



Drawing Showing Layout Of Components

5 - THE RESULTS I OBTAINED

At first all I could hear was a foreign station. But then, I tried late at night and could sometimes hear a station from Florida in English! By tuning the capacitor and moving the crocodile clips up and down the coil I managed to receive a few foreign stations on Short Wave. What I really wanted was to tune in to Medium Wave. I wanted to receive English stations like Radio Scotland and music stations. I tried everything including a longer aerial and using different parts but to no avail. I came to the conclusion that I could not get a strong enough Medium Wave signal in Northerly area of Scotland where we live.

Here is a picture of me operating my crystal set:

7 - QUIZ QUESTIONS

CRYSTAL SET QUIZ QUESTIONS:

1. What is a crystal set?
2. When were the first crystal sets sold?
3. Name 3 essential parts for a crystal set.
4. What does the earth do?
5. Does the coil pass signals of low frequency or high frequency?
6. How far apart were the screws on my crystal set?
7. What happened when I made the aerial longer?
8. What is this an anagram of: i a c c p r o t a?

(ANSWERS ARE FURTHER DOWN THIS PAGE)

PARTS THAT ARE REQUIRED

1	Wooden Base Panel
1	Coil Former 5cm dia. UPVC Pipe
1	Tuning Capacitor approx 500pF Air-Spaced or Solid Dielectric
1	Reel Of Enamelled Copper Wire for coil
1	Germanium Diode eg OA47 and IN34 which are especially suitable or other alternatives such as OA81, OA90 OA91, 1N94 etc
1	Crystal Earphone
1	47 k Ohm Resistor across earphone
6	½ inch No. 6 Brass Screws and Screw Cups
1	3.5mm mono Jack Socket
	Mounting Hardware (Meccano) for coil, capacitor and jack socket
	PVC covered wire for aerial and earth

A Superb RGD Valve Radio from 1937 - carefully restored in 1994 by Roddie Rankin

With thanks to Kenneth and Roddie Rankin for sending in this excellent article and photographs!

Crystal Sets Part 5 >

QUIZ ANSWERS

1. The first kind of radio
2. 1922.
3. Coil, diode, capacitor, earpiece, aerial, earth.
4. Gets rid of signals you don't want.
5. Low.
6. 4 cm.
7. It did not make much difference.
8. Capacitor.

No AM radio stations or transmitters in your locality or country?

Has your local medium wave broadcast station closed or been moved to VHF/FM or Digital? Don't worry. You can still build and experiment with crystal sets and TRF radios by also buying or even building a simple low power AM transmitter. So, not only can you use your crystal sets but you can also run your own radio station that can be heard in and around your home - playing the music or programmes that you want to hear!

SSTRAN AMT3000 : Superb high fidelity medium wave AM transmitter kits from SSTRAN. Versions available for 10kHz spacing in the Americas (AMT3000 or AMT3000-SM) and 9kHz spacing in Europe and other areas (AMT3000-9 and AMT3000-9SM). Superb audio quality and a great and well designed little kit to build: http://www.sstran.com/pages/products.html

http://www.sstran.com/

Other AM transmitters available:

Spitfire & Metzo: Complete, high quality ready built medium wave AM Transmitters from Vintage Components:
http://www.vcomp.co.uk/index.htm Vintage Components offer a choice of the high quality Spitfire and Metzo transmitters:

SPITFIRE AM Medium Wave Transmitter with 100 milliwatt RF output power:

http://www.vcomp.co.uk/spitfire/spitfire.htm

METZO AM Medium Wave Transmitter with built in compressor:

http://www.vcomp.co.uk/metzo/metzo.htm

AM88 LP A basic AM transmitter kit from North County Radio.
http://www.northcountryradio.com/Kitpages/am88.htm

What Do the Markings on Circuit Breakers Mean?

by Ed Larsen, P. E.

Have you ever been confused about what the markings on circuit breakers mean? Understanding the markings on electrical equipment is a fundamental need to ensure a safe and reliable electrical installation. Circuit breaker marking requirements are established by the requirements found in the *NEC* and the UL 489 product standard. This article will discuss the most common markings and where they can be found.

The UL 489 product standard for Molded Case Circuit Breakers specifies the information to be marked on circuit breakers and where it is to be located, so let's discuss what information needs to be marked on the circuit breaker and the location where you will find those markings. Keep in mind the UL® standard specifies minimum requirements. Circuit breaker manufacturers may provide additional information or provide information in a more convenient location.

Markings Visible without Removing Trims or Covers

UL 489 requires that some markings be visible without removing trims or covers. This location is typically referred to as the handle escutcheon (see photo 1).

Markings Visible with Trims or Covers Removed

UL 489 requires other markings be visible on an installed circuit breaker with trims or covers removed. This location is typically referred to as the face of the circuit breaker (see photos 2–4).

Other markings which should be visible with trims or covers removed are:

Independent trip – Multi-pole circuit breakers are constructed with either a common trip, where all poles are mechanically tripped when one of the poles trips, or an independent trip construction where only the pole that is involved with the overcurrent condition trips. If a 2-pole circuit breaker does not have an internal com-

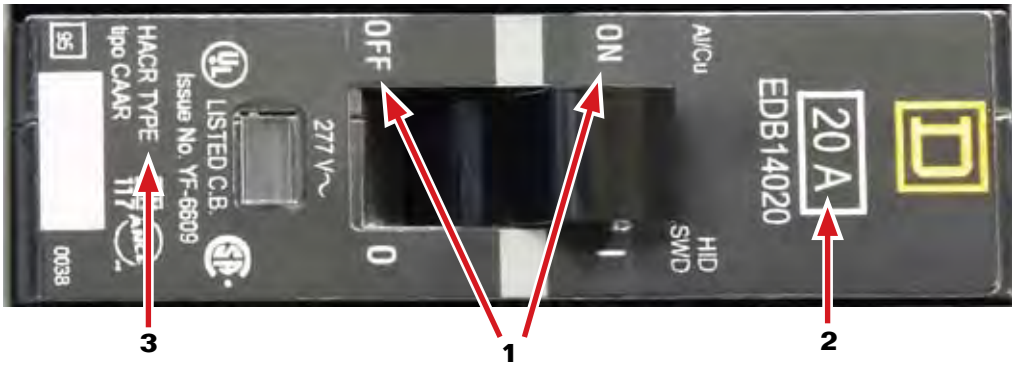

Photo 1. Markings Visible with Trims or Covers in Place

1. ON and OFF – The ON and OFF (closed and open) positions of the handle must be marked (*NEC* 240.81). These positions may also be marked with the internationally recognized "I" and "O" symbols, although this is not a UL requirement. If these markings are not visible when a motor operator is installed over the circuit breaker markings, then they must appear on the motor operator. Motor operators may be found in applications where remote or automatic operation of a circuit breaker is required.

2. Ampere rating (if 100 A or less) – The ampere rating may be located on the handle escutcheon or on the handle itself (*NEC* 240.83(B)). Circuit breakers that are rated more than 100 A may have their ampere rating marked in a position that is not visible with trims or covers in place.

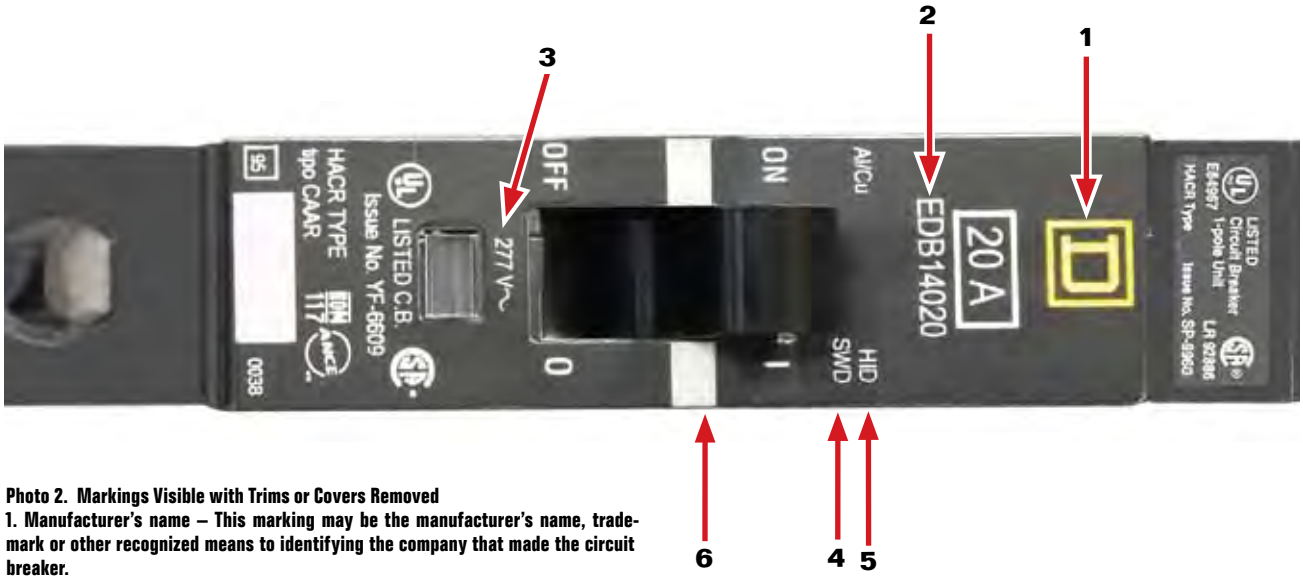

Photo 2. Markings Visible with Trims or Covers Removed

1. Manufacturer's name – This marking may be the manufacturer's name, trademark or other recognized means to identifying the company that made the circuit breaker.

2. Type designation – All circuit breakers are marked with a type designation, which may be a catalog number prefix or a separate designation. Equipment labels, such as on panelboards, will list the circuit breaker types suitable for use. Note that the word "type" may or may not be used on the circuit breaker or equipment labels. It is important to review the markings on the equipment, such as a panelboard, to make sure the circuit breaker designations on the equipment match the marking on the circuit breaker.

3. Voltage rating – All circuit breakers must be marked with a voltage rating. If the rating is not marked "ac" or "dc," then it is suitable for both. 120/240 V rated circuit breakers are suitable for use on single and three-phase 4-wire systems where the line-to-ground voltage does not exceed 120 V. Wye rated circuit breakers such as those rated 480Y/277 V, are suitable for use on three-phase 4-wire systems where the voltage to ground does not exceed 277 V. Special attention needs to be given to high leg or corner-grounded delta systems to insure that the circuit breaker has the appropriate rating. A review to see that the circuit breakers installed have a voltage rating suitable for the application is paramount for a code-compliant installation (*NEC* 240.83(E)).

4. SWD – 15- or 20-A circuit breakers rated 347 V or less may be marked "SWD," meaning that they are suitable for switching fluorescent lighting loads on a regular basis (*NEC* 240.83(D)). These circuit breakers are evaluated for high endurance use, since they will be used similar to a light switch.

5. HID – 50 A or less circuit breakers rated 480 V or less may be marked "HID," meaning they are suitable for switching high intensity discharge or fluorescent lighting loads on a regular basis. These circuit breakers may employ a different construction than a standard SWD circuit breaker in order to address the high inrush current resulting from the lower power factor created by the HID lighting (*NEC* 240.83(D)). These circuit breakers also undergo additional endurance evaluation to demonstrate their ability to perform the switching duty.

6. Trip and reset – Circuit breaker handles typically assume an intermediate position when tripped. This position must either be marked on the circuit breaker or on the equipment into which it is to be installed. If these markings are not visible when a motor operator is installed, then a "tripped" marking may appear on the motor operator.

mon trip feature, then it must be marked "Independent Trip" or "No Common Trip." *NEC* 240.20(B) is the foundational requirement for a common trip function in a circuit breaker; however, it also goes on to explain where independent trip is permitted.

For Replacement Use Only not-CTL – The Class CTL (circuit limiting) panelboard has only been in existence for about 25 years, even though the lighting and appliance branch circuit panelboard has been in the *NEC* for decades. CTL panelboards have a rejection means designed to reject more than the appropriate number of circuit breakers that can be installed in the panel. The marking "For replacement Use Only Not CTL Assemblies" means that the circuit breaker does not have CTL rejection provisions and is intended for replacement in older equipment pre-dating the CTL requirements for circuit breakers and panelboards. Circuit breakers with this designation should not be installed in a panelboard marked "Class CTL Panelboard" since that would be a violation of the listing of the assembly [*NEC* 110.3(B)].

Markings Found in Other Locations

The markings we will discuss below may appear in any location except the back of the circuit breaker. These markings include:

40°C – This marking indicates the maximum ambient temperature in which the circuit breaker can be applied at its marked ampere rating without rerating the ampacity of the circuit breaker. This marking is required for thermal-magnetic circuit breakers and is optional for electronic trip circuit breakers unless they are only suitable for a 25°C ambient, in which case they must be marked 25°C. When the ambient temperature rises above 40°C, the designer may need to consult the manufacturer to obtain rerating information (see item 4 in photo 3).

Class CTL – Circuit breakers marked Class CTL have a rejection means designed into the circuit breaker. Class CTL panelboards or assemblies, in conjunction with Class CTL circuit breakers, prevent more circuit breaker poles from being installed than the number for which the equipment is rated.

Photo 3. Markings Visible with Trims or Covers Removed

1. Line and load designation – Circuit breakers marked with "line" and "load" designations are not suitable for reverse connection. Circuit breakers with interchangeable trip units must be marked "line" and "load" unless there is no risk of shock when changing the trip unit.

2. Interrupting ratings – All circuit breakers with an interrupting rating more than 5000 A must be marked with an interrupting rating (*NEC* 240.83(C)). Interrupting ratings are stated in RMS symmetrical amperes. If the short-circuit current rating of the equipment in which the circuit breaker is installed is less than the interrupting rating of the circuit breaker, then the lesser rating applies. Circuit breakers should be reviewed after installation to ensure they have an interrupting rating suitable for the application. This marking may be found in any location except the back of circuit breakers that are 1-½ inches wide per pole or less due to the size constraint.

3. Ampere rating (if more than 100 A) – The ampere rating of a circuit breaker larger than 100 A may be found in a location that is visible after the cover or trim is removed. This marking requirement also applies to interchangeable trip units (*NEC* 240.83(A)).

5. Terminations (Cu-Al wire) – Circuit breakers must be marked with the type material (Cu-Al) and size of wire for which their terminals are suitable for use. If suitable for use with only copper or only aluminum, then the word "only" must be used. The abbreviations "CU" and "AL" are generally found on circuit breakers as permitted by the product standard. If only solid 10–14 AWG wire can be used, then that information must be noted. The number of wires per terminal will also be noted if more than one wire per terminal is permitted (*NEC* 110.14(A)).

6. Tightening torque – The nominal torque for all field-wiring terminals must be marked. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be found in any location except on the back.

7. Wire temperature ratings – Circuit breakers rated 125 A or less may be marked as suitable for use with 60°C, 60/75°C or 75°C only wire. Circuit breakers rated more than 125 A are rated for use with 75°C wire; the marking is optional. It is always permissible to use wire with a higher temperature rating, but it must be sized in accordance with the temperature marking on the circuit breaker and *NEC* Table 310.16. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be in any location except on the back (*NEC* 110.14(C)1).

8. HACR type – This marking indicates the circuit breaker is suitable for use with the group motor installations typically found in heating, air conditioning and refrigeration equipment. The *NEC* 2005 no longer has this marking requirement. The electrical industry determined that circuit breakers are considered suitable for use with such equipment without any further testing, therefore, the HACR marking is no longer required on air conditioning and refrigeration equipment or on circuit breakers for use in these applications. The requirement for this marking has also been removed from the UL 1995 product standard for HVAC equipment (see item 3 in photo 1).

Maximum wire size – Circuit breakers are typically marked with a wire range, however that marking is not mandatory. If the circuit breaker cannot accept the next larger wire size required for the ampere rating, then the maximum wire size must be marked in any location except the back (see item 5 in photo 3).

Separately shipped connectors –If connectors are not factory installed on a circuit breaker, then it must be marked with the proper connectors or terminal kits required in any location except the back (see item 8 in photo 3).

Ground-Fault Protection for People

The GFCI function, as part of a circuit breaker, provides ground-fault protection for people and has a number of unique marking and instruction requirements.

Test function – The GFCI has a test function that requires action upon installation and on a monthly basis. GFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate monthly testing.

Photo 4. 1Ø – 3Ø Marking
1. 1Ø – 3Ø marking – A 2-pole circuit breaker used to protect a 3-phase load on a corner-grounded delta system must be rated and marked for such an installation. Circuit breakers marked "1-phase – 3-phase" or "1Ø – 3Ø "are suitable for use on 3-phase corner-grounded delta or single-phase circuits (*NEC* 240.85).

Suitable for continuous operation at 100% of ampere rating only if used in a recognized enclosure 52 in. (1321 mm) by 20 in. (508 mm) x 7 1/2 in. (190 mm) deep or larger. Use only with 90° rated wire sized per the ampacity of 75° rated wire.

Figure 1. 100% Rated Marking
100 percent continuous rated – Circuit breakers are typically intended for use at not more than 80% of rated current where the load is considered continuous, or will continue for 3 hours or more (*NEC* 210.20). However, some circuit breakers are rated for continuous use at 100% of their current rating. These circuit breakers must be so marked in any location except on the back. Enclosure information such as a specific type or specific volume must also be marked. A requirement for the use of 90°C insulated wire sized to the 75°C column in *NEC* Table 310.16 and specific ventilation requirements may also be marked on the circuit breaker or equipment (*NEC* 210.20(A) and 215.3).

"Class A" marking – A "Class A" ground-fault device is intended to protect people. The Class A marking indicates that the trip threshold of the GFCI is between 4 mA and 6 mA. This marking may be in any location except the back.

Instructions – All GFCI circuit breakers must include instructions for the installer plus instructions on the use of the test function. A hangtag or self-adhesive label must also be provided, instructing the user to test the GFCI at least monthly. Inspectors should check to see that the tag or label has been properly installed.

Ground-Fault Protection for Equipment

Circuit breakers may also include a ground-fault protection for equipment (GFPE) function that, like GFCIs, has a number of unique marking and instruction requirements.

Test function – GFPE circuit breakers may have a test button or switch that may be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Trip level – GFPE circuit breakers must be marked with their trip threshold in milliamperes in a location accessible without removing trims or covers.

Instructions – All GFPE circuit breakers must include instructions for the installer.

Arc-Fault Protection

Circuit breakers may also include arc-fault protection (AFCI) that, like GFCIs, also has a number of unique marking and instruction requirements.

Device identification – AFCIs must also be identified appropriately. Branch/feeder or Combination type AFCIs must be so marked in a location visible when the trims or covers are removed. This is an important marking to note as we move into 2008, as *NEC*-2005 requires Combination AFCIs in bedrooms effective January 1, 2008 (*NEC* 210.12).

Test function – AFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Instructions – All AFCI circuit breakers must include instructions for the installer.

Circuit Breaker Markings Ensure a Safe Electrical Installation

So why are all of these markings on circuit breakers? Without them, it would be nearly impossible to install or inspect an installation for the appropriate performance ratings and fundamental electrical connections. When designing or completing an installation, key items to review are:

1. Are the voltage, continuous current, and interrupting ratings appropriate for the application?
2. Does the application require SWD or HID ratings?
3. Is the wire type and size appropriate for the circuit breaker?
4. Is the circuit breaker suitable for the equipment in which it is installed? Have other protective functions such as GFCI or AFCI been provided as required by the *NEC*?
5. Is the temperature rating of the circuit breaker suitable for the application?

The UL Marking Guide for Molded Case Circuit Breakers is a valuable resource to understand circuit breaker markings that may further explain these and other markings in detail. If you have questions about CB markings not answered here, consult the Marking Guide or the manufacturer to assist in an *NEC*-compliant installation.

Mr. Larsen, P. E., is the manager, Industry Standards for Circuit Protection for Square D Company / Schneider Electric. Mr. Larsen has served in various positions over the past 32 years. He is a member of several UL, IEEE and NEMA technical committees. His other memberships include NFPA, IAEI and CANENA.

Magnetic Loop Antenna's.

Why is an Magnetic Loop antenna so special, this antenna is picking only the MAGNETIC part of the ELEKTRO MAGNETIC radio wave. The big advantage of this antenna is that the electric interference from the big city (streetlights, television's , cars etc...) have no influence on the received signal. With the loop you can hear other stations that you can't hear if you use a DIPOLE, with a dipole the stations are buried in the noise

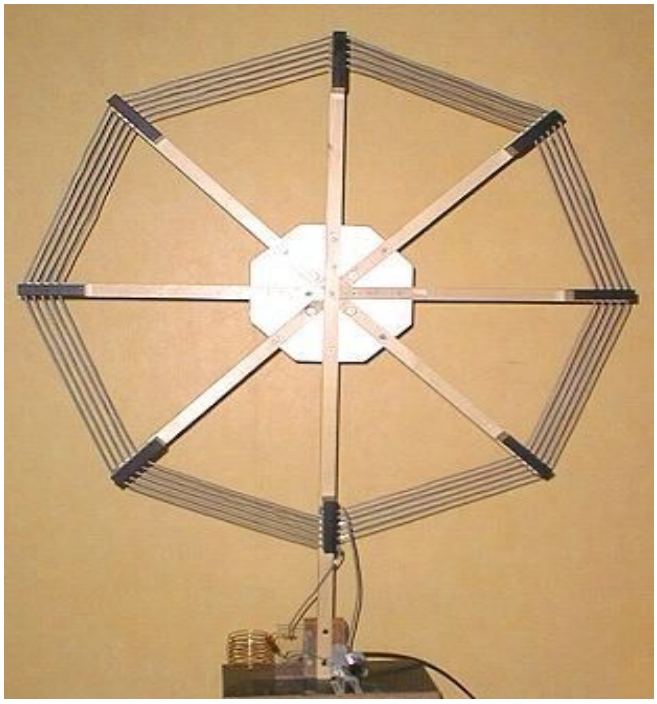
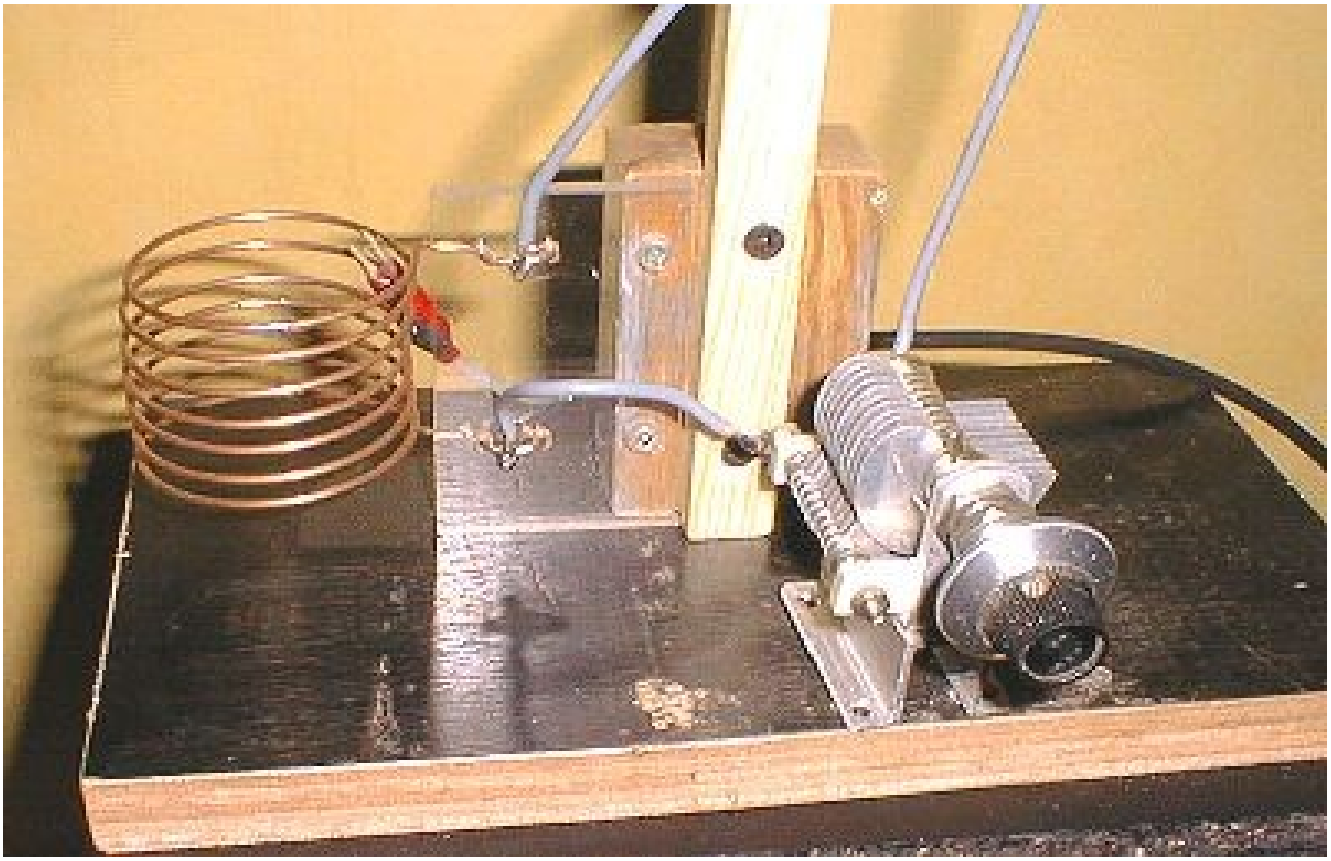
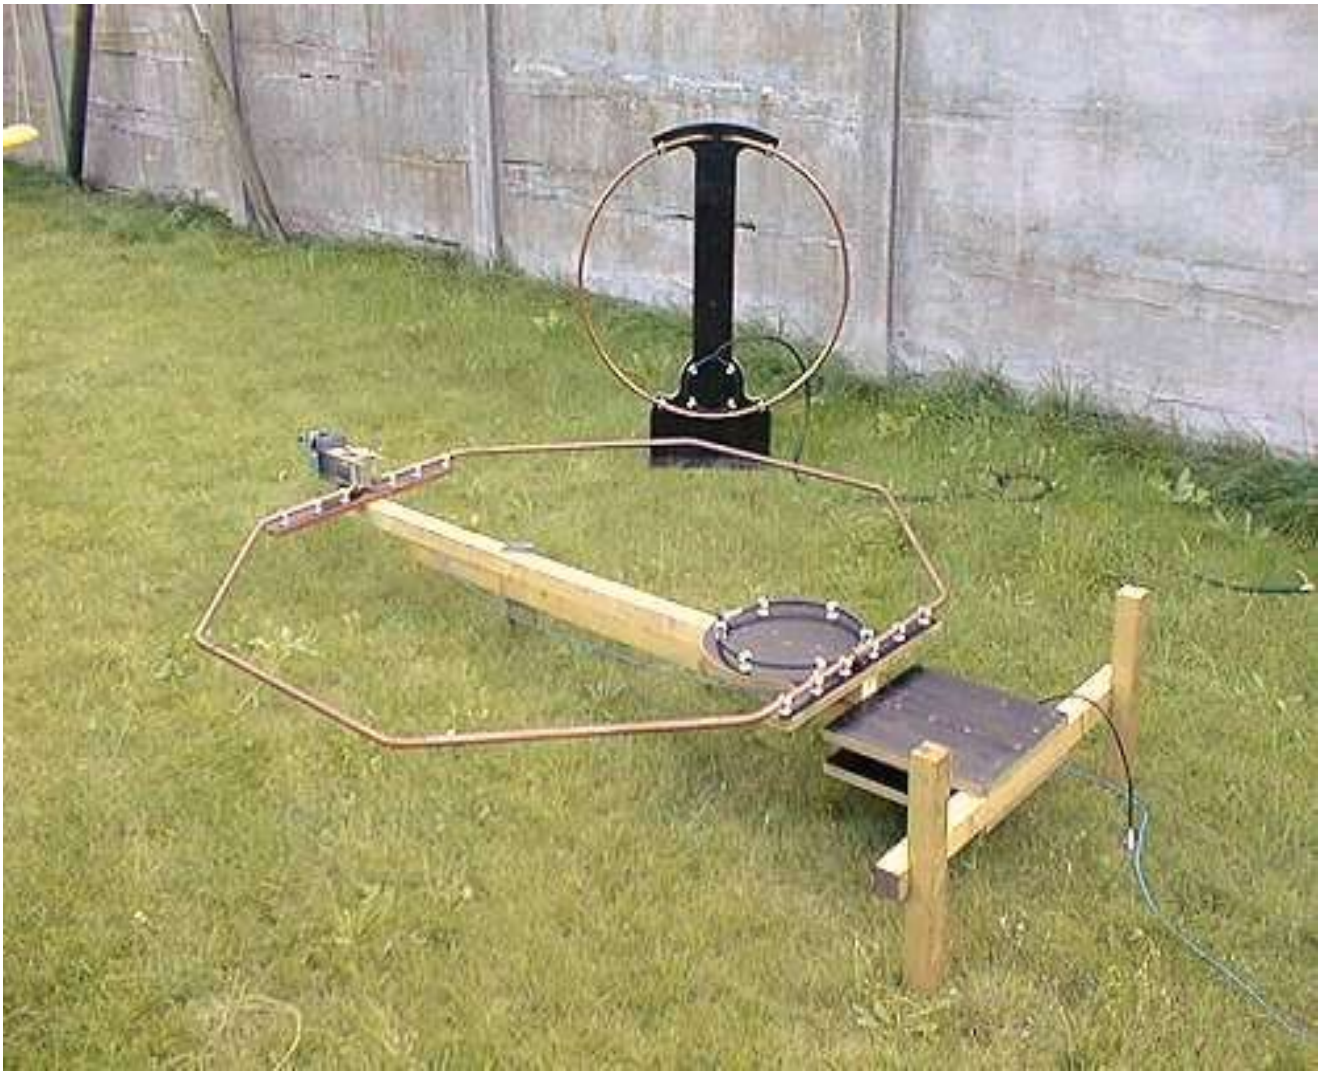
Mutil-turn Magnetic Loop

This is the first loop I build from a article in the QST from February 1996, it's 30 Inch-diameter, and it's designed by G2BZQ/WØ for 80 M



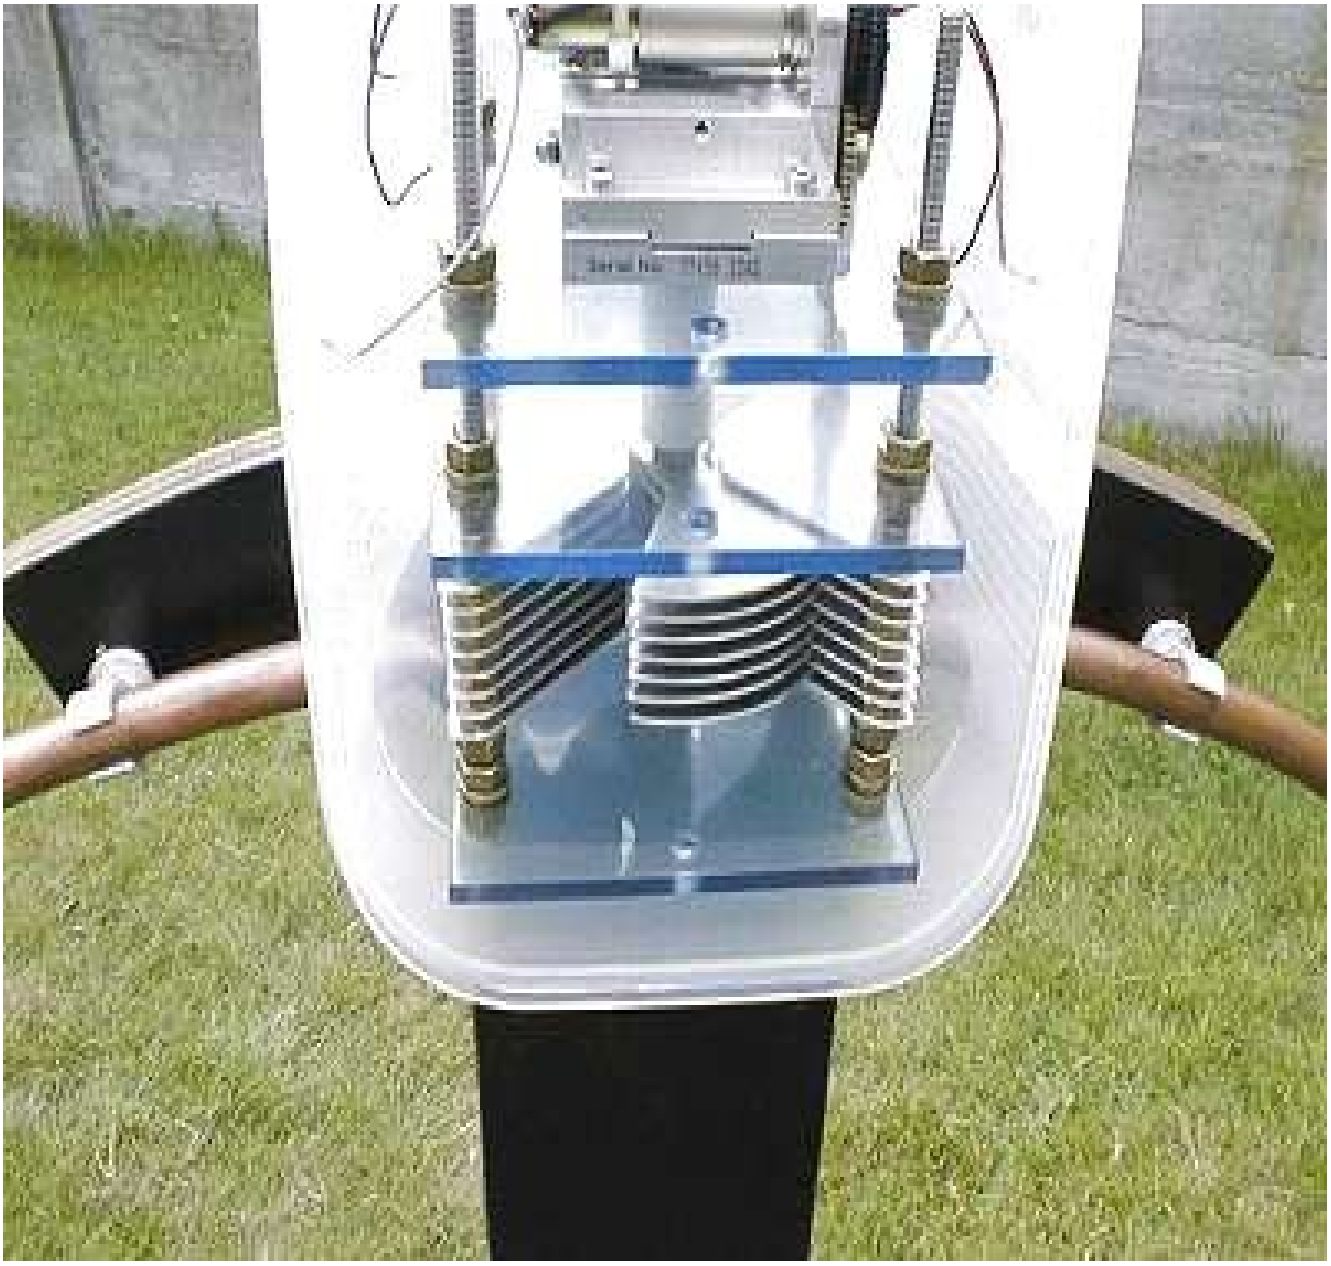


Single Turn Magnetic loops



The first one turn loop that I built was made from 75 Ohm TV Coax and with a small explanation in the RSGB handbook for radio amateurs. I used the outer screen from the coax and the results of the loop where good.The next loop I built is a octagon loop in 15mm copper tube with a circumference of 4.8 meter (16 feet).
The frequency range of this loop goes from 14 MHz to 7 MHz and works fine. The biggest problem is the tuning capacitor, if you transmit with a power of 100 W you need a capacitor with a voltage rating of 5000 Volt.

A capacitor which can handle this voltage is hard to find over here and if you find one they are very expensive. The first capacitor I built was a design from GW3JPT from a article in the RADIO COMMUNICATION from February 1994. It is a split stator capacitor with a capacitance of 140 pF and with a voltage rating of 6000 Volt. The capacitor is remote tuned with the use of a small BBQ spit motor



The second capacitor I built is my own design and it's a butterfly capacitor because the losses are lower than a split stator. The capacitance is 5-65 pF and the voltage rating is 7200 volts. I used it for the small loop with a dia. of 800 mm (2.66 feet) and the frequency range of this loop is from 28 MHz to 14 MHz. The Aluminum plates of 1 mm for the capacitors are cut with a JIG SAW

FAQ

I'd like to talk a little more on your setup. it seems like something which I could get together if only some more data was available. do you have any notes etc still laying about since its build ?

The theory for calculating the loop is very simple. The circumference of a magnetic loop is 1/4 wave of the design frequency.

Example for 14 MHz.

300 / 14 MHz = 21.428 m is 1 wave
21.428 / 4 = 5.357 m is 1/4 wave circumference
5.357 / 3.14 = 1.706 m diameter.

The recommendations are that you can tune the loop from the design frequency to the frequency divided by 2 to keep the efficiency acceptable.

14 MHz / 2 = 7 MHz

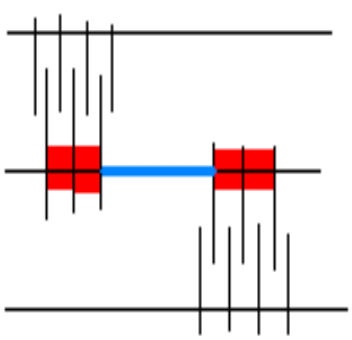
I made the small loop (800mm / 31.5 ") from soft copper tube on a role that you can buy in a plumber shop and it's easy to make a nice circle if you draw on the ground a circle with a rope and a piece of chalk.

For mounting the loop to the hardboard I used plastic clamps that they use for mounting copper tube on the wall.

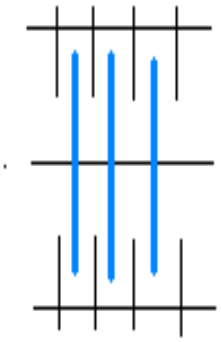
Why is a butterfly capacitor better?

For high voltages and currents the use of Capacitors with wiper contacts is not recommended. That's why they use capacitors in series. The pro for series's capacitors is that the voltage rating is doubled. The anti is that the value of capacitance is divided by 2. For the split stator capacitor the 2 capacitors are connected in series by the shaft (blue) and the red spots on the first drawing are losses.

For the butterfly capacitor the 2 capacitors are directly connected in series by the rotors and gives less losses.



Split stator



Butterfly

Do you know of anyone that has built a similar loop that outperformed a garden variety dipole?

Comparing antennas is very difficult , sometimes I have heard 60 % better signals in RX and TX on the loops then on the dipole.

In theorie the performance of a magnetic loop is - 0.4 dB lower then a dipole or a vertical .

I have a homebrew trap dipole from 40-20-15-10m and the height above ground is only 7 m(23 ft). For a good performance on 40 m the dipole must have a height of 1/2 wave above ground (66ft). I don't have a radiation angle on 40 m and it's only good for contacts in Europe and not good for DX, now the 1.5 m loop tuned to 7 MHz with a efficiency of 38 % (38 w ERP) and a angle radiation of about 20 degrees performs better than the dipole because the vertical magnetic loop only 1 M above ground as a angle radiation and the dipole don't.

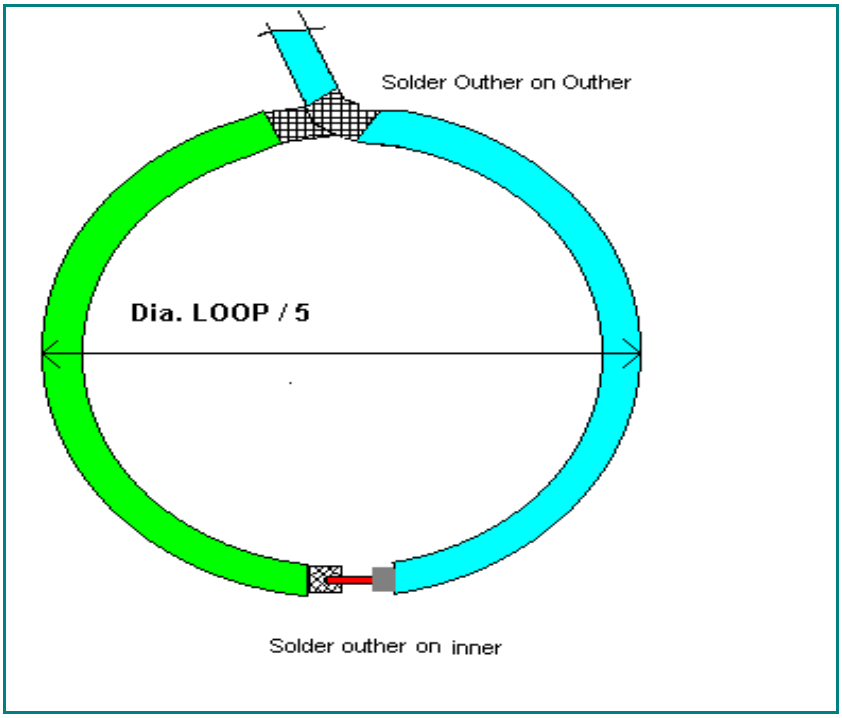
Another advantage is that the reception on a loop is much better, on 20m I have with the dipole S5 noise from the big city, if I switch to the loop I have S1 noise and hear stations who are buried in the noise when I use a dipole.

Coupling loop dimensions?

I find that the best way to feed the loop is with the shielded 1/5 Faraday loop made from coax RG213 or RG8, I tried the gamma match bud I had problems to keep the VSWR low on all Bands, the shielded loop gives on all bands VSWR 1.1 and reduce more noise pick-up then the gamma match.

I found out that if you use a 1/5 Faraday loop, that the loop is to big, making the loop smaller with 0.5 inch by the time in circumference and checking with a field strength meter you can see that the radiated power increase.

The place off the feeding loop is placed at the electrically neutral point on the loop and that is 180° from the capacitor and I have the best results with the feeding loop close to the ground and the capacitor far from the ground.



I was wondering if you worried about the resistance of the mechanical joints (copper pipe bolted to the capacitor) significantly reducing your radiation efficiency as I think the radiation of these antennas can get as low as .01 ohms?

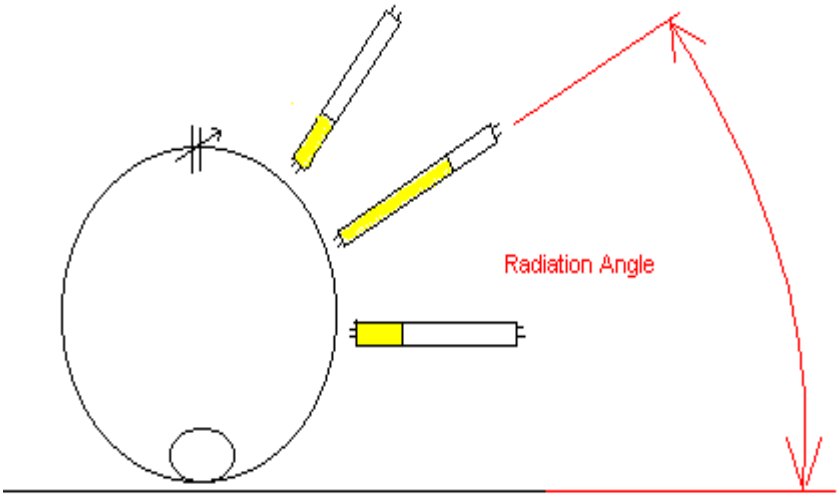
Solder or weld the capacitor plates is always the best, but I'm afraid if you make the spacers and the plates in ALU that with welding everything is going to bend from the heat and I know from practice (I work in a maintenance workshop) that welding ALU is coarse. Another possibility is using all brass or copper and solder, there are hams that using double PC board for the plates.I made a QSO in phone with Florida, RPRT 5-5 and the other station used a vertical antenna, with the small loop (800mm and theoretical efficiency 41 % on 14 Mc) vertical in the garden and the states side is through the house. I was very happy with the results , so I think that a capacitor made with torqued compressed joints is good enough for using 100 W.

Have the dissimilar metal joints weather well?

To keep the oxidation low on the dissimilar metals I used a thin coat of Vaseline after assemble the capacitor and with the Tupperware a like plastic box it is good protect against all weather conditions.

How to find the radiation angle of the antenna? Can it be found practically?

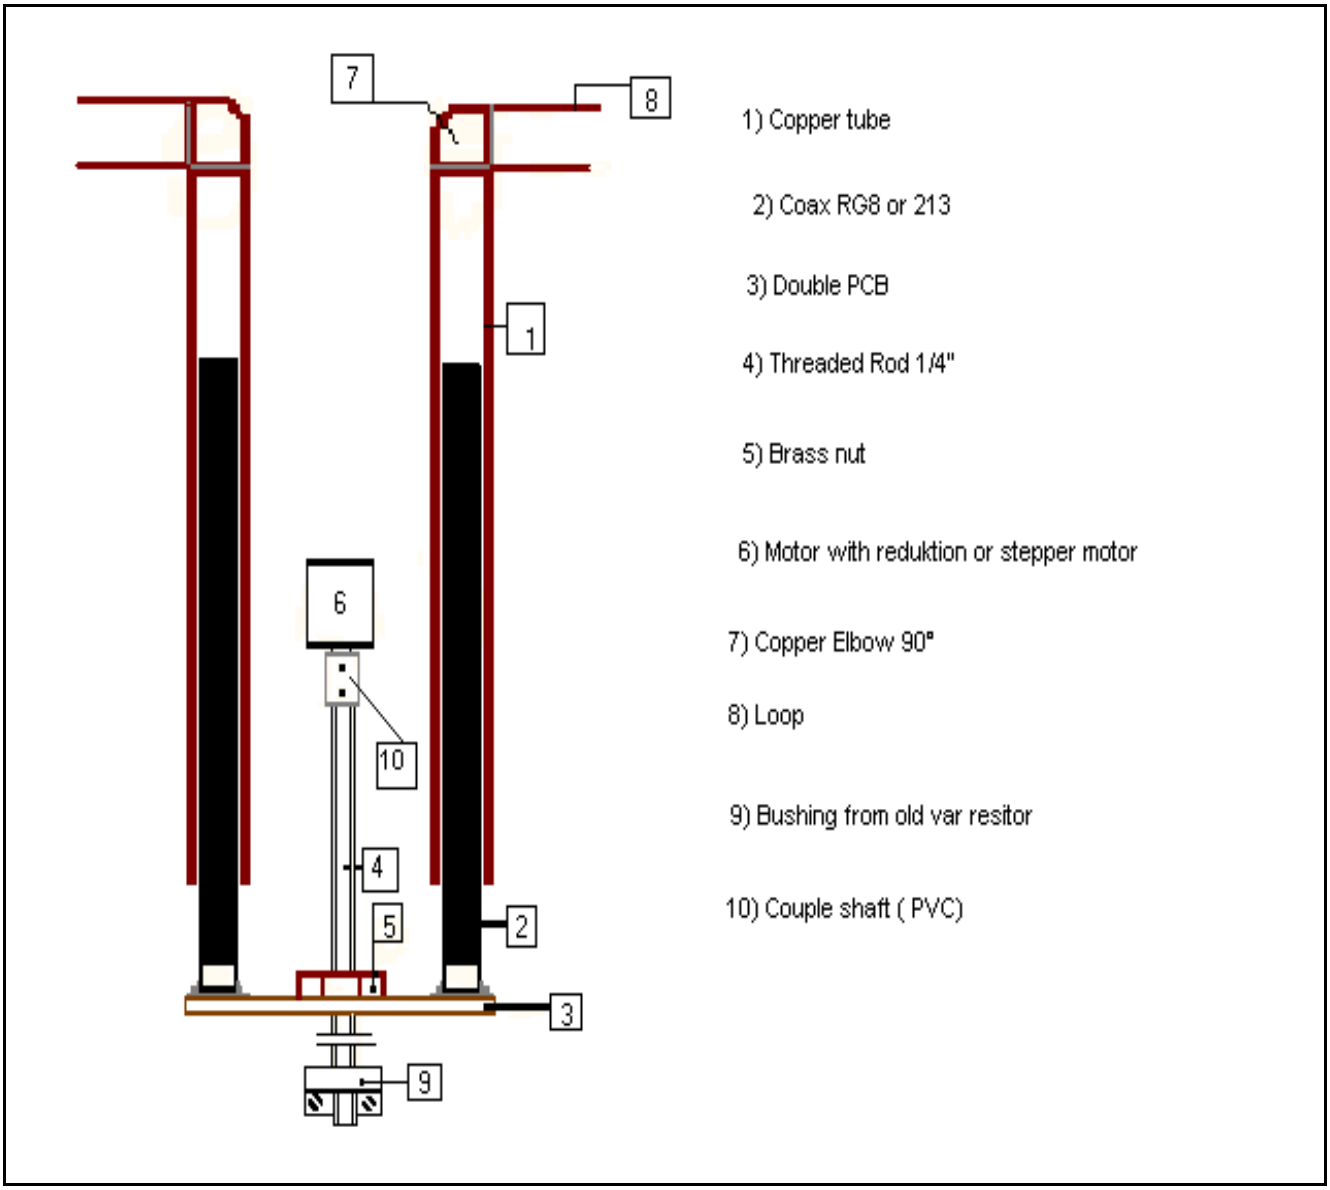
Finding the radiation of a magnetic loop is very easy, with a TL-light tube you can see it, with about 10 w power on the the loop with the TL-tube in the plane of the loop at right angle to the circle you see the tube lighting, there where the the light is the farthest on the tube thats the radiation angle.



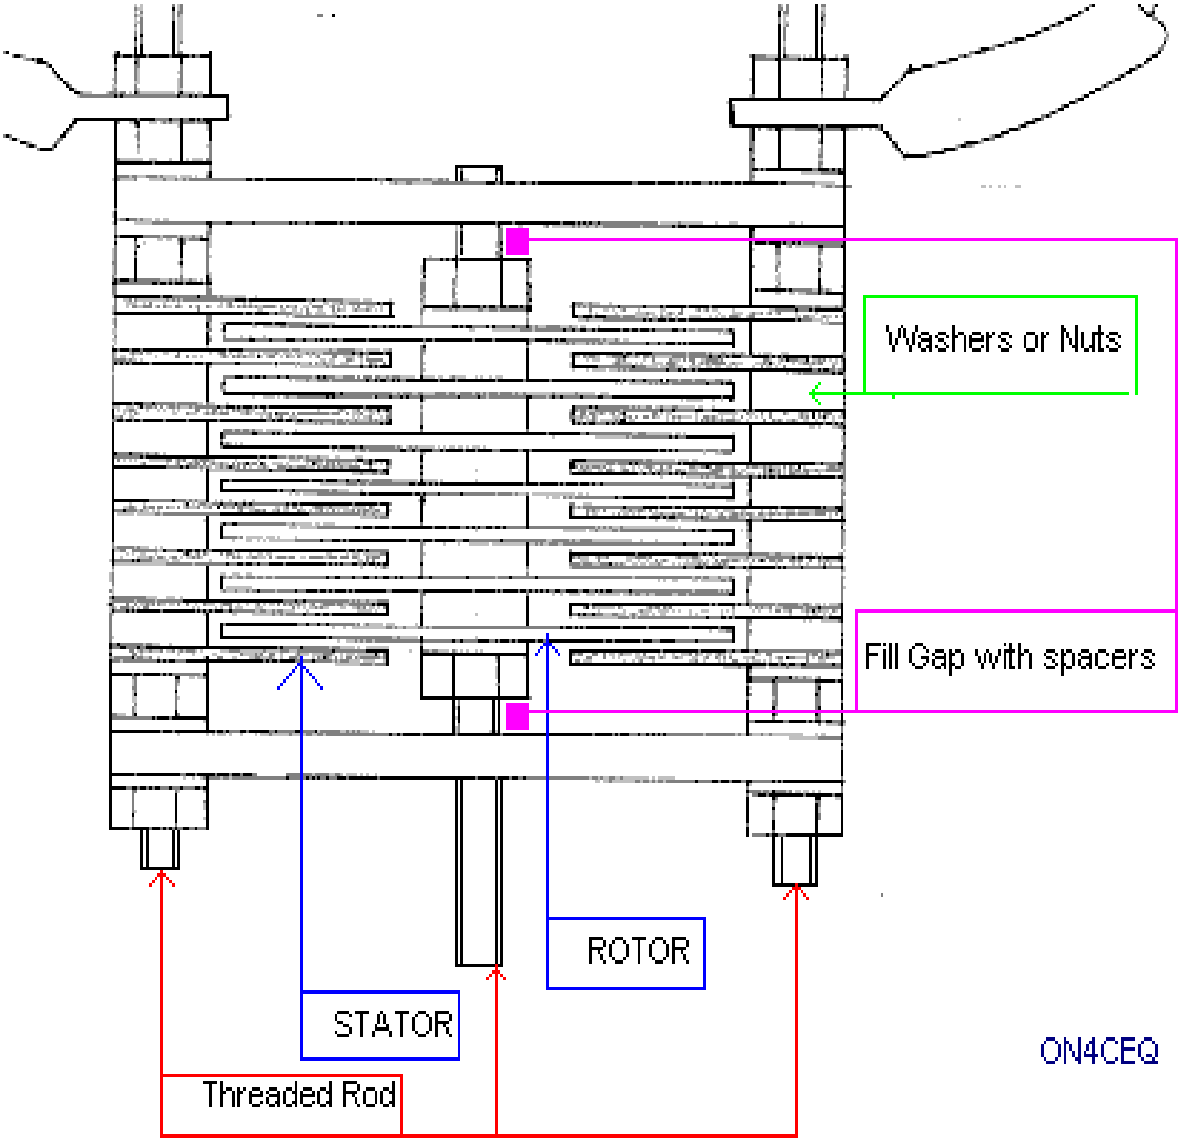
When you refer to washers, nuts and rods you use the term "M6".Please forgive my ignorance, but to what does "M6" refer? Does this mean 6mm?

M6 is (M=metrical) and 6 is indeed 6 mm threaded rod and you can compare the size with W1/4" (6.35mm)

A very easy to build Piston Capacitor.



How to build your own Butterfly Capacitor.



The best material for the front and the back is CLEAR PVC 3 or 5 mm thick as alternative you can use GREY PVC or 2 sheets pc board together with the copper removed .

The best material for the washers, nuts (M6) and threaded rod (M6) is brass or stainless steel,(NON MAGNETIC MATERIALS for the losses).

For the spacing of the vanes you can use 2 washers M6= (6Kv) or a nut M6 =(12 Kv) if you use aluminum plate 1 mm thick.

If you use a nut then the best thing to do is remove the thread by drilling withØ 6.2 mm.
The effective area for the vanes is 11.7 cm² and with the formula

for 2 washers = (0.0885 x 11.7 cm²)/ 0.1 cm = 10.35 pF for 1 air gap.

for 1 nut = (0.0885 x 11.7 cm²)/0.2 cm = 5.17 pF for 1 air gap

Example:

If you you make a capacitor with 2 washers as spacing and you make
5 rotor vanes and 6 stator vanes then you have 10 air gaps.

10.35 pF x 10 = 103 pF + 10 pF stray capacitance = 113 pF / 2 = 56 pF

The final result is a capacitor with a value from 5 - 56 pF.

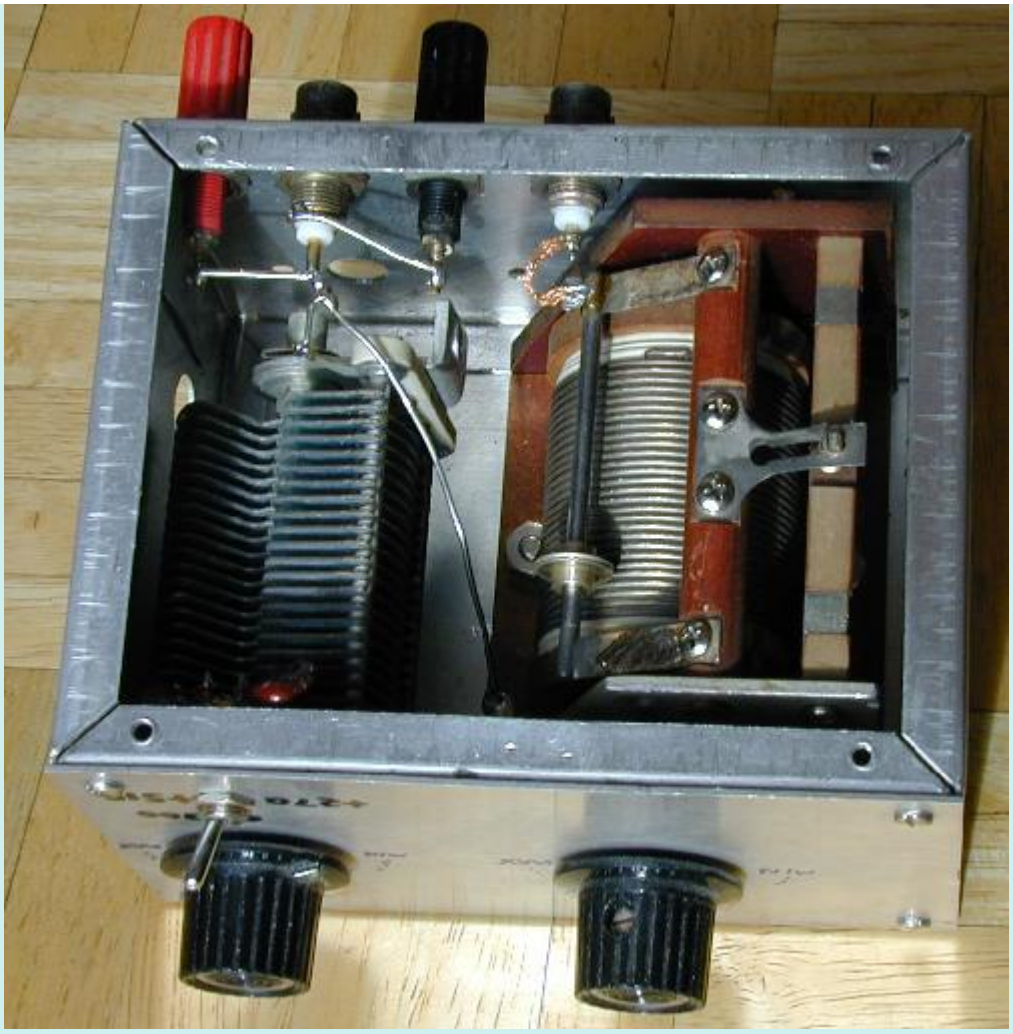
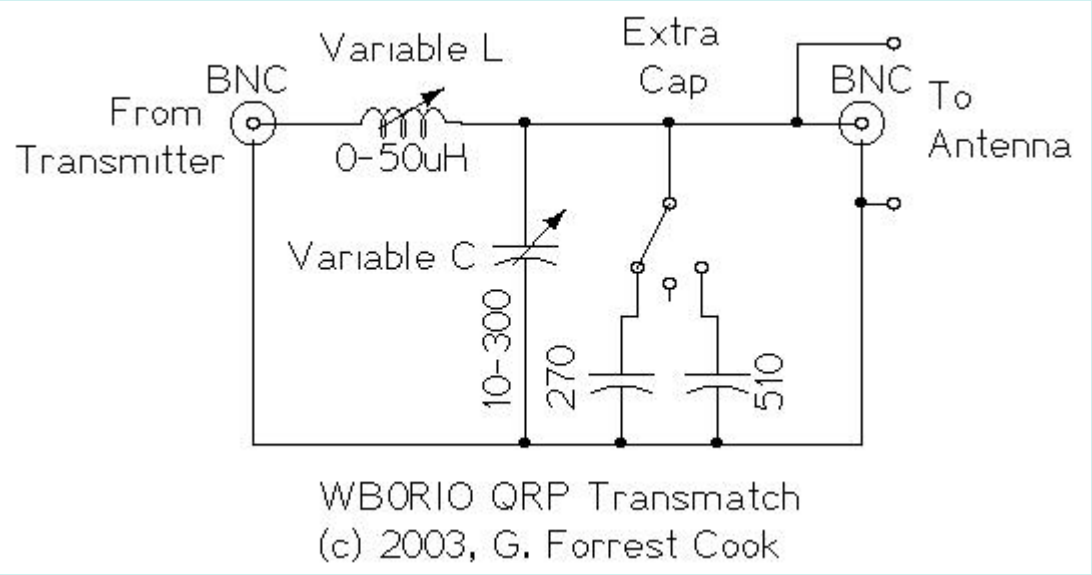
QRP Antenna Tuner

(C) 2003, G. Forrest Cook





Introduction

This circuit is for a QRP (low power) antenna tuner (transmatch) for use in the short wave amateur radio bands from 3-30 Mhz. It allows a wide variety of antennas to be connected to a low power transmitter. When the circuit is properly tuned, the maximum transmitter power will be delivered to the antenna. The tuner is normally is used in conjunction with a standing wave ratio (SWR) meter.

This is *not* the most versatile antenna tuner circuit, it will not match any possible load. This tuner *is* efficient and it is very simple to build and use. It is small enough for backpacking applications and is useful for matching many of the types of antennas that one might throw up on a camping trip.

Theory

The purpose of a transmatch is to match the impedance of a transmitter, typically 50 ohms, to an unknown antenna impedance. The circuit consists of a variable series inductor followed by a variable capacitor to ground. Most transmitter outputs consist of a PI low pass network. The transmatch is essentially an adjustable extension of that network. With the parts shown, maximum power through the unit is approximately 50 watts.

Construction

The tuner was built in an aluminum project box. Various holes were drilled in the box for mounting all of the components. When laying out the parts, leave plenty of room around the sides of the components to prevent RF arcing. Be sure to keep both sides of the variable inductor insulated from the box, you may need to use insulated bushings (non-conductive washers) on the inductor's shaft. Use heavy hook-up wire to connect the various components together, I recommend 18 gauge tinned cooper wire, or thicker. Use the shortest wire lengths possible. I used a fairly small box for the components that I had, a larger box would make the project somewhat easier to build.

Use

Connect the transmitter output to an SWR meter, connect the SWR meter output to the input of the antenna tuner, and connect the antenna to the output of the tuner. Antennas with a coaxial feedline should be connected to the BNC output connector. Random wire antennas should be connected to the banana jacks. The transmitter should be connected to a good earth ground at its chassis, the ground can also be connected to the lower (black) banana jack on the tuner.

With coax-fed antennas, the best location for an antenna tuner is where the coax feeds the antenna. Logistically, this may cause the tuner to be in a location that is difficult or impossible for the operator to tune so most people locate the tuner on the transmitter side of the coax.

Set the capacitance switch to 0 (center), adjust the variable capacitor to the mid point. Adjust the inductor to near the minimum inductance. Briefly transmit a CW carrier and observe the SWR reading. If your transmitter has an adjustable output power level, start the adjustment with low power then increase the power and fine-tune when a good match has been found.

Increase the inductance until the minimum reflected power and maximum forward power is observed. Adjust the capacitance for the best SWR reading. It is necessary to go back and forth on the adjustments to find the best match. If the best match is found with the capacitor at the max value, switch in either the 270pf or 510 pf parallel capacitors and re-adjust the variable capacitor and inductor.

Be careful not to leave the transmitter on for too long in the unmatched condition, doing so can damage the transmitter's output transistors. If your transmitter has a variable output power, tune up at low power then re-adjust the circuit at full power. Tube-based transmitters are generally more able to handle large output mis-matches.

Caution: higher power transmitters can generate high voltages within this circuit, don't touch any of the wires when the transmitter is operating. If the roller inductor's adjustment shaft is connected to the inductor's wiring, the shaft should be mounted so that it does not come in contact with the metal box. The set screw on the inductor's knob may be electrically hot during use, you may want to cover it with a drop of plastic glue or silicone after tightening.

Parts

- variable inductor (roller), approximately 0-50 uH

- variable capacitor, 0-300pf or 0-360pf, can be scavanged from an old tube radio
- center off spdt switch
- 270pf, 200V silver mica capacitor
- 510pf, 200V silver mica capacitor
- two BNC connectors (or PL-259, the connector that won WWII, if you prefer)
- two banana jacks
- two insulated plastic knobs
- miscellaneous screws, nuts, and washers
- solid hook-up wire, 18 gauge or similar
- aluminum box, big enough to easily contain all of the components

The variable inductor may be difficult to find, the best places to look are at ham radio swap fests and surplus electronics parts companies. A fixed inductor with switched taps can be substituted. An air-core formed inductor will probably give the best results in this circuit, a toroidal ferrite core inductor will also work, but it may absorb some of the available RF power.

See Wikipedia's Antenna tuner article for more background information and Ulrich L. Rohde's (N1UL) antenna tuner circuit which can tune a wider range of antenna impedances. Ulrich Rohde has also published a more detailed article (zip) in German.

Design and Implementation of Ambient RF Energy Harvesting Circuits

Walter Ciccognani, Sergio Colangeli, Mirko Palomba, Ernesto Limiti and Lucio Scucchia*

Department of Electronics Engineering
University of Roma "Tor Vergata", Roma ,Italy.
Tel: +39 06 72597345; Fax: +39 06 72597353; E-mail: scucchia@uniroma2.it

***Abstract* - This paper presents design strategies and measurements of two RF energy harvesting circuits working at UHF frequencies (around 480 MHz). Ambient RF sources are considered so for the circuit designs low power levels have been assumed. The circuits were implemented and the RF/DC conversion efficiency was measured.**

***Index Terms* – Matching network, RF energy harvesting, schottky diode, voltage doubler.**

I. INTRODUCTION

In general the energy harvesting denotes all processes through which the energy, coming from alternative sources, as sun and wind, is caught and stored, a particular technique is the RF energy harvesting where the irradiated RF energy is processed. On the other hand, the electrical power levels, generated using this technique, are very low, some milliwatts, but still enough to drive low power devices.

The block diagram of an energy harvesting system is shown in Fig.1, it is composed by the matching network, the multiplier and the DC-load circuit [1]. In this system the matching network permits to maximize the power transfer whereas the voltage multiplier performs the effective conversion from RF to DC. Consequently, the conversion efficiency depends on the type and number of nonlinear devices, which form the multiplier, and is affected by the matching structure.

In addition the characteristics of the RF signal have a direct effect on the RF/DC conversion efficiency, which is characterized by the ratio between the DC power and the RF power.

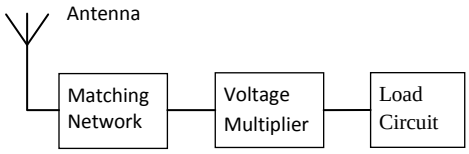

Fig.1. Block diagram of an energy harvesting system.

The RF energy sources can be parted into three general groups: intentional sources, known and unknown ambient sources [2]. This work considers known ambient sources, as antennas that radiate in the UHF frequencies around 480 MHz. In particular, this study is aimed at identifying the potential efficiency of an RF/DC conversion system made with hybrid technology using Schottky diodes and capacitors. Therefore, the voltage multiplier is examined in its simplest form: the voltage doubler. Selected the voltage doubler structures, the study was carried out throw the following steps, firstly, a particular Schottky diode was chosen and its model was implemented on the CAD software used to synthesize the circuits. Secondly, voltage doublers and matching networks were synthesized and realized; successively the achieved circuits were tested in order to verify their correspondence with what was designed. Finally, the real target of this study, measurements to define the RF/DC power conversion were carried out.

INTERNATIONAL JOURNAL OF MICROWAVE AND OPTICAL TECHNOLOGY,

VOL.9, NO.1, JANUARY 2014

II. SELECTION AND MODELING OF THE DIODE

Schottky diodes can be parted in two basic categories: diodes realized using n or p silicon; the first are characterized by relatively high barrier and low series resistance, consequently they are suitable for detectors and mixers where DC bias is available. On the other hand, the p silicon diodes are characterized by low barrier and high series resistance; these devices were accomplished for application where DC bias can not be used. Therefore, taking into account studies reported in [3], [4] where diode performances are examined the schottky diode HSMS-285C from Agilent were selected. The HSMS-285x family includes zero biased diodes which are optimized for low signal (<-20dBm) applications at frequencies below 1.5GHz.

The diode parameters are reported in the Agilent data sheet in particular the nonlinear behavior of diode is described by the SPICE parameters reported in Table 1[5].

Table 1: SPICE parameters

Parameter	Units	Value
B_V (Vbr)	V	3.8
C_{JO}	pF	0.18
E_G	eV	0.69
I_{BV}	A	3.0E-4
I_S	A	3.0E-6
N	-	1.06
R_S	Ohms	25
P_B (Vj)	V	0.35
P_T (XTI)	-	2
M	-	0.5

The SPICE parameters permit to model the diode chip, however to obtain accurate linear and nonlinear analysis also the package equivalent circuit must be considered [6].

Fig.2 shows the equivalent circuit of the HSMS-285C package (SOT-323) and the component values.

III. VOLTAGE DOUBLERS

The considered voltage doublers are the Greinacher and Delon circuits, the first, shown in Fig. 3, is composed by a Villard cell and a peak detector.

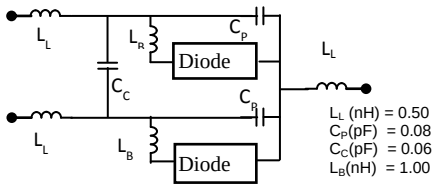

Fig.2. Model of the SOT323 package.

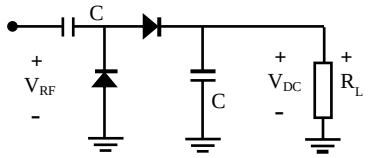

Fig.3. Greinacher circuit.

The effect of the first cell is to shift up the RF waveform so that the negative peaks are clamped to about 0 V. The second cell reduces the ripple providing a DC voltage about equal to the double of RF signal amplitude.

The Delon circuit, shown in the Fig.4, is realized connecting in series two peak detectors, the first detects the positive peak and the second the negative peak, and the total DC voltage is provided across the two capacitors.

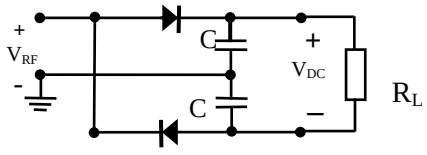

Fig.4 Delon circuit.

In general, the capacitors C do not affect significantly the output voltage. However, the fundamental requirement is to keep their related

impedance low with respect the diode impedance. So capacitors with a value of 100pF are used, they present at the 480MHz frequency a reactance much less than the impedance of a single diode operating at -30dBm. Consequently, the capacitors are short-circuits and the Schottky diodes are put in parallel.

IV. VOLTAGE DOUBLER DESIGN

Chosen the diode, selected the voltage doublers and implemented both on the used CAD software, Advanced Design System (ADS) by Agilent Technoklogies, the design problem consists in the achievement of a matching network between the source at 50 and the voltage doubler input impedance. It is important to note that the diode has an impedance function of the power levels of the RF signal [3],[4]. Therefore, the matching network was synthesized considering a reference power level equal to -30 dBm. In particular, to reduce losses due to passive components, the simplest circuit solutions have been chosen, namely the L networks.

The Fig.5 shows the achieved Greinacher doubler, where the matching network is constituted by the components C_1=0.8pF and L_1=56nH. The element HSMS285C represents the pair of diodes and the package model.

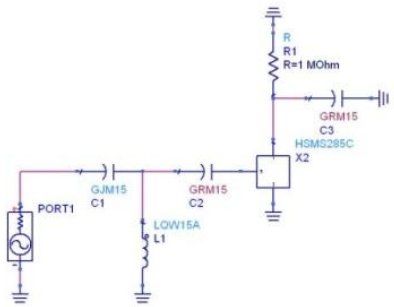

Fig.5. Simplified scheme of Greinacher doubler.

The resulting input impedance of the doubler, without and with matching network, is shown in Fig.6.

The Fig 7 shows the Delon doubler, where in the L matching network C_1=0.9pF and L_1=68nH result. Fig. 8 describes the doubler input impedances without and with the L network.

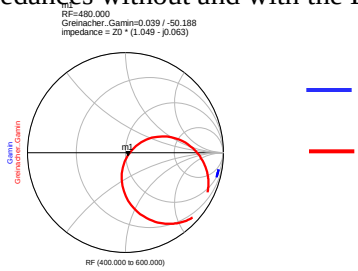

Fig.6 Greinacher doubler input impedance.

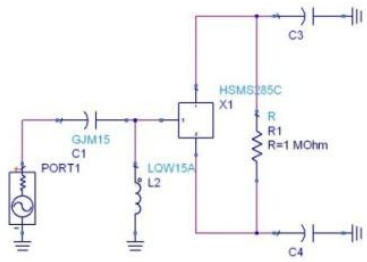

Fig.7 Simplified scheme of Delon doubler.

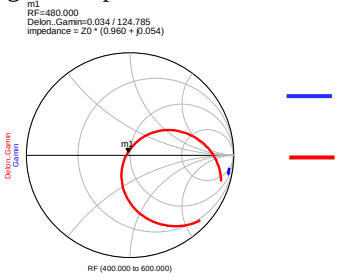

Fig.8 Delon doubler input impedance.

For simplicity in the schemes shown in Fig.5 and Fig. 7 the microstrip connections are not reported. However, in the real design, microstrips, vias have been taken into account. Moreover, to ensure a good match between simulations and measurements the structure discontinuities have been characterized using the Momentum, which is electromagnetic simulator of ADS.

For the two doubler achievements is assumed the use of FR4 (e_r = 4.35, substrate thickness =1.6 mm, conductivity = 5.8 e7 S/m, conductor thickness = 35 μm, tan δ = 0.018).

V. VOLTAGE DOUBLER REALIZATION

In order to perform the desired measures the two voltage doublers have been realized and the obtained circuit photos are shown in Fig. 9 and Fig. 10.

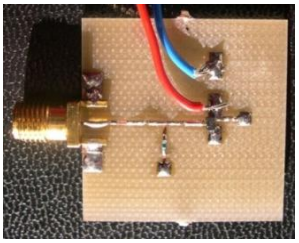

Fig.9. Greinacher doubler photo.

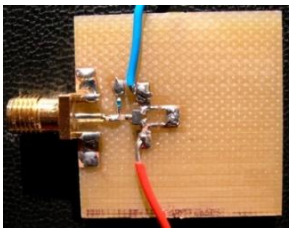

Fig.10. Delon doubler photo.

Measurements by using Anritsu 37397D VNA were done to verify the fitting between designs and produced circuits, and S_{11} measures and simulations were compared for different signal power levels. In particular Fig.11 and Fig.12 show the return loss, obtained assuming a power level equal to -30 dBm.

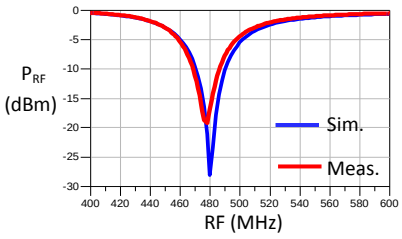

Fig.11. Return loss of the Greinacher doubler.

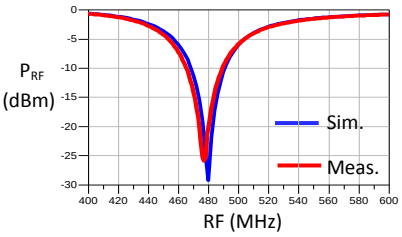

Fig.12. Return loss of the Delon doubler.

VI. MEASUREMENTS

Verified the correspondence between design and implementation for the voltage doublers, measurements were carried out to obtain the DC voltage values resulting from the RF input. This result was achieved using as RF source the Agilent E4438C vector signal generator. Several measurements were made for different loads and RF power levels; Fig.13 and Fig.14 show the obtained voltage values for RF power levels equal to -40, -30 and -20 dBm for the two selected configurations.

The best performance are obtained around 480MHz and, for a load equal 10MΩ, an input RF power of 1μW produces about 70 mV. Obviously, for lower load values, the results decrease, so at 100KΩ and 10KΩ the DC voltage values are around 55 mV and 25 mV for an input RF power equal to 1μW.

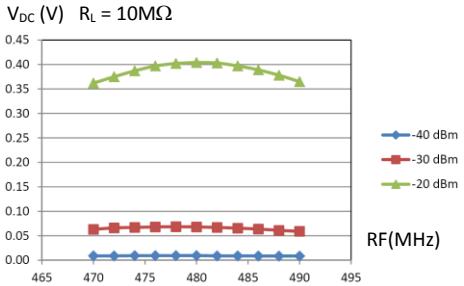

Fig.13. Voltage values by Greinacher doubler.

INTERNATIONAL JOURNAL OF MICROWAVE AND OPTICAL TECHNOLOGY,

VOL.9, NO.1, JANUARY 2014

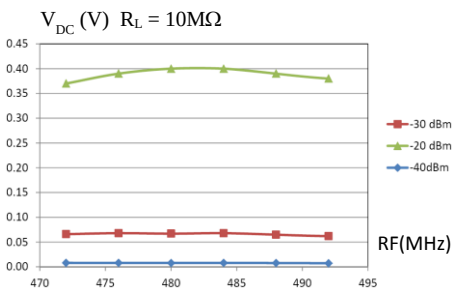

Fig.14. Voltage values by Delon doubler.

The collected measurements were processed in order to achieve the RF/DC power conversion efficiency. The Fig.15 shows the conversion efficiency values obtained for different power levels and different loads. So at a 1μW the greatest conversion efficiency value is about 6% achieved with a load of 10KΩ.

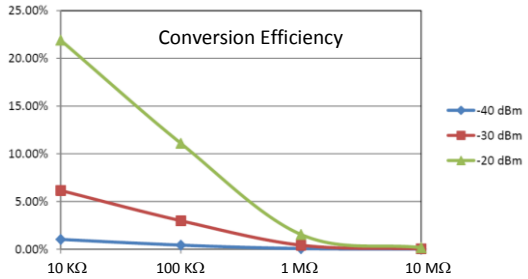

Fig.15. RF/DC conversion efficiency by Greinacher doubler.

VII CONCLUSION

This work was aimed to acquire knowledge on the RF/DC conversion efficiency values which can be achieved by hybrid technology, using Schottky diodes and capacitors. UHF TV broadcasting frequencies around 480 MHz have been taken into account. The desired result was performed, firstly designing and realizing two different RF/DC conversion systems and then measuring and processing the collected data. In particular, for a load equal 10 MΩ with an input RF power of 1μW a DC voltage equal 70 mV was achieved.

Description

This article describes how to build a wireless harvesting device that will capture stray 2.5GHz energy from a microwave oven and convert it into a useable voltage that will light up a red light emitting diode (LED). Hobbyists can modify the antenna with longer wires and try to pick up other signals such as AM/FM radio, mobile phone signals and other wireless energy. The LED's light will be visible when the module picks up 1 milliwatt-10 milliwatts of microwave power. Usually the most power leaks out of the door seam of a microwave oven.

What you need:

1 RFD102A (RF-DC Converter) module available at

http://www.rfdiagnostics.com/product/rfd102a/

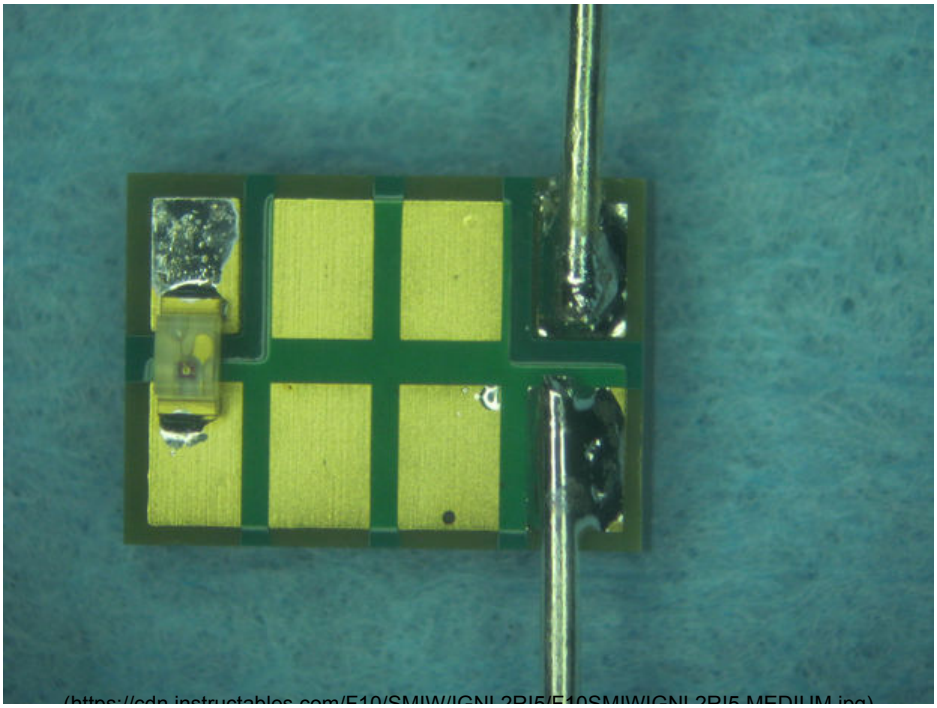
1 ¼ watt leaded resistor (any value) or two wires that are 1 1/8 inches long (28.6mm)

1 Kingbright Surface mount red LED (part number: APT1608EC) available at Digikey/Mouser/Newark

Fine tipped soldering iron

Solder paste or Fine Solder

Step 1: Assembly Instructions

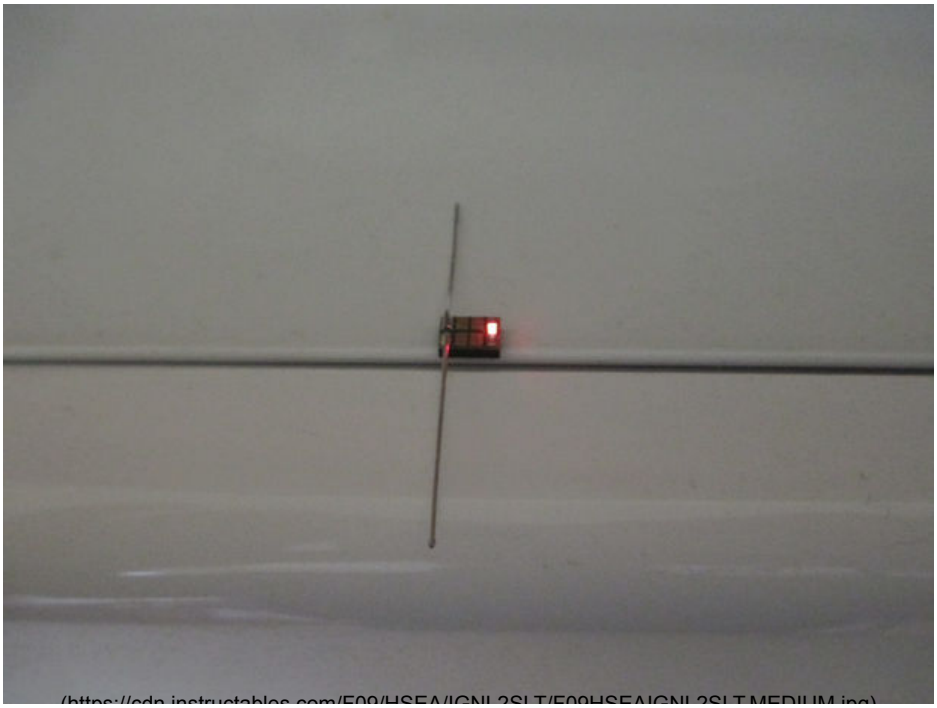


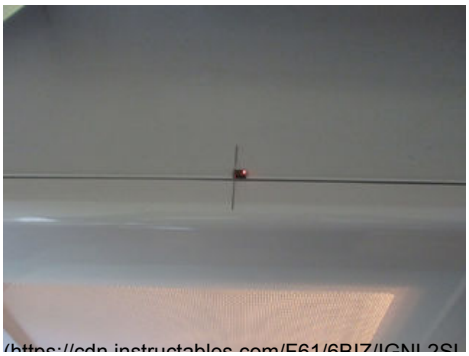
Cut the resistor wires off next to the resistor. These are just the right size at 1 1/8” long for a 2.5GHz dipole. Throw away the resistor and keep the wires.

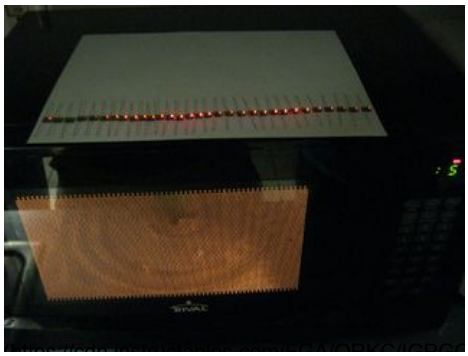
Put solder paste on the module at pins 1 & 8 and at pins 4 and 5.Place the wires on pins 4 and 5 and solder carefully using tweezers to hold the wires (it will burn you otherwise). Solder at the lowest soldering temperature possible to avoid damaging the module. If the iron is too hot then you may damage the internal connections inside the module. Use a minimum of time for soldering (<10secs). The wires work as a dipole antenna to collect the 2.5GHz energy into the RF (Radio Frequency) Input of the module.

Place the LED with the anode (positive side) onto pin 1 and the cathode (negative side) on pin 8 and solder carefully. For those not familiar with LEDs, the triangle symbol of the diode should point to the ground pin of the module (pin 8). Your final microwave harvester should look like figure 2

Step 2: Test on Your Microwave Oven







Now put some water in a mug and put it in the microwave oven and cook on high for 2 minutes. While the microwave is running, hold the module and move the module antenna around to find a hot spot on the microwave. Tape the module on the ground wire to the microwave to keep it in place. If all is well then you will see the LED light up and dim as the electric fields change while the mug rotates in the microwave oven. The above figures show the microwave energy harvester in action. Experiment with antenna shapes and sizes. If you go too big or too small with the antenna then less energy will be collected. You can also put the assembled module near an 802.11b/g/n wireless LAN router and watch it flicker as the router transmits and receives 2.4-2.5GHz energy. Enjoy!

Other Project Ideas:

- Harvest AM/FM Radio Signals

FAQ

- What is the maximum current this module can provide? Ans: Typical current is ~0.5-5mA. Max current is 18mA.

- What is the efficiency of converting RF energy to a DC voltage? Ans: If the input power to the module is around 10-50mW then the RFD102A can achieve >50% efficiency if the resistance seen by the DC output is ~10kOhm.

- I don't have a soldering iron and am all thumbs. Where can I get a detector like this already built up? Ans. The RFD102A-DET is available http://www.rfdiagnostics.com/product/microwave-oven-window-energy-

harvesting-kit/

- What is the maximum output voltage this module can produce? Ans: With 0.5W input power the module can produce up to 37V at 915MHz.

- Can I charge my mobile phone with this? Ans: It is possible with 4 RFD102A modules and antennas to produce enough current to charge a mobile phone. The hard part is the wireless source would need to be so powerful that you wouldn't want to be in the same room during charging. You may hurt your eyes by cooking them.

I had an explosion of ideas from this project, I had to make this account :p

1> you seem to use specific dimensions/material of wire to tune it to 2.5 GHz, whats going on here? Can I use a sheet of metal? Can I tune it to some other frequency on this module? If so, how?

2> What is the ideal output from this model you made under ideal conditions (V & I)? Is it versatile enough to be used as a small power source for something if I join enough of them in series and parallel? Say 1000 of them in 10x10 series and parallel connection harnessing a constant strong signal, can the module support a tiny load (bit more than LED)?

I'm sorry if it sounds too stupid, but I'm only wanting to know a bit more fine details before I head to the drawing board :)

tbudka (/member/tbudka/) ▸ utg001 (/member/utg001/) 2015-11-14 Reply

1. Dipole antennas are usually sized to be 1/2 of a wavelength so each wire in this dipole is 1/4 of a wavelength. At 2.5GHz the 1/4 wavelength (c/f) = 0.25 * (3.0E10cm/sec)/(2.5E9 Hz) = 3cm. The leaded resistor wires are 2.86 cm (1 1/8 inch) long so that checks out. Sheet metal could be used for a bow-tie antenna or a cross pattern to pick up the other polarization. Size does matter. A larger dipole will pick up lower frequencies. The RFD102A module is broadband and limited by the frequency response of the antenna.

2. I posted a photo at the end of an array of 30 detectors picking up the energy. Your idea of putting a 10x10 array is a good one to scale up the power harvested. Kind of like having a larger solar panel. That would be a cool project to make.

Thanks for your questions/comments.

ke8bg (/member/ke8bg/) 2015-11-14 Reply

From the FDA website on leakage..

Use to work on microwave ovens.. We had to leakage check each one before they went back into service. Most likely leakage is around the door. A door out of adjustment can spew out all sorts of radiation. Redundant door safety switches are there for a reason. I've been 'dosed' a couple of times by a technician who had left off the brass Magnetron gasket and couldn't figure out why the control board would shut down right after he pushed the start button. 500 watts at 2.4 ghz will overwelm a CPU chip. Be careful. 2.4ghz can cook you too!!!

BTW as stated below the power level drops off 'inverse square of the distance'.

"A Federal standard limits the amount of microwaves that can leak from an oven throughout its lifetime to 5 milliwatts (mW) of microwave radiation per square centimeter at approximately 2 inches from the oven surface. This limit is far below the level known to harm people. Microwave energy also decreases dramatically as you move away from the source of radiation. A measurement made 20 inches from an oven would be approximately one one-hundredth of the value measured at 2 inches."

tbudka (/member/tbudka/) ▸ ke8bg (/member/ke8bg/) 2015-11-14 Reply

Thanks for this information and it's nice to meet someone familiar with microwave leakage/exposure. The light from the detector definitely gets dimmer very quickly as I pull it away from the microwave door. 5mW is very small and is only seen with this detector close to the microwave oven (<2inches). This is why I think we can only harvest energy close to the microwave rather than at the kitchen table. I would need to add an amplifier to pick up the weak microwave energy from the microwave if I were >5ft away.

MarcoG6 (/member/MarcoG6/) 2015-11-08 Reply

there was a kickstarter that made a phone case to turn the stray signals from ur phone to charge the phone they claimed to get 3x the battery life in a iphone 5 but the case was like 100$ maby u can make a chaeper one

tbucka is right, it just doesn't seem... legit.

Dashing Rainbow Dash (/member/Dashing+Rainbow+Dash/) ▸ Dashing Rainbow Dash (/member/Dashing+Rainbow+Dash/) 2015-11-13 Reply

*tbudka sorry

tbudka (/member/tbudka/) ▸ MarcoG6 (/member/MarcoG6/) 2015-11-09 Reply

That claim doesn't seem realistic. If the charger is collecting a lot of power from the phone then it's probably hurting its transmission/reception. The RFD102A module is very sensitive to low input powers but didn't get much power from my phone with a log periodic antenna. At 0.04mW/915MHz the module produces 0.5V output into a voltmeter. When I was testing the RFD102A-TB (TB=test board) my phone while on a call to my answering machine, I got up to 4V output from the module but that is into a high impedance. I think my next instructable will document this tests with a phone and a base station. Thanks for your comment.

MichiganDave (/member/MichiganDave/) 2015-11-07 Reply

A BIG Thanks for sharing and a small question for you: If you can harvest this energy can you save it? I am imagining doing this in order to save the "free" energy until its useful. Will it take a thousand years to power a flashlight, or merely ten?

tbudka (/member/tbudka/) ▸ MichiganDave (/member/MichiganDave/) Reply 2015-11-08

To answer your question about charging a flashlight, yes it is possible to charge a flashlight in a reasonable time with your microwave oven if you have ~10-20 of these detectors to generate 50-100mA to charge up the batteries. Please see my last photo with 30 detectors on a microwave all lighting up. Then you need to make sure the oven is on a lot (like at Subway). Unfortunately you need to be so close the microwave to get this power. So IMHO, if you are going to try to get free energy, you need a good source in mind. Stray cell phone and WiFi power aren't high enough. An array of antennas pointing at a base station may give you some small amount of power but it won't be cost effective.

tbudka (/member/tbudka/) ▸ MichiganDave (/member/MichiganDave/) Reply 2015-11-07

Yes. You can save the energy but not indefinitely. There are always small leakage paths to rob you of this hard fought free energy. The RFD102A has 60kOhms resistance to GND so if you had been able to charge a supercap (1F) to 5V, it would take 60000secs (1000mins or 16.67hrs) to discharge the capacitor by 36.8% of its energy (RC time constant). Supercaps also have their own leakage resistance. So you need to make sure you understand your microwave source and the leakage resistances of your components. TinkerJim has a great instructable on a Solar Engine that is very useful with this module. I am planning on posting about an improved module with TinkerJim's design. Another great question. Thanks for your interest.

turbiny (/member/turbiny/) 2015-11-06 Reply

Is it possible to recharge a phone via wifi router?

tbudka (/member/tbudka/) ▸ turbiny (/member/turbiny/) 2015-11-06 Reply

No. Most WiFi routers are very low output power. If you have a WiFi Booster Amplifier (2W) then there is a chance to get some power from this system to charge your phone but I wouldn't want to stay in that room with all that power. Most WiFi signals are <0.05W coming out of the router. This detector will light up and flicker close to an 802.11b/g router (2.5GHz) but that's only a few milliamps of current at 1.5V. Sorry about this but I agree with Dave Jone's eeVblog #55 that you won't be able to charge your cell phone from WiFi unless the transmitted power gets raised. Great question.

whyjbe (/member/whyjbe/) 2015-11-06 Reply

Thanks tbudka for the tips. It's good to know that the power level drops quickly with distance. My microwave is still 'new' since I do not use it.

tbudka (/member/tbudka/) ▸ whyjbe (/member/whyjbe/) 2015-11-06 Reply

There is really not much to worry about with microwave ovens, cell phones and base stations for health issues. I tested this module with a broadband antenna around a base station and I got a very low voltage out (1.5V max) which would mean there is less than 0.0005W of power right next to a base station. The cell phone companies do a great job keeping that power low around the base stations. Also since the wavelengths are large (inches/cm) there can't be much if any damage at the cell level (microns). IMHO I don't see much of a chance for low power (<10mW) microwaves to cause any health problems. Just don't stare at the microwave popcorn right next to the window... :)

whyjbe (/member/whyjbe/) 2015-11-06 Reply

Thanks tbudka for the tips. It's good to know that the power level drops quickly with distance. My microwave is still 'new' since I do not use it.

whyjbe (/member/whyjbe/) 2015-11-06 Reply

So is this another way of saying that this module transmutes the harmful EMF (electromagnetic frequency) waves coming off the microwave since it converts it to electrical power? If so that's awesome!

tbudka (/member/tbudka/) ▸ whyjbe (/member/whyjbe/) 2015-11-06 Reply

This detector helps give the average person a way to "see" the levels of microwave energy leaking out. The power level drops extremely quickly with distance from your microwave so usually there is no need to worry about it. As you move this detector more than a few inches from most microwave ovens you won't see any light from the LED. This indicates that the power is less than 1mW which is tiny for exposure. For microwave

ovens, the main danger is for your eyeballs where heating could cause cataracts. I don't believe there are any other harmful effects than that from your microwave at powers <10mW. If you have a loose door then I would recommend getting a new microwave. Please don't put your eyes close to the window or door seam or side vent of your microwave.

Wireless device converts ‘lost’ microwave energy into electric power

November 8, 2013

Using inexpensive materials configured and tuned to capture microwave signals, researchers at Duke University’s Pratt School of Engineering have designed a power-harvesting device with efficiency similar to that of modern solar panels.

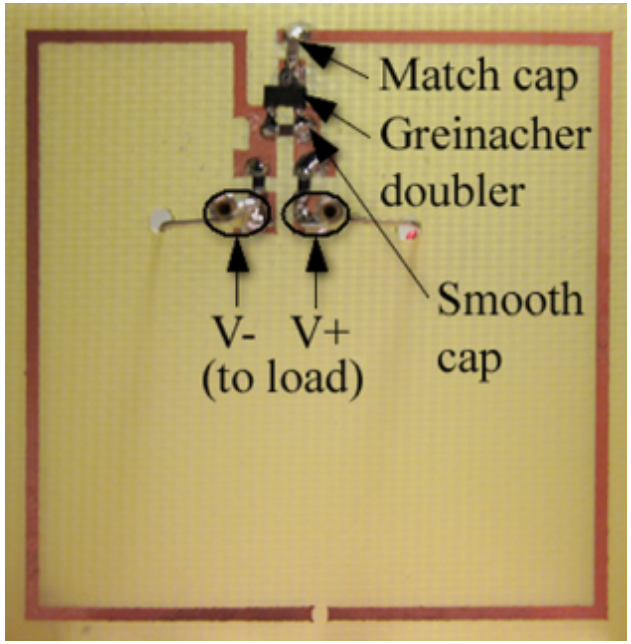
The device wirelessly converts a microwave signal to direct current voltage that is capable of recharging a cell phone battery or other small electronic device.

It operates on a principle similar to that of solar panels, which convert light energy into electrical current. But this versatile energy harvester could be tuned to harvest the signal from other energy sources, including Wi-Fi signals, satellite signals, or even sound signals, the researchers say.

The key to the power harvester lies in its application of metamaterials, engineered structures that can capture various forms of wave energy and tune them for useful applications.

Undergraduate engineering student Allen Hawkes, working with graduate student Alexander Katko and lead investigator Steven Cummer, professor of electrical and computer engineering, designed an electrical circuit capable of harvesting microwaves.

They used a series of five fiberglass and copper energy conductors wired together as an array on a circuit board to convert microwaves with an RF-to-DC conversion efficiency of 37 percent.



Prototype power harvester resonant at 900MHz (a GSM cell-phone frequency) (credit: Allen M. Hawkes at al./*Applied Physics Letters*)

The efficiency of solar cells

That efficiency is comparable to what is achieved in solar cells, according to Hawkes.

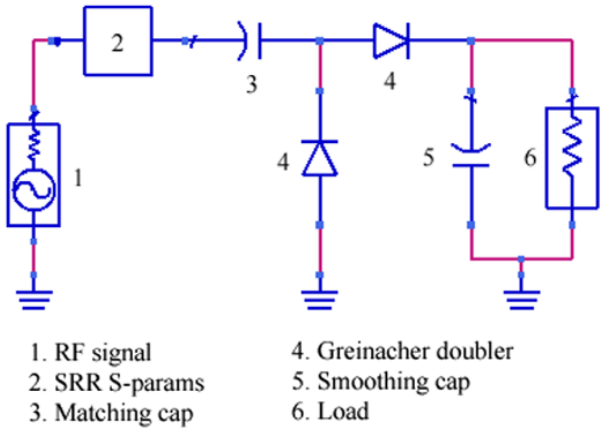
“It’s possible to use this design for a lot of different frequencies and types of energy, including vibration and sound energy harvesting. Until now, a lot of work with metamaterials has been theoretical. We are showing that with a little work, these materials can be useful for consumer applications.”

For instance, a coating could be applied to the ceiling of a room to redirect and recover a Wi-Fi signal that would otherwise be lost, Katko said. Another application could be to improve the energy efficiency of appliances by wirelessly recovering power that is now lost during use.

"The properties of metamaterials allow for design flexibility not possible with ordinary devices like antennas," said Katko. "When traditional antennas are close to each other in space they talk to each other and interfere with each other's operation. The design process used to create our metamaterial array takes these effects into account, allowing the cells to work together."

Wireless recharging for cell phones

With additional modifications, the researchers said the power-harvesting metamaterial could potentially be built into a cell phone, allowing the phone to recharge wirelessly while not in use. This feature could, in principle, allow people living in locations without ready access to a conventional power outlet to harvest energy from a nearby cell phone tower instead.



Schematic of power harvester (credit: Allen M. Hawkes at al./*Applied Physics Letters*)

"Our work demonstrates a simple and inexpensive approach to electromagnetic power harvesting," said Cummer. "The beauty of the design is that the basic building blocks are self-contained and additive. One can simply assemble more blocks to increase the scavenged power."

For example, a series of power-harvesting blocks could be assembled to capture the signal from a known set of satellites passing overhead, the researchers explained. The small amount of energy generated from these signals might power a sensor network in a remote location such as a mountaintop or desert, allowing data collection for a long-term study that takes infrequent measurements.

The research was supported by a Multidisciplinary University Research Initiative from the Army Research Office.

Abstract of *Applied Physics Letters* paper

We present the design and experimental implementation of a power harvesting metamaterial. A maximum of 36.8% of the incident power from a 900 MHz signal is experimentally rectified by an array of metamaterial unit cells. We demonstrate that the maximum harvested power occurs for a resistive load close to 70 Ω in both simulation and experiment. The power harvesting metamaterial is an example of a functional metamaterial that may be suitable for a wide variety of applications that require power delivery to any active components integrated into the metamaterial.

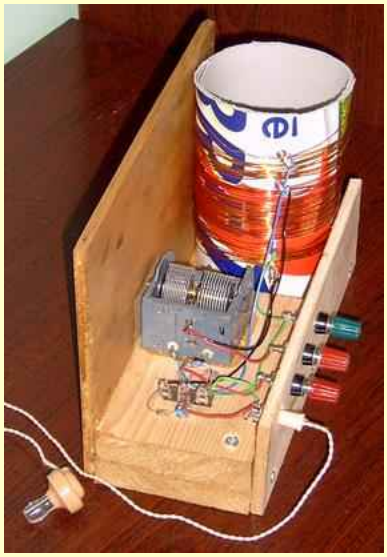
An old fashioned style detector that is housed in a glass tube. The point of the cat's whisker touches the crystal (galena) on the left & is adjusted with the black handle.



CRYSTAL SETS PART 1 - INTRODUCTION

What They Are, Why They Came Into Being and How YOU Can Build Your Own CRYSTAL SET!

What are Crystal Sets? I am glad you asked! It is a fascinating subject dating back to 1920 when Marconi first started experimenting with radio broadcasting from his station 2MT in Chelmsford.

The earliest listeners to Marconi's experimental radio programmes would have mainly used the most basic of radio sets called a Crystal Set. Companies such as the W.G Pye began producing early radio sets in 1921 which used electronic components called 'valves', the forerunner to today's transistors and silicon chips). These glass valves could be arranged to amplify the weak radio signal to make them louder - enough to operate a loudspeaker. However these radios were expensive and needed electricity or bulky lead acid batteries to operate.

THE MAGIC OF A CRYSTAL SET

The crystal set was popular during the 1920's and 30's because it was cheap to buy, much cheaper if you built one yourself, perhaps only a few shillings. Additionally a Crystal Set did not require electricity or expensive batteries, however it could only provide enough volume for headphone listening, and if it was situated in an area of low signal strength the listener would also require a very quiet room as the volume would be low. However In the 1920's hearing voices and music from a station miles away with no wires (hence the term Wireless) really was a magical experience! Listeners in the early twenties were also tinkerers and experimenters, trying different designs of crystal set in an attempt to get the loudest and clearest reception.

Since crystal sets have no batteries and no mains power, they rely entirely from the electrical energy developed between the aerial an earth connections - producing sounds as if by magic.

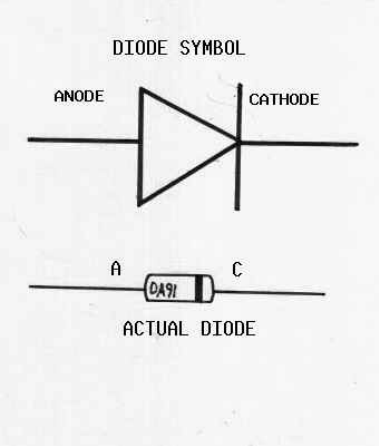
The crystal set had to be carefully tuned into the station by making adjustments to a tuning coil and condenser, these early crystal sets had the added complication of using a 'Cats Whisker' as the detector. The detector converted the radio waves received from the radio station into an audio wave that could be heard in the headphones. The Cats Whisker was a fine wire that rested onto a piece of galena, the crystal, and had to be very finely adjusted to obtain the loudest and clearest sound. Once the 'sweet spot' was found it was important not to move it, it would be very frustrating if someone bumped into the table and dislodged it!

To work at all a crystal set requires a very large aerial, but this is nothing more than a long piece of wire, perhaps 20 to 50 yards of insulated copper wire, hung outside around a garden between poles or trees, or even around the loft space. For the aerial to be effective it needs to be balanced with an earth. An earth is simply a copper rod or pipe about one yard long driven into some soft damp earth with a mallet. At the top of the pipe is fitted a jubilee or hose-clip to which is attached a length of insulated copper wire which is then fed into the house, along with the aerial wire, to the room where the crystal set will be operated and connected to the set's terminals.

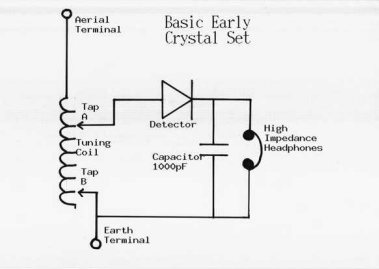
It is quite possible to build your own crystal set. In its very simplest early form a crystal set consisted of a coil of wire, something called a 'detector' and a pair of very special headphones.

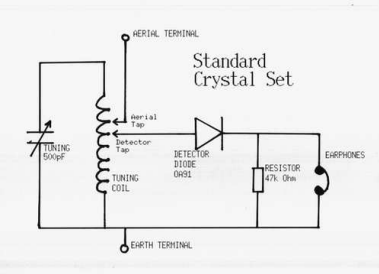
THE CONSTITUENT PARTS

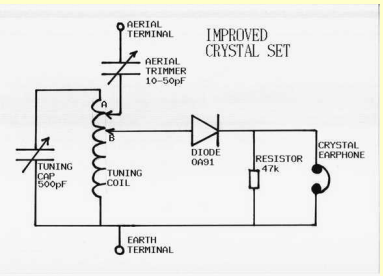
Above: A REAL Crystal Set
You Can Build One Too!
HERE



An illustration of a modern diode which is often encapsulated in glass and is about 7mm long. Above is the electronic symbol for a diode.







The coil of wire is called a Tuning Coil, and the number of turns of wire on the coil determines the wavelength (frequency) that the set is tuned into. Tuning to different stations can be accomplished by varying the number of turms on the coil, or more easily by having many different tapping points on the coil so that adjustments can be made.

To make tuning easier a component called a tuning capacitor can be included in the circuit. In very early sets a tuning capacitor was not always included to keep costs down, or due to their being difficult to obtain.

The Detector converts the radio wave received into an electrical wave that is suitable for the headphones to, in turn, convert into sound waves that can be heard by the human ear. In the very early days of the crystal set the detector consisted of a holder containing a piece of galena crystal that had a very thin and springy wire placed on its surface that had to be very delicately adjusted to find the sweet spot where the radio station could be heard. This was commonly referred to as a "Cat's Whisker". Modern detectors are called diodes and are more efficient than early detectors and cats whiskers. Diodes are still quite readily available and inexpensive. Part numbers for modern diodes include OA90, OA91 and IN34. Diode part numbers that are perhaps now more difficult to obtain include OA47 and OA81.

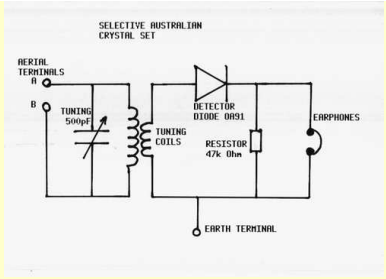
The headphones have to be of a very special type called high impedance headphones. Because there is no additional power source in a crystal set the current generated in the circuit is tiny - minuscule in fact. Ordinary low impedance headphones, such as Walkman headphones, would present a virtual short circuit to the crystal set allowing the tiny signals to drain away to earth & consequently producing no sound - not very useful!

High impedance headphones, on the other hand, reduce or impede the flow of current down to earth, in effect saving the tiny signals to produce sounds from the headphones that we can then hear.

There is a problem however, these high impedance headphones that were so readily available in the 1920's and 1930's are to so easy to obtain today, but some specialist vintage radio outlets still stock them though the price can be quite high. They can still be seen in museums of course. All is not lost though, today we can obtain a special earphone called, appropriately, a crystal earpiece very easily and far more cheaply than. An electronic component, called a resistor, must be connected accross the crystal earphone to allow a path for DC current to get to earth. The value of the resistor is usually 47,000 Ohms and without it a crystal earphone tends to block DC current and as a consequence the sound will be very quiet and distorted.

Aerial and Earth: For a crystal set work it needs an efficient aerial and earth. Since a crystal radio has no power - no batteries or mains electricity - it relies entirely on the radio wave energy sent out from the radio station's transmitter and collected by the aerial to work. The aerial simply consists of a length of wire, but it necessarily has to be quite long, usually in the order of 10 to 20 meters. For the aerial to be effective the crystal radio set also has to be connected to a good earth point. A good earth often consists of a 3 or 4 foot copper stake driven into the ground, but sometimes a water pipe can be used to reasonable effect. (Safety: Never use the earth pin of a household mains plug)

The circuit diagram (schematic) for a crystal set is shown below. Practical designs are shown on the following pages.



No AM radio stations or transmitters in your locality or country?

Has your local medium wave broadcast station closed or been moved to VHF/FM or Digital? Don't worry! You can still build and experiment with crystal sets and TRF radios by also building or buying a simple low power AM transmitter. So, not only can you use your crystal sets but you can also run your own radio station that can be heard in and around your home - playing the music or programmes that you want to hear!

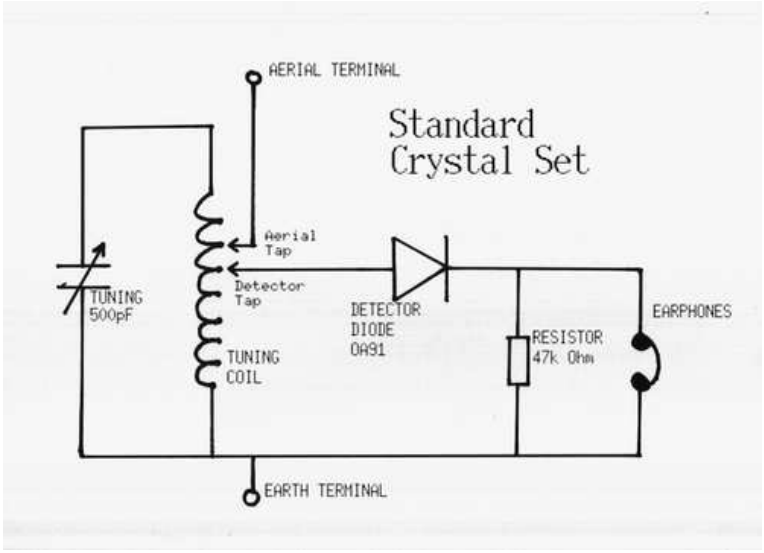
AM88 LP : AM transmitter kit from North County Radio.
http://www.northcountryradio.com /Kitpages/am88.htm



Above: The circuit diagram for the standard Crystal Radio

Above: A commercially made crystal set from around 1940

There is no variable tuning capacitor (condenser) in the above design. The capacitor is a fixed component and tuning is achieved by varying the coil inductance with the rotating switch. The detector is a galena crystal, seen at the top of the panel. A pair of high impedance magnetic headphones can just be seen to the right of this shot. (photo sent in by our reader Krysatec in Czechoslovakia - thanks!)

EXCELLENT RESULTS

Almost certainly when building a crystal set today a crystal earphone will need to be used. A crystal earphone is not quite as good as the old high impedance headphones as it is not quite as sensitive and therefore not quite so loud, however today's transmitters are much more powerful than those of the 1920's and so really excellent results are very often obtained - just don't expect to hear everything that you might on a top quality portable radio!

Crystal sets are fascinating because they are so simple to build, and because there is no power required they remain magical to this day. I have built several over the years, with differing designs, and if you'd like to build one yourself, it's easy, and I have described some circuits in part 2 with some more experimental ideas in part 5.

I have a crystal set that receives BBC Radio 4 on long wave and 3 local stations and 3 national stations on medium wave and another that also receives shortwave

stations. Not bad for radios with no battery or other power - and such as set could be very useful in an emergency.

More About Diodes - unconventional and new ideas (by Felix Scerri)

While messing around with diodes for crystal sets recently, I tried something as a theory that actually works very well in practice, and with one or two actual advantages.

Ordinarily the ubiquitous 1N914 or IN4148 silicon switching diodes are pretty hopeless as RF detectors unless RF signals are *very* strong! However there is a simple way of making these diodes work very well as RF detectors, by the addition of adjustable voltage bias. I have used adjustable voltage bias with diodes before with very good results, but using bias with IN914 or 1N4148's is a relatively new idea!

Interestingly enough with voltage bias correctly adjusted, 'weak signal' performance and sound quality is actually very good, with that typically 'crisp' silicon diode 'sound'. I use a simple bias network with a 1.5 v AA battery and a 1 Megohm potentiometer applied to the diode directly with the incoming RF fed into the diode through a 1 uf plastic film capacitor (as shown). The use of adjustable bias seems to help most with 'repositioning' the position of the knee in the diodes curve and weak signal performance is excellent, easily as good as any 'proper' germanium diode.

Another 'tweak' that is actually quite beneficial is 'paralleling' several diodes together. This doesn't work with ordinary germanium diodes but definitely works with BAT46 'germanium equivalent' diodes and the effect of three of these diodes together is to make a better 'single' diode. The turn on voltage is noticeably reduced and the 'square law; region of detection is definitely improved and so is the rectified audio quality. These diodes are relatively inexpensive (at least in this country), so it is worth trying. 73 Felix vk4fuq 080214.

What Do the Markings on Circuit Breakers Mean?

by Ed Larsen, P. E.

Have you ever been confused about what the markings on circuit breakers mean? Understanding the markings on electrical equipment is a fundamental need to ensure a safe and reliable electrical installation. Circuit breaker marking requirements are established by the requirements found in the *NEC* and the UL 489 product standard. This article will discuss the most common markings and where they can be found.

The UL 489 product standard for Molded Case Circuit Breakers specifies the information to be marked on circuit breakers and where it is to be located, so let's discuss what information needs to be marked on the circuit breaker and the location where you will find those markings. Keep in mind the UL® standard specifies minimum requirements. Circuit breaker manufacturers may provide additional information or provide information in a more convenient location.

Markings Visible without Removing Trims or Covers

UL 489 requires that some markings be visible without removing trims or covers. This location is typically referred to as the handle escutcheon (see photo 1).

Markings Visible with Trims or Covers Removed

UL 489 requires other markings be visible on an installed circuit breaker with trims or covers removed. This location is typically referred to as the face of the circuit breaker (see photos 2–4).

Other markings which should be visible with trims or covers removed are:

Independent trip – Multi-pole circuit breakers are constructed with either a common trip, where all poles are mechanically tripped when one of the poles trips, or an independent trip construction where only the pole that is involved with the overcurrent condition trips. If a 2-pole circuit breaker does not have an internal com-

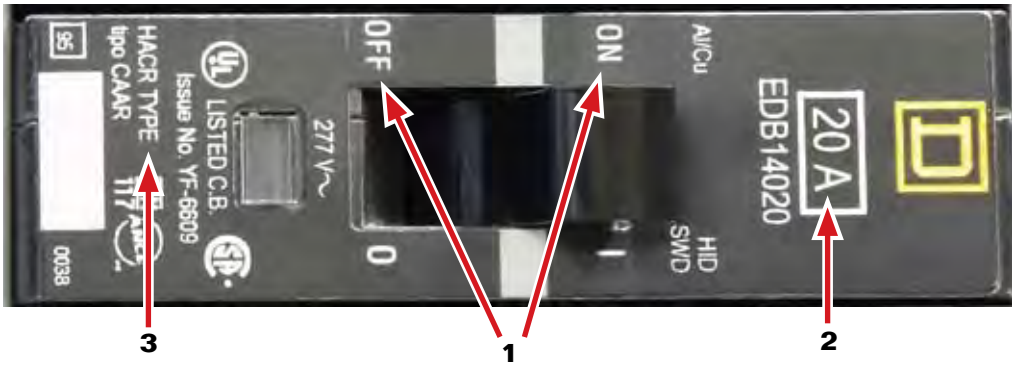

Photo 1. Markings Visible with Trims or Covers in Place

1. ON and OFF – The ON and OFF (closed and open) positions of the handle must be marked (*NEC* 240.81). These positions may also be marked with the internationally recognized "I" and "O" symbols, although this is not a UL requirement. If these markings are not visible when a motor operator is installed over the circuit breaker markings, then they must appear on the motor operator. Motor operators may be found in applications where remote or automatic operation of a circuit breaker is required.

2. Ampere rating (if 100 A or less) – The ampere rating may be located on the handle escutcheon or on the handle itself (*NEC* 240.83(B)). Circuit breakers that are rated more than 100 A may have their ampere rating marked in a position that is not visible with trims or covers in place.

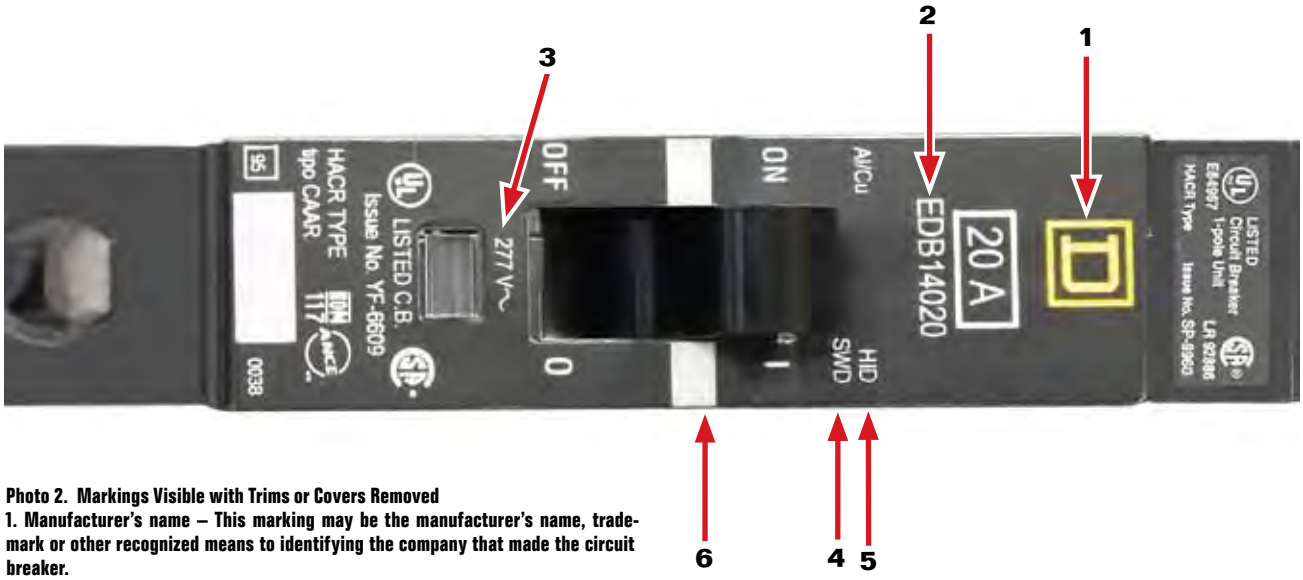

Photo 2. Markings Visible with Trims or Covers Removed

1. Manufacturer's name – This marking may be the manufacturer's name, trademark or other recognized means to identifying the company that made the circuit breaker.

2. Type designation – All circuit breakers are marked with a type designation, which may be a catalog number prefix or a separate designation. Equipment labels, such as on panelboards, will list the circuit breaker types suitable for use. Note that the word "type" may or may not be used on the circuit breaker or equipment labels. It is important to review the markings on the equipment, such as a panelboard, to make sure the circuit breaker designations on the equipment match the marking on the circuit breaker.

3. Voltage rating – All circuit breakers must be marked with a voltage rating. If the rating is not marked "ac" or "dc," then it is suitable for both. 120/240 V rated circuit breakers are suitable for use on single and three-phase 4-wire systems where the line-to-ground voltage does not exceed 120 V. Wye rated circuit breakers such as those rated 480Y/277 V, are suitable for use on three-phase 4-wire systems where the voltage to ground does not exceed 277 V. Special attention needs to be given to high leg or corner-grounded delta systems to insure that the circuit breaker has the appropriate rating. A review to see that the circuit breakers installed have a voltage rating suitable for the application is paramount for a code-compliant installation (*NEC* 240.83(E)).

4. SWD – 15- or 20-A circuit breakers rated 347 V or less may be marked "SWD," meaning that they are suitable for switching fluorescent lighting loads on a regular basis (*NEC* 240.83(D)). These circuit breakers are evaluated for high endurance use, since they will be used similar to a light switch.

5. HID – 50 A or less circuit breakers rated 480 V or less may be marked "HID," meaning they are suitable for switching high intensity discharge or fluorescent lighting loads on a regular basis. These circuit breakers may employ a different construction than a standard SWD circuit breaker in order to address the high inrush current resulting from the lower power factor created by the HID lighting (*NEC* 240.83(D)). These circuit breakers also undergo additional endurance evaluation to demonstrate their ability to perform the switching duty.

6. Trip and reset – Circuit breaker handles typically assume an intermediate position when tripped. This position must either be marked on the circuit breaker or on the equipment into which it is to be installed. If these markings are not visible when a motor operator is installed, then a "tripped" marking may appear on the motor operator.

mon trip feature, then it must be marked "Independent Trip" or "No Common Trip." *NEC* 240.20(B) is the foundational requirement for a common trip function in a circuit breaker; however, it also goes on to explain where independent trip is permitted.

For Replacement Use Only not-CTL – The Class CTL (circuit limiting) panelboard has only been in existence for about 25 years, even though the lighting and appliance branch circuit panelboard has been in the *NEC* for decades. CTL panelboards have a rejection means designed to reject more than the appropriate number of circuit breakers that can be installed in the panel. The marking "For replacement Use Only Not CTL Assemblies" means that the circuit breaker does not have CTL rejection provisions and is intended for replacement in older equipment pre-dating the CTL requirements for circuit breakers and panelboards. Circuit breakers with this designation should not be installed in a panelboard marked "Class CTL Panelboard" since that would be a violation of the listing of the assembly [*NEC* 110.3(B)].

Markings Found in Other Locations

The markings we will discuss below may appear in any location except the back of the circuit breaker. These markings include:

40°C – This marking indicates the maximum ambient temperature in which the circuit breaker can be applied at its marked ampere rating without rerating the ampacity of the circuit breaker. This marking is required for thermal-magnetic circuit breakers and is optional for electronic trip circuit breakers unless they are only suitable for a 25°C ambient, in which case they must be marked 25°C. When the ambient temperature rises above 40°C, the designer may need to consult the manufacturer to obtain rerating information (see item 4 in photo 3).

Class CTL – Circuit breakers marked Class CTL have a rejection means designed into the circuit breaker. Class CTL panelboards or assemblies, in conjunction with Class CTL circuit breakers, prevent more circuit breaker poles from being installed than the number for which the equipment is rated.

Photo 3. Markings Visible with Trims or Covers Removed

1. Line and load designation – Circuit breakers marked with "line" and "load" designations are not suitable for reverse connection. Circuit breakers with interchangeable trip units must be marked "line" and "load" unless there is no risk of shock when changing the trip unit.

2. Interrupting ratings – All circuit breakers with an interrupting rating more than 5000 A must be marked with an interrupting rating (*NEC* 240.83(C)). Interrupting ratings are stated in RMS symmetrical amperes. If the short-circuit current rating of the equipment in which the circuit breaker is installed is less than the interrupting rating of the circuit breaker, then the lesser rating applies. Circuit breakers should be reviewed after installation to ensure they have an interrupting rating suitable for the application. This marking may be found in any location except the back of circuit breakers that are 1-½ inches wide per pole or less due to the size constraint.

3. Ampere rating (if more than 100 A) – The ampere rating of a circuit breaker larger than 100 A may be found in a location that is visible after the cover or trim is removed. This marking requirement also applies to interchangeable trip units (*NEC* 240.83(A)).

5. Terminations (Cu-Al wire) – Circuit breakers must be marked with the type material (Cu-Al) and size of wire for which their terminals are suitable for use. If suitable for use with only copper or only aluminum, then the word "only" must be used. The abbreviations "CU" and "AL" are generally found on circuit breakers as permitted by the product standard. If only solid 10–14 AWG wire can be used, then that information must be noted. The number of wires per terminal will also be noted if more than one wire per terminal is permitted (*NEC* 110.14(A)).

6. Tightening torque – The nominal torque for all field-wiring terminals must be marked. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be found in any location except on the back.

7. Wire temperature ratings – Circuit breakers rated 125 A or less may be marked as suitable for use with 60°C, 60/75°C or 75°C only wire. Circuit breakers rated more than 125 A are rated for use with 75°C wire; the marking is optional. It is always permissible to use wire with a higher temperature rating, but it must be sized in accordance with the temperature marking on the circuit breaker and *NEC* Table 310.16. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be in any location except on the back (*NEC* 110.14(C)1).

8. HACR type – This marking indicates the circuit breaker is suitable for use with the group motor installations typically found in heating, air conditioning and refrigeration equipment. The *NEC* 2005 no longer has this marking requirement. The electrical industry determined that circuit breakers are considered suitable for use with such equipment without any further testing, therefore, the HACR marking is no longer required on air conditioning and refrigeration equipment or on circuit breakers for use in these applications. The requirement for this marking has also been removed from the UL 1995 product standard for HVAC equipment (see item 3 in photo 1).

Maximum wire size – Circuit breakers are typically marked with a wire range, however that marking is not mandatory. If the circuit breaker cannot accept the next larger wire size required for the ampere rating, then the maximum wire size must be marked in any location except the back (see item 5 in photo 3).

Separately shipped connectors –If connectors are not factory installed on a circuit breaker, then it must be marked with the proper connectors or terminal kits required in any location except the back (see item 8 in photo 3).

Ground-Fault Protection for People

The GFCI function, as part of a circuit breaker, provides ground-fault protection for people and has a number of unique marking and instruction requirements.

Test function – The GFCI has a test function that requires action upon installation and on a monthly basis. GFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate monthly testing.

Photo 4. 1Ø – 3Ø Marking
1. 1Ø – 3Ø marking – A 2-pole circuit breaker used to protect a 3-phase load on a corner-grounded delta system must be rated and marked for such an installation. Circuit breakers marked "1-phase – 3-phase" or "1Ø – 3Ø "are suitable for use on 3-phase corner-grounded delta or single-phase circuits (*NEC* 240.85).

Suitable for continuous operation at 100% of ampere rating only if used in a recognized enclosure 52 in. (1321 mm) by 20 in. (508 mm) x 7 1/2 in. (190 mm) deep or larger. Use only with 90° rated wire sized per the ampacity of 75° rated wire.

Figure 1. 100% Rated Marking
100 percent continuous rated – Circuit breakers are typically intended for use at not more than 80% of rated current where the load is considered continuous, or will continue for 3 hours or more (*NEC* 210.20). However, some circuit breakers are rated for continuous use at 100% of their current rating. These circuit breakers must be so marked in any location except on the back. Enclosure information such as a specific type or specific volume must also be marked. A requirement for the use of 90°C insulated wire sized to the 75°C column in *NEC* Table 310.16 and specific ventilation requirements may also be marked on the circuit breaker or equipment (*NEC* 210.20(A) and 215.3).

"Class A" marking – A "Class A" ground-fault device is intended to protect people. The Class A marking indicates that the trip threshold of the GFCI is between 4 mA and 6 mA. This marking may be in any location except the back.

Instructions – All GFCI circuit breakers must include instructions for the installer plus instructions on the use of the test function. A hangtag or self-adhesive label must also be provided, instructing the user to test the GFCI at least monthly. Inspectors should check to see that the tag or label has been properly installed.

Ground-Fault Protection for Equipment

Circuit breakers may also include a ground-fault protection for equipment (GFPE) function that, like GFCIs, has a number of unique marking and instruction requirements.

Test function – GFPE circuit breakers may have a test button or switch that may be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Trip level – GFPE circuit breakers must be marked with their trip threshold in milliamperes in a location accessible without removing trims or covers.

Instructions – All GFPE circuit breakers must include instructions for the installer.

Arc-Fault Protection

Circuit breakers may also include arc-fault protection (AFCI) that, like GFCIs, also has a number of unique marking and instruction requirements.

Device identification – AFCIs must also be identified appropriately. Branch/feeder or Combination type AFCIs must be so marked in a location visible when the trims or covers are removed. This is an important marking to note as we move into 2008, as *NEC*-2005 requires Combination AFCIs in bedrooms effective January 1, 2008 (*NEC* 210.12).

Test function – AFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Instructions – All AFCI circuit breakers must include instructions for the installer.

Circuit Breaker Markings Ensure a Safe Electrical Installation

So why are all of these markings on circuit breakers? Without them, it would be nearly impossible to install or inspect an installation for the appropriate performance ratings and fundamental electrical connections. When designing or completing an installation, key items to review are:

1. Are the voltage, continuous current, and interrupting ratings appropriate for the application?
2. Does the application require SWD or HID ratings?
3. Is the wire type and size appropriate for the circuit breaker?
4. Is the circuit breaker suitable for the equipment in which it is installed? Have other protective functions such as GFCI or AFCI been provided as required by the *NEC*?
5. Is the temperature rating of the circuit breaker suitable for the application?

The UL Marking Guide for Molded Case Circuit Breakers is a valuable resource to understand circuit breaker markings that may further explain these and other markings in detail. If you have questions about CB markings not answered here, consult the Marking Guide or the manufacturer to assist in an *NEC*-compliant installation.

Mr. Larsen, P. E., is the manager, Industry Standards for Circuit Protection for Square D Company / Schneider Electric. Mr. Larsen has served in various positions over the past 32 years. He is a member of several UL, IEEE and NEMA technical committees. His other memberships include NFPA, IAEI and CANENA.

What Do the Markings on Circuit Breakers Mean?

by Ed Larsen, P. E.

Have you ever been confused about what the markings on circuit breakers mean? Understanding the markings on electrical equipment is a fundamental need to ensure a safe and reliable electrical installation. Circuit breaker marking requirements are established by the requirements found in the *NEC* and the UL 489 product standard. This article will discuss the most common markings and where they can be found.

The UL 489 product standard for Molded Case Circuit Breakers specifies the information to be marked on circuit breakers and where it is to be located, so let's discuss what information needs to be marked on the circuit breaker and the location where you will find those markings. Keep in mind the UL® standard specifies minimum requirements. Circuit breaker manufacturers may provide additional information or provide information in a more convenient location.

Markings Visible without Removing Trims or Covers

UL 489 requires that some markings be visible without removing trims or covers. This location is typically referred to as the handle escutcheon (see photo 1).

Markings Visible with Trims or Covers Removed

UL 489 requires other markings be visible on an installed circuit breaker with trims or covers removed. This location is typically referred to as the face of the circuit breaker (see photos 2–4).

Other markings which should be visible with trims or covers removed are:

Independent trip – Multi-pole circuit breakers are constructed with either a common trip, where all poles are mechanically tripped when one of the poles trips, or an independent trip construction where only the pole that is involved with the overcurrent condition trips. If a 2-pole circuit breaker does not have an internal com-

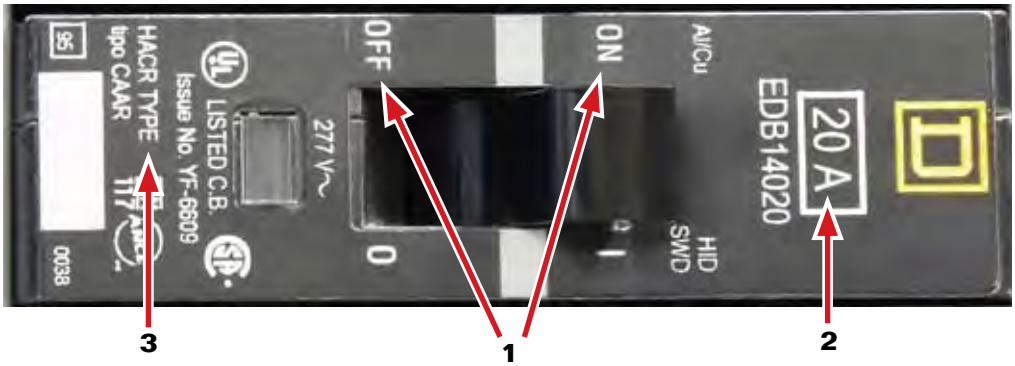

Photo 1. Markings Visible with Trims or Covers in Place

1. ON and OFF – The ON and OFF (closed and open) positions of the handle must be marked (*NEC* 240.81). These positions may also be marked with the internationally recognized "I" and "O" symbols, although this is not a UL requirement. If these markings are not visible when a motor operator is installed over the circuit breaker markings, then they must appear on the motor operator. Motor operators may be found in applications where remote or automatic operation of a circuit breaker is required.

2. Ampere rating (if 100 A or less) – The ampere rating may be located on the handle escutcheon or on the handle itself (*NEC* 240.83(B)). Circuit breakers that are rated more than 100 A may have their ampere rating marked in a position that is not visible with trims or covers in place.

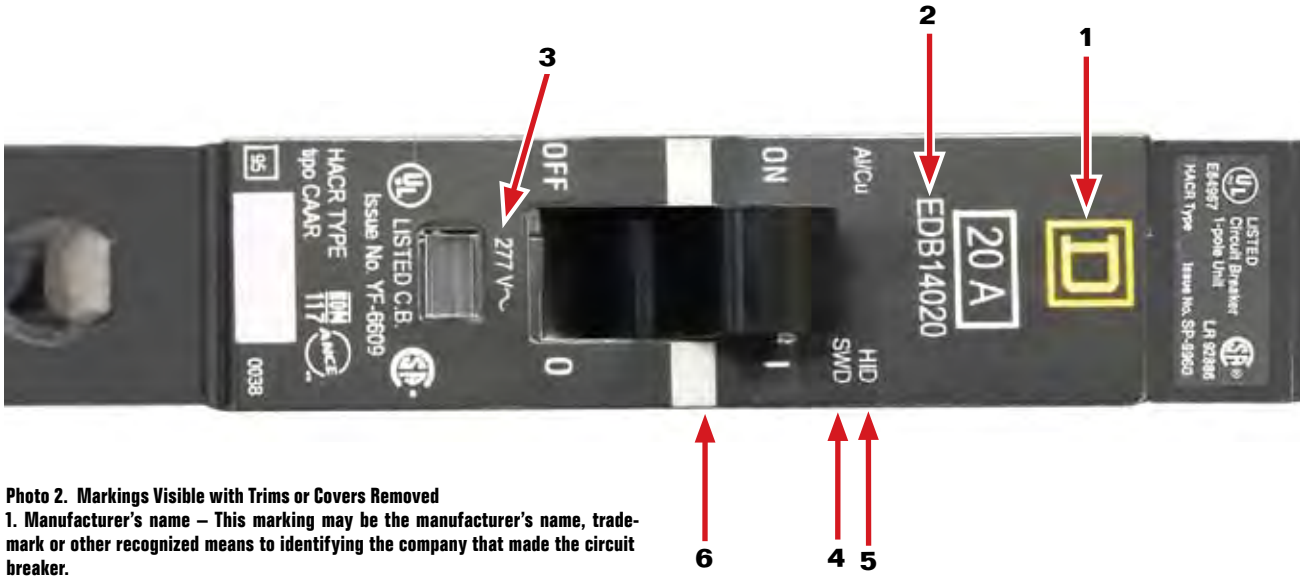

Photo 2. Markings Visible with Trims or Covers Removed

1. Manufacturer's name – This marking may be the manufacturer's name, trademark or other recognized means to identifying the company that made the circuit breaker.

2. Type designation – All circuit breakers are marked with a type designation, which may be a catalog number prefix or a separate designation. Equipment labels, such as on panelboards, will list the circuit breaker types suitable for use. Note that the word "type" may or may not be used on the circuit breaker or equipment labels. It is important to review the markings on the equipment, such as a panelboard, to make sure the circuit breaker designations on the equipment match the marking on the circuit breaker.

3. Voltage rating – All circuit breakers must be marked with a voltage rating. If the rating is not marked "ac" or "dc," then it is suitable for both. 120/240 V rated circuit breakers are suitable for use on single and three-phase 4-wire systems where the line-to-ground voltage does not exceed 120 V. Wye rated circuit breakers such as those rated 480Y/277 V, are suitable for use on three-phase 4-wire systems where the voltage to ground does not exceed 277 V. Special attention needs to be given to high leg or corner-grounded delta systems to insure that the circuit breaker has the appropriate rating. A review to see that the circuit breakers installed have a voltage rating suitable for the application is paramount for a code-compliant installation (*NEC* 240.83(E)).

4. SWD – 15- or 20-A circuit breakers rated 347 V or less may be marked "SWD," meaning that they are suitable for switching fluorescent lighting loads on a regular basis (*NEC* 240.83(D)). These circuit breakers are evaluated for high endurance use, since they will be used similar to a light switch.

5. HID – 50 A or less circuit breakers rated 480 V or less may be marked "HID," meaning they are suitable for switching high intensity discharge or fluorescent lighting loads on a regular basis. These circuit breakers may employ a different construction than a standard SWD circuit breaker in order to address the high inrush current resulting from the lower power factor created by the HID lighting (*NEC* 240.83(D)). These circuit breakers also undergo additional endurance evaluation to demonstrate their ability to perform the switching duty.

6. Trip and reset – Circuit breaker handles typically assume an intermediate position when tripped. This position must either be marked on the circuit breaker or on the equipment into which it is to be installed. If these markings are not visible when a motor operator is installed, then a "tripped" marking may appear on the motor operator.

mon trip feature, then it must be marked "Independent Trip" or "No Common Trip." *NEC* 240.20(B) is the foundational requirement for a common trip function in a circuit breaker; however, it also goes on to explain where independent trip is permitted.

For Replacement Use Only not-CTL – The Class CTL (circuit limiting) panelboard has only been in existence for about 25 years, even though the lighting and appliance branch circuit panelboard has been in the *NEC* for decades. CTL panelboards have a rejection means designed to reject more than the appropriate number of circuit breakers that can be installed in the panel. The marking "For replacement Use Only Not CTL Assemblies" means that the circuit breaker does not have CTL rejection provisions and is intended for replacement in older equipment pre-dating the CTL requirements for circuit breakers and panelboards. Circuit breakers with this designation should not be installed in a panelboard marked "Class CTL Panelboard" since that would be a violation of the listing of the assembly [*NEC* 110.3(B)].

Markings Found in Other Locations

The markings we will discuss below may appear in any location except the back of the circuit breaker. These markings include:

40°C – This marking indicates the maximum ambient temperature in which the circuit breaker can be applied at its marked ampere rating without rerating the ampacity of the circuit breaker. This marking is required for thermal-magnetic circuit breakers and is optional for electronic trip circuit breakers unless they are only suitable for a 25°C ambient, in which case they must be marked 25°C. When the ambient temperature rises above 40°C, the designer may need to consult the manufacturer to obtain rerating information (see item 4 in photo 3).

Class CTL – Circuit breakers marked Class CTL have a rejection means designed into the circuit breaker. Class CTL panelboards or assemblies, in conjunction with Class CTL circuit breakers, prevent more circuit breaker poles from being installed than the number for which the equipment is rated.

Photo 3. Markings Visible with Trims or Covers Removed

1. Line and load designation – Circuit breakers marked with "line" and "load" designations are not suitable for reverse connection. Circuit breakers with interchangeable trip units must be marked "line" and "load" unless there is no risk of shock when changing the trip unit.

2. Interrupting ratings – All circuit breakers with an interrupting rating more than 5000 A must be marked with an interrupting rating (*NEC* 240.83(C)). Interrupting ratings are stated in RMS symmetrical amperes. If the short-circuit current rating of the equipment in which the circuit breaker is installed is less than the interrupting rating of the circuit breaker, then the lesser rating applies. Circuit breakers should be reviewed after installation to ensure they have an interrupting rating suitable for the application. This marking may be found in any location except the back of circuit breakers that are 1-½ inches wide per pole or less due to the size constraint.

3. Ampere rating (if more than 100 A) – The ampere rating of a circuit breaker larger than 100 A may be found in a location that is visible after the cover or trim is removed. This marking requirement also applies to interchangeable trip units (*NEC* 240.83(A)).

5. Terminations (Cu-Al wire) – Circuit breakers must be marked with the type material (Cu-Al) and size of wire for which their terminals are suitable for use. If suitable for use with only copper or only aluminum, then the word "only" must be used. The abbreviations "CU" and "AL" are generally found on circuit breakers as permitted by the product standard. If only solid 10–14 AWG wire can be used, then that information must be noted. The number of wires per terminal will also be noted if more than one wire per terminal is permitted (*NEC* 110.14(A)).

6. Tightening torque – The nominal torque for all field-wiring terminals must be marked. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be found in any location except on the back.

7. Wire temperature ratings – Circuit breakers rated 125 A or less may be marked as suitable for use with 60°C, 60/75°C or 75°C only wire. Circuit breakers rated more than 125 A are rated for use with 75°C wire; the marking is optional. It is always permissible to use wire with a higher temperature rating, but it must be sized in accordance with the temperature marking on the circuit breaker and *NEC* Table 310.16. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be in any location except on the back (*NEC* 110.14(C)1).

8. HACR type – This marking indicates the circuit breaker is suitable for use with the group motor installations typically found in heating, air conditioning and refrigeration equipment. The *NEC* 2005 no longer has this marking requirement. The electrical industry determined that circuit breakers are considered suitable for use with such equipment without any further testing, therefore, the HACR marking is no longer required on air conditioning and refrigeration equipment or on circuit breakers for use in these applications. The requirement for this marking has also been removed from the UL 1995 product standard for HVAC equipment (see item 3 in photo 1).

Maximum wire size – Circuit breakers are typically marked with a wire range, however that marking is not mandatory. If the circuit breaker cannot accept the next larger wire size required for the ampere rating, then the maximum wire size must be marked in any location except the back (see item 5 in photo 3).

Separately shipped connectors –If connectors are not factory installed on a circuit breaker, then it must be marked with the proper connectors or terminal kits required in any location except the back (see item 8 in photo 3).

Ground-Fault Protection for People

The GFCI function, as part of a circuit breaker, provides ground-fault protection for people and has a number of unique marking and instruction requirements.

Test function – The GFCI has a test function that requires action upon installation and on a monthly basis. GFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate monthly testing.

Photo 4. 1Ø – 3Ø Marking
1. 1Ø – 3Ø marking – A 2-pole circuit breaker used to protect a 3-phase load on a corner-grounded delta system must be rated and marked for such an installation. Circuit breakers marked "1-phase – 3-phase" or "1Ø – 3Ø "are suitable for use on 3-phase corner-grounded delta or single-phase circuits (*NEC* 240.85).

Suitable for continuous operation at 100% of ampere rating only if used in a recognized enclosure 52 in. (1321 mm) by 20 in. (508 mm) x 7 1/2 in. (190 mm) deep or larger. Use only with 90° rated wire sized per the ampacity of 75° rated wire.

Figure 1. 100% Rated Marking
100 percent continuous rated – Circuit breakers are typically intended for use at not more than 80% of rated current where the load is considered continuous, or will continue for 3 hours or more (*NEC* 210.20). However, some circuit breakers are rated for continuous use at 100% of their current rating. These circuit breakers must be so marked in any location except on the back. Enclosure information such as a specific type or specific volume must also be marked. A requirement for the use of 90°C insulated wire sized to the 75°C column in *NEC* Table 310.16 and specific ventilation requirements may also be marked on the circuit breaker or equipment (*NEC* 210.20(A) and 215.3).

"Class A" marking – A "Class A" ground-fault device is intended to protect people. The Class A marking indicates that the trip threshold of the GFCI is between 4 mA and 6 mA. This marking may be in any location except the back.

Instructions – All GFCI circuit breakers must include instructions for the installer plus instructions on the use of the test function. A hangtag or self-adhesive label must also be provided, instructing the user to test the GFCI at least monthly. Inspectors should check to see that the tag or label has been properly installed.

Ground-Fault Protection for Equipment

Circuit breakers may also include a ground-fault protection for equipment (GFPE) function that, like GFCIs, has a number of unique marking and instruction requirements.

Test function – GFPE circuit breakers may have a test button or switch that may be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Trip level – GFPE circuit breakers must be marked with their trip threshold in milliamperes in a location accessible without removing trims or covers.

Instructions – All GFPE circuit breakers must include instructions for the installer.

Arc-Fault Protection

Circuit breakers may also include arc-fault protection (AFCI) that, like GFCIs, also has a number of unique marking and instruction requirements.

Device identification – AFCIs must also be identified appropriately. Branch/feeder or Combination type AFCIs must be so marked in a location visible when the trims or covers are removed. This is an important marking to note as we move into 2008, as *NEC*-2005 requires Combination AFCIs in bedrooms effective January 1, 2008 (*NEC* 210.12).

Test function – AFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Instructions – All AFCI circuit breakers must include instructions for the installer.

Circuit Breaker Markings Ensure a Safe Electrical Installation

So why are all of these markings on circuit breakers? Without them, it would be nearly impossible to install or inspect an installation for the appropriate performance ratings and fundamental electrical connections. When designing or completing an installation, key items to review are:

1. Are the voltage, continuous current, and interrupting ratings appropriate for the application?
2. Does the application require SWD or HID ratings?
3. Is the wire type and size appropriate for the circuit breaker?
4. Is the circuit breaker suitable for the equipment in which it is installed? Have other protective functions such as GFCI or AFCI been provided as required by the *NEC*?
5. Is the temperature rating of the circuit breaker suitable for the application?

The UL Marking Guide for Molded Case Circuit Breakers is a valuable resource to understand circuit breaker markings that may further explain these and other markings in detail. If you have questions about CB markings not answered here, consult the Marking Guide or the manufacturer to assist in an *NEC*-compliant installation.

Mr. Larsen, P. E., is the manager, Industry Standards for Circuit Protection for Square D Company / Schneider Electric. Mr. Larsen has served in various positions over the past 32 years. What Do the Markings on Circuit Breakers Mean?

by Ed Larsen, P. E.

Have you ever been confused about what the markings on circuit breakers mean? Understanding the markings on electrical equipment is a fundamental need to ensure a safe and reliable electrical installation. Circuit breaker marking requirements are established by the requirements found in the *NEC* and the UL 489 product standard. This article will discuss the most common markings and where they can be found.

The UL 489 product standard for Molded Case Circuit Breakers specifies the information to be marked on circuit breakers and where it is to be located, so let's discuss what information needs to be marked on the circuit breaker and the location where you will find those markings. Keep in mind the UL® standard specifies minimum requirements. Circuit breaker manufacturers may provide additional information or provide information in a more convenient location.

Markings Visible without Removing Trims or Covers

UL 489 requires that some markings be visible without removing trims or covers. This location is typically referred to as the handle escutcheon (see photo 1).

Markings Visible with Trims or Covers Removed

UL 489 requires other markings be visible on an installed circuit breaker with trims or covers removed. This location is typically referred to as the face of the circuit breaker (see photos 2–4).

Other markings which should be visible with trims or covers removed are:

Independent trip – Multi-pole circuit breakers are constructed with either a common trip, where all poles are mechanically tripped when one of the poles trips, or an independent trip construction where only the pole that is involved with the overcurrent condition trips. If a 2-pole circuit breaker does not have an internal com-

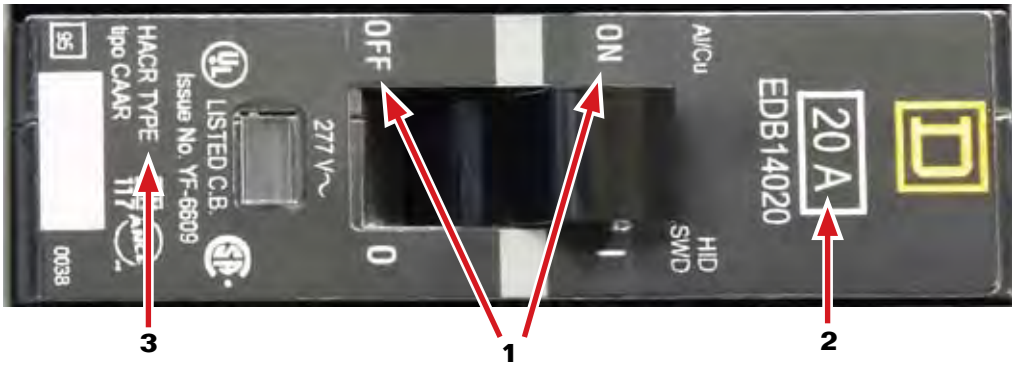

Photo 1. Markings Visible with Trims or Covers in Place

1. ON and OFF – The ON and OFF (closed and open) positions of the handle must be marked (*NEC* 240.81). These positions may also be marked with the internationally recognized "I" and "O" symbols, although this is not a UL requirement. If these markings are not visible when a motor operator is installed over the circuit breaker markings, then they must appear on the motor operator. Motor operators may be found in applications where remote or automatic operation of a circuit breaker is required.

2. Ampere rating (if 100 A or less) – The ampere rating may be located on the handle escutcheon or on the handle itself (*NEC* 240.83(B)). Circuit breakers that are rated more than 100 A may have their ampere rating marked in a position that is not visible with trims or covers in place.

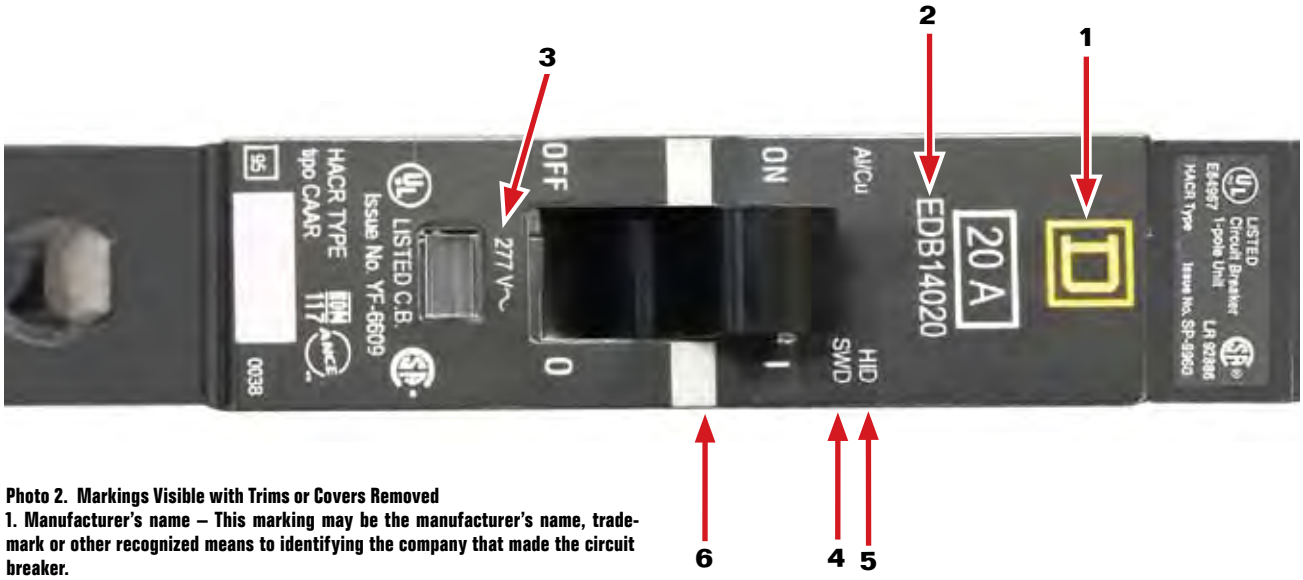

Photo 2. Markings Visible with Trims or Covers Removed

1. Manufacturer's name – This marking may be the manufacturer's name, trademark or other recognized means to identifying the company that made the circuit breaker.

2. Type designation – All circuit breakers are marked with a type designation, which may be a catalog number prefix or a separate designation. Equipment labels, such as on panelboards, will list the circuit breaker types suitable for use. Note that the word "type" may or may not be used on the circuit breaker or equipment labels. It is important to review the markings on the equipment, such as a panelboard, to make sure the circuit breaker designations on the equipment match the marking on the circuit breaker.

3. Voltage rating – All circuit breakers must be marked with a voltage rating. If the rating is not marked "ac" or "dc," then it is suitable for both. 120/240 V rated circuit breakers are suitable for use on single and three-phase 4-wire systems where the line-to-ground voltage does not exceed 120 V. Wye rated circuit breakers such as those rated 480Y/277 V, are suitable for use on three-phase 4-wire systems where the voltage to ground does not exceed 277 V. Special attention needs to be given to high leg or corner-grounded delta systems to insure that the circuit breaker has the appropriate rating. A review to see that the circuit breakers installed have a voltage rating suitable for the application is paramount for a code-compliant installation (*NEC* 240.83(E)).

4. SWD – 15- or 20-A circuit breakers rated 347 V or less may be marked "SWD," meaning that they are suitable for switching fluorescent lighting loads on a regular basis (*NEC* 240.83(D)). These circuit breakers are evaluated for high endurance use, since they will be used similar to a light switch.

5. HID – 50 A or less circuit breakers rated 480 V or less may be marked "HID," meaning they are suitable for switching high intensity discharge or fluorescent lighting loads on a regular basis. These circuit breakers may employ a different construction than a standard SWD circuit breaker in order to address the high inrush current resulting from the lower power factor created by the HID lighting (*NEC* 240.83(D)). These circuit breakers also undergo additional endurance evaluation to demonstrate their ability to perform the switching duty.

6. Trip and reset – Circuit breaker handles typically assume an intermediate position when tripped. This position must either be marked on the circuit breaker or on the equipment into which it is to be installed. If these markings are not visible when a motor operator is installed, then a "tripped" marking may appear on the motor operator.

mon trip feature, then it must be marked "Independent Trip" or "No Common Trip." *NEC* 240.20(B) is the foundational requirement for a common trip function in a circuit breaker; however, it also goes on to explain where independent trip is permitted.

For Replacement Use Only not-CTL – The Class CTL (circuit limiting) panelboard has only been in existence for about 25 years, even though the lighting and appliance branch circuit panelboard has been in the *NEC* for decades. CTL panelboards have a rejection means designed to reject more than the appropriate number of circuit breakers that can be installed in the panel. The marking "For replacement Use Only Not CTL Assemblies" means that the circuit breaker does not have CTL rejection provisions and is intended for replacement in older equipment pre-dating the CTL requirements for circuit breakers and panelboards. Circuit breakers with this designation should not be installed in a panelboard marked "Class CTL Panelboard" since that would be a violation of the listing of the assembly [*NEC* 110.3(B)].

Markings Found in Other Locations

The markings we will discuss below may appear in any location except the back of the circuit breaker. These markings include:

40°C – This marking indicates the maximum ambient temperature in which the circuit breaker can be applied at its marked ampere rating without rerating the ampacity of the circuit breaker. This marking is required for thermal-magnetic circuit breakers and is optional for electronic trip circuit breakers unless they are only suitable for a 25°C ambient, in which case they must be marked 25°C. When the ambient temperature rises above 40°C, the designer may need to consult the manufacturer to obtain rerating information (see item 4 in photo 3).

Class CTL – Circuit breakers marked Class CTL have a rejection means designed into the circuit breaker. Class CTL panelboards or assemblies, in conjunction with Class CTL circuit breakers, prevent more circuit breaker poles from being installed than the number for which the equipment is rated.

Photo 3. Markings Visible with Trims or Covers Removed

1. Line and load designation – Circuit breakers marked with "line" and "load" designations are not suitable for reverse connection. Circuit breakers with interchangeable trip units must be marked "line" and "load" unless there is no risk of shock when changing the trip unit.

2. Interrupting ratings – All circuit breakers with an interrupting rating more than 5000 A must be marked with an interrupting rating (*NEC* 240.83(C)). Interrupting ratings are stated in RMS symmetrical amperes. If the short-circuit current rating of the equipment in which the circuit breaker is installed is less than the interrupting rating of the circuit breaker, then the lesser rating applies. Circuit breakers should be reviewed after installation to ensure they have an interrupting rating suitable for the application. This marking may be found in any location except the back of circuit breakers that are 1-½ inches wide per pole or less due to the size constraint.

3. Ampere rating (if more than 100 A) – The ampere rating of a circuit breaker larger than 100 A may be found in a location that is visible after the cover or trim is removed. This marking requirement also applies to interchangeable trip units (*NEC* 240.83(A)).

5. Terminations (Cu-Al wire) – Circuit breakers must be marked with the type material (Cu-Al) and size of wire for which their terminals are suitable for use. If suitable for use with only copper or only aluminum, then the word "only" must be used. The abbreviations "CU" and "AL" are generally found on circuit breakers as permitted by the product standard. If only solid 10–14 AWG wire can be used, then that information must be noted. The number of wires per terminal will also be noted if more than one wire per terminal is permitted (*NEC* 110.14(A)).

6. Tightening torque – The nominal torque for all field-wiring terminals must be marked. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be found in any location except on the back.

7. Wire temperature ratings – Circuit breakers rated 125 A or less may be marked as suitable for use with 60°C, 60/75°C or 75°C only wire. Circuit breakers rated more than 125 A are rated for use with 75°C wire; the marking is optional. It is always permissible to use wire with a higher temperature rating, but it must be sized in accordance with the temperature marking on the circuit breaker and *NEC* Table 310.16. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be in any location except on the back (*NEC* 110.14(C)1).

8. HACR type – This marking indicates the circuit breaker is suitable for use with the group motor installations typically found in heating, air conditioning and refrigeration equipment. The *NEC* 2005 no longer has this marking requirement. The electrical industry determined that circuit breakers are considered suitable for use with such equipment without any further testing, therefore, the HACR marking is no longer required on air conditioning and refrigeration equipment or on circuit breakers for use in these applications. The requirement for this marking has also been removed from the UL 1995 product standard for HVAC equipment (see item 3 in photo 1).

Maximum wire size – Circuit breakers are typically marked with a wire range, however that marking is not mandatory. If the circuit breaker cannot accept the next larger wire size required for the ampere rating, then the maximum wire size must be marked in any location except the back (see item 5 in photo 3).

Separately shipped connectors –If connectors are not factory installed on a circuit breaker, then it must be marked with the proper connectors or terminal kits required in any location except the back (see item 8 in photo 3).

Ground-Fault Protection for People

The GFCI function, as part of a circuit breaker, provides ground-fault protection for people and has a number of unique marking and instruction requirements.

Test function – The GFCI has a test function that requires action upon installation and on a monthly basis. GFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate monthly testing.

Photo 4. 1Ø – 3Ø Marking
1. 1Ø – 3Ø marking – A 2-pole circuit breaker used to protect a 3-phase load on a corner-grounded delta system must be rated and marked for such an installation. Circuit breakers marked "1-phase – 3-phase" or "1Ø – 3Ø "are suitable for use on 3-phase corner-grounded delta or single-phase circuits (*NEC* 240.85).

Suitable for continuous operation at 100% of ampere rating only if used in a recognized enclosure 52 in. (1321 mm) by 20 in. (508 mm) x 7 1/2 in. (190 mm) deep or larger. Use only with 90° rated wire sized per the ampacity of 75° rated wire.

Figure 1. 100% Rated Marking
100 percent continuous rated – Circuit breakers are typically intended for use at not more than 80% of rated current where the load is considered continuous, or will continue for 3 hours or more (*NEC* 210.20). However, some circuit breakers are rated for continuous use at 100% of their current rating. These circuit breakers must be so marked in any location except on the back. Enclosure information such as a specific type or specific volume must also be marked. A requirement for the use of 90°C insulated wire sized to the 75°C column in *NEC* Table 310.16 and specific ventilation requirements may also be marked on the circuit breaker or equipment (*NEC* 210.20(A) and 215.3).

"Class A" marking – A "Class A" ground-fault device is intended to protect people. The Class A marking indicates that the trip threshold of the GFCI is between 4 mA and 6 mA. This marking may be in any location except the back.

Instructions – All GFCI circuit breakers must include instructions for the installer plus instructions on the use of the test function. A hangtag or self-adhesive label must also be provided, instructing the user to test the GFCI at least monthly. Inspectors should check to see that the tag or label has been properly installed.

Ground-Fault Protection for Equipment

Circuit breakers may also include a ground-fault protection for equipment (GFPE) function that, like GFCIs, has a number of unique marking and instruction requirements.

Test function – GFPE circuit breakers may have a test button or switch that may be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Trip level – GFPE circuit breakers must be marked with their trip threshold in milliamperes in a location accessible without removing trims or covers.

Instructions – All GFPE circuit breakers must include instructions for the installer.

Arc-Fault Protection

Circuit breakers may also include arc-fault protection (AFCI) that, like GFCIs, also has a number of unique marking and instruction requirements.

Device identification – AFCIs must also be identified appropriately. Branch/feeder or Combination type AFCIs must be so marked in a location visible when the trims or covers are removed. This is an important marking to note as we move into 2008, as *NEC*-2005 requires Combination AFCIs in bedrooms effective January 1, 2008 (*NEC* 210.12).

Test function – AFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Instructions – All AFCI circuit breakers must include instructions for the installer.

Circuit Breaker Markings Ensure a Safe Electrical Installation

So why are all of these markings on circuit breakers? Without them, it would be nearly impossible to install or inspect an installation for the appropriate performance ratings and fundamental electrical connections. When designing or completing an installation, key items to review are:

1. Are the voltage, continuous current, and interrupting ratings appropriate for the application?
2. Does the application require SWD or HID ratings?
3. Is the wire type and size appropriate for the circuit breaker?
4. Is the circuit breaker suitable for the equipment in which it is installed? Have other protective functions such as GFCI or AFCI been provided as required by the *NEC*?
5. Is the temperature rating of the circuit breaker suitable for the application?

The UL Marking Guide for Molded Case Circuit Breakers is a valuable resource to understand circuit breaker markings that may further explain these and other markings in detail. If you have questions about CB markings not answered here, consult the Marking Guide or the manufacturer to assist in an *NEC*-compliant installation.

Mr. Larsen, P. E., is the manager, Industry Standards for Circuit Protection for Square D Company / Schneider Electric. Mr. Larsen has served in various positions over the past 32 years. He is a member of several UL, IEEE and NEMA technical committees. His other memberships include NFPA, IAEI and CANENA.

What Do the Markings on Circuit Breakers Mean?

by Ed Larsen, P. E.

Have you ever been confused about what the markings on circuit breakers mean? Understanding the markings on electrical equipment is a fundamental need to ensure a safe and reliable electrical installation. Circuit breaker marking requirements are established by the requirements found in the *NEC* and the UL 489 product standard. This article will discuss the most common markings and where they can be found.

The UL 489 product standard for Molded Case Circuit Breakers specifies the information to be marked on circuit breakers and where it is to be located, so let's discuss what information needs to be marked on the circuit breaker and the location where you will find those markings. Keep in mind the UL® standard specifies minimum requirements. Circuit breaker manufacturers may provide additional information or provide information in a more convenient location.

Markings Visible without Removing Trims or Covers

UL 489 requires that some markings be visible without removing trims or covers. This location is typically referred to as the handle escutcheon (see photo 1).

Markings Visible with Trims or Covers Removed

UL 489 requires other markings be visible on an installed circuit breaker with trims or covers removed. This location is typically referred to as the face of the circuit breaker (see photos 2–4).

Other markings which should be visible with trims or covers removed are:

Independent trip – Multi-pole circuit breakers are constructed with either a common trip, where all poles are mechanically tripped when one of the poles trips, or an independent trip construction where only the pole that is involved with the overcurrent condition trips. If a 2-pole circuit breaker does not have an internal com-

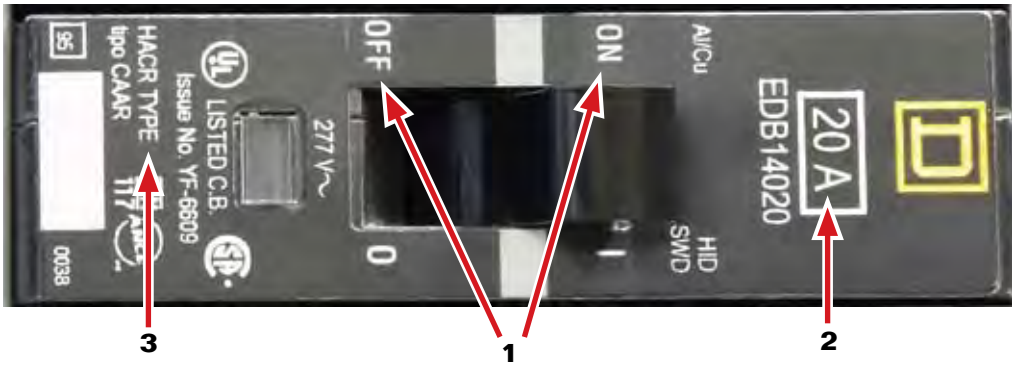

Photo 1. Markings Visible with Trims or Covers in Place

1. ON and OFF – The ON and OFF (closed and open) positions of the handle must be marked (*NEC* 240.81). These positions may also be marked with the internationally recognized "I" and "O" symbols, although this is not a UL requirement. If these markings are not visible when a motor operator is installed over the circuit breaker markings, then they must appear on the motor operator. Motor operators may be found in applications where remote or automatic operation of a circuit breaker is required.

2. Ampere rating (if 100 A or less) – The ampere rating may be located on the handle escutcheon or on the handle itself (*NEC* 240.83(B)). Circuit breakers that are rated more than 100 A may have their ampere rating marked in a position that is not visible with trims or covers in place.

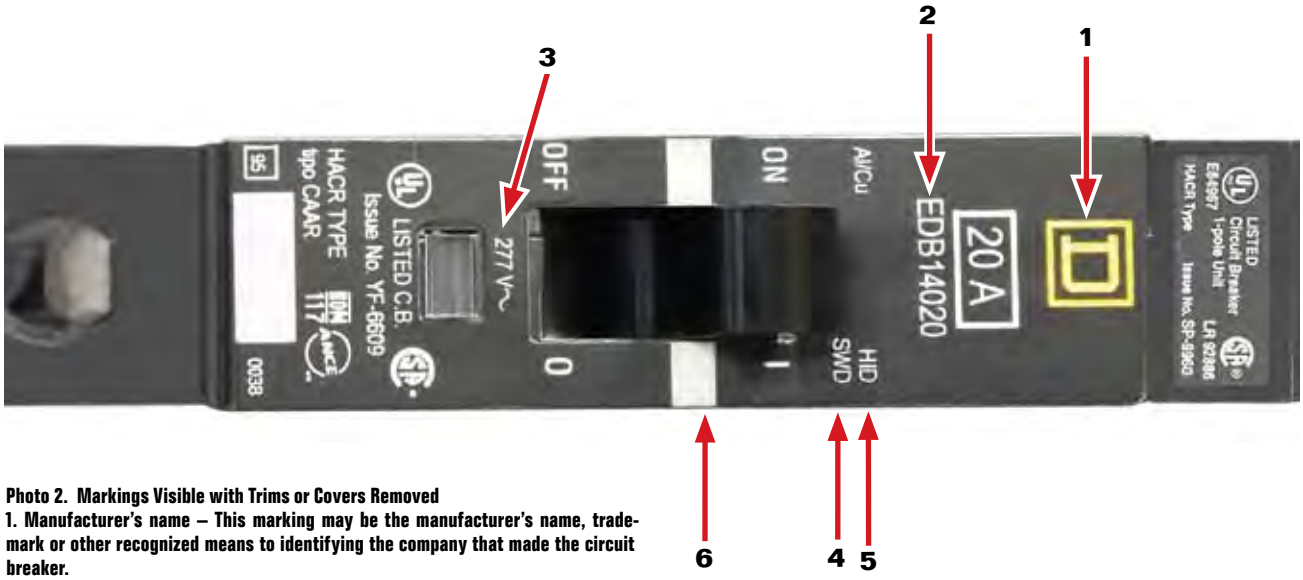

Photo 2. Markings Visible with Trims or Covers Removed

1. Manufacturer's name – This marking may be the manufacturer's name, trademark or other recognized means to identifying the company that made the circuit breaker.

2. Type designation – All circuit breakers are marked with a type designation, which may be a catalog number prefix or a separate designation. Equipment labels, such as on panelboards, will list the circuit breaker types suitable for use. Note that the word "type" may or may not be used on the circuit breaker or equipment labels. It is important to review the markings on the equipment, such as a panelboard, to make sure the circuit breaker designations on the equipment match the marking on the circuit breaker.

3. Voltage rating – All circuit breakers must be marked with a voltage rating. If the rating is not marked "ac" or "dc," then it is suitable for both. 120/240 V rated circuit breakers are suitable for use on single and three-phase 4-wire systems where the line-to-ground voltage does not exceed 120 V. Wye rated circuit breakers such as those rated 480Y/277 V, are suitable for use on three-phase 4-wire systems where the voltage to ground does not exceed 277 V. Special attention needs to be given to high leg or corner-grounded delta systems to insure that the circuit breaker has the appropriate rating. A review to see that the circuit breakers installed have a voltage rating suitable for the application is paramount for a code-compliant installation (*NEC* 240.83(E)).

4. SWD – 15- or 20-A circuit breakers rated 347 V or less may be marked "SWD," meaning that they are suitable for switching fluorescent lighting loads on a regular basis (*NEC* 240.83(D)). These circuit breakers are evaluated for high endurance use, since they will be used similar to a light switch.

5. HID – 50 A or less circuit breakers rated 480 V or less may be marked "HID," meaning they are suitable for switching high intensity discharge or fluorescent lighting loads on a regular basis. These circuit breakers may employ a different construction than a standard SWD circuit breaker in order to address the high inrush current resulting from the lower power factor created by the HID lighting (*NEC* 240.83(D)). These circuit breakers also undergo additional endurance evaluation to demonstrate their ability to perform the switching duty.

6. Trip and reset – Circuit breaker handles typically assume an intermediate position when tripped. This position must either be marked on the circuit breaker or on the equipment into which it is to be installed. If these markings are not visible when a motor operator is installed, then a "tripped" marking may appear on the motor operator.

mon trip feature, then it must be marked "Independent Trip" or "No Common Trip." *NEC* 240.20(B) is the foundational requirement for a common trip function in a circuit breaker; however, it also goes on to explain where independent trip is permitted.

For Replacement Use Only not-CTL – The Class CTL (circuit limiting) panelboard has only been in existence for about 25 years, even though the lighting and appliance branch circuit panelboard has been in the *NEC* for decades. CTL panelboards have a rejection means designed to reject more than the appropriate number of circuit breakers that can be installed in the panel. The marking "For replacement Use Only Not CTL Assemblies" means that the circuit breaker does not have CTL rejection provisions and is intended for replacement in older equipment pre-dating the CTL requirements for circuit breakers and panelboards. Circuit breakers with this designation should not be installed in a panelboard marked "Class CTL Panelboard" since that would be a violation of the listing of the assembly [*NEC* 110.3(B)].

Markings Found in Other Locations

The markings we will discuss below may appear in any location except the back of the circuit breaker. These markings include:

40°C – This marking indicates the maximum ambient temperature in which the circuit breaker can be applied at its marked ampere rating without rerating the ampacity of the circuit breaker. This marking is required for thermal-magnetic circuit breakers and is optional for electronic trip circuit breakers unless they are only suitable for a 25°C ambient, in which case they must be marked 25°C. When the ambient temperature rises above 40°C, the designer may need to consult the manufacturer to obtain rerating information (see item 4 in photo 3).

Class CTL – Circuit breakers marked Class CTL have a rejection means designed into the circuit breaker. Class CTL panelboards or assemblies, in conjunction with Class CTL circuit breakers, prevent more circuit breaker poles from being installed than the number for which the equipment is rated.

Photo 3. Markings Visible with Trims or Covers Removed

1. Line and load designation – Circuit breakers marked with "line" and "load" designations are not suitable for reverse connection. Circuit breakers with interchangeable trip units must be marked "line" and "load" unless there is no risk of shock when changing the trip unit.

2. Interrupting ratings – All circuit breakers with an interrupting rating more than 5000 A must be marked with an interrupting rating (*NEC* 240.83(C)). Interrupting ratings are stated in RMS symmetrical amperes. If the short-circuit current rating of the equipment in which the circuit breaker is installed is less than the interrupting rating of the circuit breaker, then the lesser rating applies. Circuit breakers should be reviewed after installation to ensure they have an interrupting rating suitable for the application. This marking may be found in any location except the back of circuit breakers that are 1-½ inches wide per pole or less due to the size constraint.

3. Ampere rating (if more than 100 A) – The ampere rating of a circuit breaker larger than 100 A may be found in a location that is visible after the cover or trim is removed. This marking requirement also applies to interchangeable trip units (*NEC* 240.83(A)).

5. Terminations (Cu-Al wire) – Circuit breakers must be marked with the type material (Cu-Al) and size of wire for which their terminals are suitable for use. If suitable for use with only copper or only aluminum, then the word "only" must be used. The abbreviations "CU" and "AL" are generally found on circuit breakers as permitted by the product standard. If only solid 10–14 AWG wire can be used, then that information must be noted. The number of wires per terminal will also be noted if more than one wire per terminal is permitted (*NEC* 110.14(A)).

6. Tightening torque – The nominal torque for all field-wiring terminals must be marked. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be found in any location except on the back.

7. Wire temperature ratings – Circuit breakers rated 125 A or less may be marked as suitable for use with 60°C, 60/75°C or 75°C only wire. Circuit breakers rated more than 125 A are rated for use with 75°C wire; the marking is optional. It is always permissible to use wire with a higher temperature rating, but it must be sized in accordance with the temperature marking on the circuit breaker and *NEC* Table 310.16. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be in any location except on the back (*NEC* 110.14(C)1).

8. HACR type – This marking indicates the circuit breaker is suitable for use with the group motor installations typically found in heating, air conditioning and refrigeration equipment. The *NEC* 2005 no longer has this marking requirement. The electrical industry determined that circuit breakers are considered suitable for use with such equipment without any further testing, therefore, the HACR marking is no longer required on air conditioning and refrigeration equipment or on circuit breakers for use in these applications. The requirement for this marking has also been removed from the UL 1995 product standard for HVAC equipment (see item 3 in photo 1).

Maximum wire size – Circuit breakers are typically marked with a wire range, however that marking is not mandatory. If the circuit breaker cannot accept the next larger wire size required for the ampere rating, then the maximum wire size must be marked in any location except the back (see item 5 in photo 3).

Separately shipped connectors –If connectors are not factory installed on a circuit breaker, then it must be marked with the proper connectors or terminal kits required in any location except the back (see item 8 in photo 3).

Ground-Fault Protection for People

The GFCI function, as part of a circuit breaker, provides ground-fault protection for people and has a number of unique marking and instruction requirements.

Test function – The GFCI has a test function that requires action upon installation and on a monthly basis. GFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate monthly testing.

Photo 4. 1Ø – 3Ø Marking
1. 1Ø – 3Ø marking – A 2-pole circuit breaker used to protect a 3-phase load on a corner-grounded delta system must be rated and marked for such an installation. Circuit breakers marked "1-phase – 3-phase" or "1Ø – 3Ø "are suitable for use on 3-phase corner-grounded delta or single-phase circuits (*NEC* 240.85).

Suitable for continuous operation at 100% of ampere rating only if used in a recognized enclosure 52 in. (1321 mm) by 20 in. (508 mm) x 7 1/2 in. (190 mm) deep or larger. Use only with 90° rated wire sized per the ampacity of 75° rated wire.

Figure 1. 100% Rated Marking
100 percent continuous rated – Circuit breakers are typically intended for use at not more than 80% of rated current where the load is considered continuous, or will continue for 3 hours or more (*NEC* 210.20). However, some circuit breakers are rated for continuous use at 100% of their current rating. These circuit breakers must be so marked in any location except on the back. Enclosure information such as a specific type or specific volume must also be marked. A requirement for the use of 90°C insulated wire sized to the 75°C column in *NEC* Table 310.16 and specific ventilation requirements may also be marked on the circuit breaker or equipment (*NEC* 210.20(A) and 215.3).

"Class A" marking – A "Class A" ground-fault device is intended to protect people. The Class A marking indicates that the trip threshold of the GFCI is between 4 mA and 6 mA. This marking may be in any location except the back.

Instructions – All GFCI circuit breakers must include instructions for the installer plus instructions on the use of the test function. A hangtag or self-adhesive label must also be provided, instructing the user to test the GFCI at least monthly. Inspectors should check to see that the tag or label has been properly installed.

Ground-Fault Protection for Equipment

Circuit breakers may also include a ground-fault protection for equipment (GFPE) function that, like GFCIs, has a number of unique marking and instruction requirements.

Test function – GFPE circuit breakers may have a test button or switch that may be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Trip level – GFPE circuit breakers must be marked with their trip threshold in milliamperes in a location accessible without removing trims or covers.

Instructions – All GFPE circuit breakers must include instructions for the installer.

Arc-Fault Protection

Circuit breakers may also include arc-fault protection (AFCI) that, like GFCIs, also has a number of unique marking and instruction requirements.

Device identification – AFCIs must also be identified appropriately. Branch/feeder or Combination type AFCIs must be so marked in a location visible when the trims or covers are removed. This is an important marking to note as we move into 2008, as *NEC*-2005 requires Combination AFCIs in bedrooms effective January 1, 2008 (*NEC* 210.12).

Test function – AFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Instructions – All AFCI circuit breakers must include instructions for the installer.

Circuit Breaker Markings Ensure a Safe Electrical Installation

So why are all of these markings on circuit breakers? Without them, it would be nearly impossible to install or inspect an installation for the appropriate performance ratings and fundamental electrical connections. When designing or completing an installation, key items to review are:

1. Are the voltage, continuous current, and interrupting ratings appropriate for the application?
2. Does the application require SWD or HID ratings?
3. Is the wire type and size appropriate for the circuit breaker?
4. Is the circuit breaker suitable for the equipment in which it is installed? Have other protective functions such as GFCI or AFCI been provided as required by the *NEC*?
5. Is the temperature rating of the circuit breaker suitable for the application?

The UL Marking Guide for Molded Case Circuit Breakers is a valuable resource to understand circuit breaker markings that may further explain these and other markings in detail. If you have questions about CB markings not answered here, consult the Marking Guide or the manufacturer to assist in an *NEC*-compliant installation.

Mr. Larsen, P. E., is the manager, Industry Standards for Circuit Protection for Square D Company / Schneider Electric. Mr. Larsen has served in various positions over the past 32 years. What Do the Markings on Circuit Breakers Mean?

by Ed Larsen, P. E.

Have you ever been confused about what the markings on circuit breakers mean? Understanding the markings on electrical equipment is a fundamental need to ensure a safe and reliable electrical installation. Circuit breaker marking requirements are established by the requirements found in the *NEC* and the UL 489 product standard. This article will discuss the most common markings and where they can be found.

The UL 489 product standard for Molded Case Circuit Breakers specifies the information to be marked on circuit breakers and where it is to be located, so let's discuss what information needs to be marked on the circuit breaker and the location where you will find those markings. Keep in mind the UL® standard specifies minimum requirements. Circuit breaker manufacturers may provide additional information or provide information in a more convenient location.

Markings Visible without Removing Trims or Covers

UL 489 requires that some markings be visible without removing trims or covers. This location is typically referred to as the handle escutcheon (see photo 1).

Markings Visible with Trims or Covers Removed

UL 489 requires other markings be visible on an installed circuit breaker with trims or covers removed. This location is typically referred to as the face of the circuit breaker (see photos 2–4).

Other markings which should be visible with trims or covers removed are:

Independent trip – Multi-pole circuit breakers are constructed with either a common trip, where all poles are mechanically tripped when one of the poles trips, or an independent trip construction where only the pole that is involved with the overcurrent condition trips. If a 2-pole circuit breaker does not have an internal com-

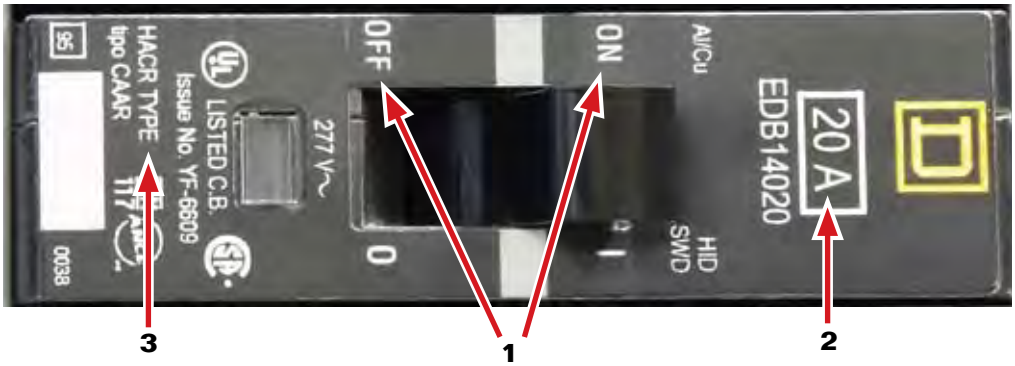

Photo 1. Markings Visible with Trims or Covers in Place

1. ON and OFF – The ON and OFF (closed and open) positions of the handle must be marked (*NEC* 240.81). These positions may also be marked with the internationally recognized "I" and "O" symbols, although this is not a UL requirement. If these markings are not visible when a motor operator is installed over the circuit breaker markings, then they must appear on the motor operator. Motor operators may be found in applications where remote or automatic operation of a circuit breaker is required.

2. Ampere rating (if 100 A or less) – The ampere rating may be located on the handle escutcheon or on the handle itself (*NEC* 240.83(B)). Circuit breakers that are rated more than 100 A may have their ampere rating marked in a position that is not visible with trims or covers in place.

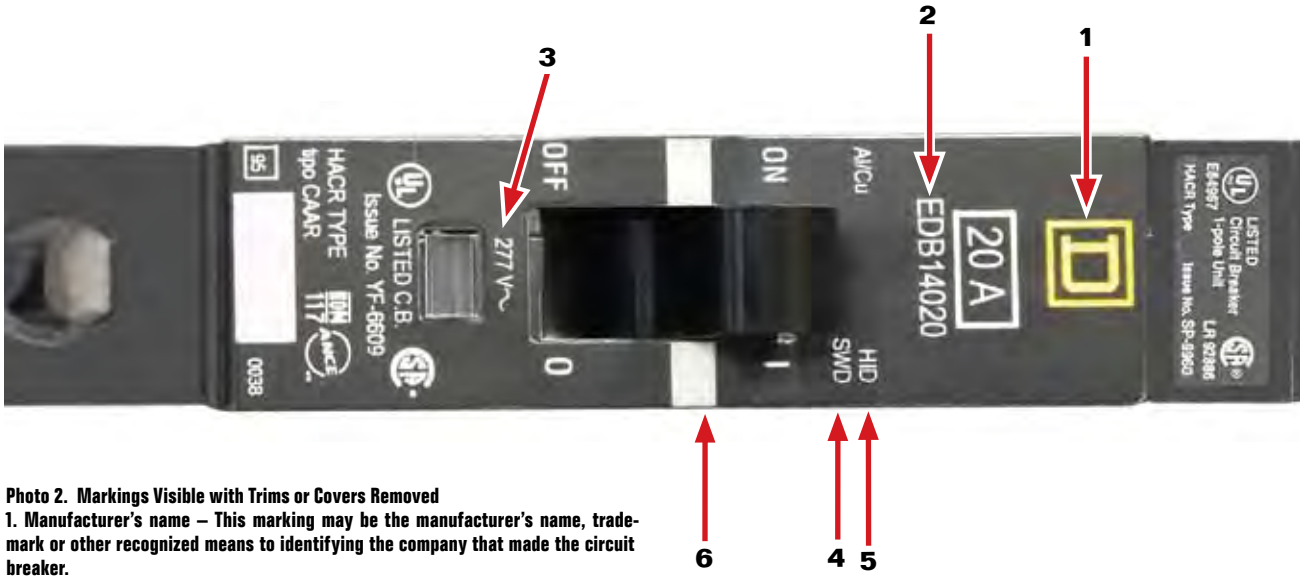

Photo 2. Markings Visible with Trims or Covers Removed

1. Manufacturer's name – This marking may be the manufacturer's name, trademark or other recognized means to identifying the company that made the circuit breaker.

2. Type designation – All circuit breakers are marked with a type designation, which may be a catalog number prefix or a separate designation. Equipment labels, such as on panelboards, will list the circuit breaker types suitable for use. Note that the word "type" may or may not be used on the circuit breaker or equipment labels. It is important to review the markings on the equipment, such as a panelboard, to make sure the circuit breaker designations on the equipment match the marking on the circuit breaker.

3. Voltage rating – All circuit breakers must be marked with a voltage rating. If the rating is not marked "ac" or "dc," then it is suitable for both. 120/240 V rated circuit breakers are suitable for use on single and three-phase 4-wire systems where the line-to-ground voltage does not exceed 120 V. Wye rated circuit breakers such as those rated 480Y/277 V, are suitable for use on three-phase 4-wire systems where the voltage to ground does not exceed 277 V. Special attention needs to be given to high leg or corner-grounded delta systems to insure that the circuit breaker has the appropriate rating. A review to see that the circuit breakers installed have a voltage rating suitable for the application is paramount for a code-compliant installation (*NEC* 240.83(E)).

4. SWD – 15- or 20-A circuit breakers rated 347 V or less may be marked "SWD," meaning that they are suitable for switching fluorescent lighting loads on a regular basis (*NEC* 240.83(D)). These circuit breakers are evaluated for high endurance use, since they will be used similar to a light switch.

5. HID – 50 A or less circuit breakers rated 480 V or less may be marked "HID," meaning they are suitable for switching high intensity discharge or fluorescent lighting loads on a regular basis. These circuit breakers may employ a different construction than a standard SWD circuit breaker in order to address the high inrush current resulting from the lower power factor created by the HID lighting (*NEC* 240.83(D)). These circuit breakers also undergo additional endurance evaluation to demonstrate their ability to perform the switching duty.

6. Trip and reset – Circuit breaker handles typically assume an intermediate position when tripped. This position must either be marked on the circuit breaker or on the equipment into which it is to be installed. If these markings are not visible when a motor operator is installed, then a "tripped" marking may appear on the motor operator.

mon trip feature, then it must be marked "Independent Trip" or "No Common Trip." *NEC* 240.20(B) is the foundational requirement for a common trip function in a circuit breaker; however, it also goes on to explain where independent trip is permitted.

For Replacement Use Only not-CTL – The Class CTL (circuit limiting) panelboard has only been in existence for about 25 years, even though the lighting and appliance branch circuit panelboard has been in the *NEC* for decades. CTL panelboards have a rejection means designed to reject more than the appropriate number of circuit breakers that can be installed in the panel. The marking "For replacement Use Only Not CTL Assemblies" means that the circuit breaker does not have CTL rejection provisions and is intended for replacement in older equipment pre-dating the CTL requirements for circuit breakers and panelboards. Circuit breakers with this designation should not be installed in a panelboard marked "Class CTL Panelboard" since that would be a violation of the listing of the assembly [*NEC* 110.3(B)].

Markings Found in Other Locations

The markings we will discuss below may appear in any location except the back of the circuit breaker. These markings include:

40°C – This marking indicates the maximum ambient temperature in which the circuit breaker can be applied at its marked ampere rating without rerating the ampacity of the circuit breaker. This marking is required for thermal-magnetic circuit breakers and is optional for electronic trip circuit breakers unless they are only suitable for a 25°C ambient, in which case they must be marked 25°C. When the ambient temperature rises above 40°C, the designer may need to consult the manufacturer to obtain rerating information (see item 4 in photo 3).

Class CTL – Circuit breakers marked Class CTL have a rejection means designed into the circuit breaker. Class CTL panelboards or assemblies, in conjunction with Class CTL circuit breakers, prevent more circuit breaker poles from being installed than the number for which the equipment is rated.

Photo 3. Markings Visible with Trims or Covers Removed

1. Line and load designation – Circuit breakers marked with "line" and "load" designations are not suitable for reverse connection. Circuit breakers with interchangeable trip units must be marked "line" and "load" unless there is no risk of shock when changing the trip unit.

2. Interrupting ratings – All circuit breakers with an interrupting rating more than 5000 A must be marked with an interrupting rating (*NEC* 240.83(C)). Interrupting ratings are stated in RMS symmetrical amperes. If the short-circuit current rating of the equipment in which the circuit breaker is installed is less than the interrupting rating of the circuit breaker, then the lesser rating applies. Circuit breakers should be reviewed after installation to ensure they have an interrupting rating suitable for the application. This marking may be found in any location except the back of circuit breakers that are 1-½ inches wide per pole or less due to the size constraint.

3. Ampere rating (if more than 100 A) – The ampere rating of a circuit breaker larger than 100 A may be found in a location that is visible after the cover or trim is removed. This marking requirement also applies to interchangeable trip units (*NEC* 240.83(A)).

5. Terminations (Cu-Al wire) – Circuit breakers must be marked with the type material (Cu-Al) and size of wire for which their terminals are suitable for use. If suitable for use with only copper or only aluminum, then the word "only" must be used. The abbreviations "CU" and "AL" are generally found on circuit breakers as permitted by the product standard. If only solid 10–14 AWG wire can be used, then that information must be noted. The number of wires per terminal will also be noted if more than one wire per terminal is permitted (*NEC* 110.14(A)).

6. Tightening torque – The nominal torque for all field-wiring terminals must be marked. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be found in any location except on the back.

7. Wire temperature ratings – Circuit breakers rated 125 A or less may be marked as suitable for use with 60°C, 60/75°C or 75°C only wire. Circuit breakers rated more than 125 A are rated for use with 75°C wire; the marking is optional. It is always permissible to use wire with a higher temperature rating, but it must be sized in accordance with the temperature marking on the circuit breaker and *NEC* Table 310.16. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be in any location except on the back (*NEC* 110.14(C)1).

8. HACR type – This marking indicates the circuit breaker is suitable for use with the group motor installations typically found in heating, air conditioning and refrigeration equipment. The *NEC* 2005 no longer has this marking requirement. The electrical industry determined that circuit breakers are considered suitable for use with such equipment without any further testing, therefore, the HACR marking is no longer required on air conditioning and refrigeration equipment or on circuit breakers for use in these applications. The requirement for this marking has also been removed from the UL 1995 product standard for HVAC equipment (see item 3 in photo 1).

Maximum wire size – Circuit breakers are typically marked with a wire range, however that marking is not mandatory. If the circuit breaker cannot accept the next larger wire size required for the ampere rating, then the maximum wire size must be marked in any location except the back (see item 5 in photo 3).

Separately shipped connectors –If connectors are not factory installed on a circuit breaker, then it must be marked with the proper connectors or terminal kits required in any location except the back (see item 8 in photo 3).

Ground-Fault Protection for People

The GFCI function, as part of a circuit breaker, provides ground-fault protection for people and has a number of unique marking and instruction requirements.

Test function – The GFCI has a test function that requires action upon installation and on a monthly basis. GFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate monthly testing.

Photo 4. 1Ø – 3Ø Marking
1. 1Ø – 3Ø marking – A 2-pole circuit breaker used to protect a 3-phase load on a corner-grounded delta system must be rated and marked for such an installation. Circuit breakers marked "1-phase – 3-phase" or "1Ø – 3Ø "are suitable for use on 3-phase corner-grounded delta or single-phase circuits (*NEC* 240.85).

Suitable for continuous operation at 100% of ampere rating only if used in a recognized enclosure 52 in. (1321 mm) by 20 in. (508 mm) x 7 1/2 in. (190 mm) deep or larger. Use only with 90° rated wire sized per the ampacity of 75° rated wire.

Figure 1. 100% Rated Marking
100 percent continuous rated – Circuit breakers are typically intended for use at not more than 80% of rated current where the load is considered continuous, or will continue for 3 hours or more (*NEC* 210.20). However, some circuit breakers are rated for continuous use at 100% of their current rating. These circuit breakers must be so marked in any location except on the back. Enclosure information such as a specific type or specific volume must also be marked. A requirement for the use of 90°C insulated wire sized to the 75°C column in *NEC* Table 310.16 and specific ventilation requirements may also be marked on the circuit breaker or equipment (*NEC* 210.20(A) and 215.3).

"Class A" marking – A "Class A" ground-fault device is intended to protect people. The Class A marking indicates that the trip threshold of the GFCI is between 4 mA and 6 mA. This marking may be in any location except the back.

Instructions – All GFCI circuit breakers must include instructions for the installer plus instructions on the use of the test function. A hangtag or self-adhesive label must also be provided, instructing the user to test the GFCI at least monthly. Inspectors should check to see that the tag or label has been properly installed.

Ground-Fault Protection for Equipment

Circuit breakers may also include a ground-fault protection for equipment (GFPE) function that, like GFCIs, has a number of unique marking and instruction requirements.

Test function – GFPE circuit breakers may have a test button or switch that may be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Trip level – GFPE circuit breakers must be marked with their trip threshold in milliamperes in a location accessible without removing trims or covers.

Instructions – All GFPE circuit breakers must include instructions for the installer.

Arc-Fault Protection

Circuit breakers may also include arc-fault protection (AFCI) that, like GFCIs, also has a number of unique marking and instruction requirements.

Device identification – AFCIs must also be identified appropriately. Branch/feeder or Combination type AFCIs must be so marked in a location visible when the trims or covers are removed. This is an important marking to note as we move into 2008, as *NEC*-2005 requires Combination AFCIs in bedrooms effective January 1, 2008 (*NEC* 210.12).

Test function – AFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Instructions – All AFCI circuit breakers must include instructions for the installer.

Circuit Breaker Markings Ensure a Safe Electrical Installation

So why are all of these markings on circuit breakers? Without them, it would be nearly impossible to install or inspect an installation for the appropriate performance ratings and fundamental electrical connections. When designing or completing an installation, key items to review are:

1. Are the voltage, continuous current, and interrupting ratings appropriate for the application?
2. Does the application require SWD or HID ratings?
3. Is the wire type and size appropriate for the circuit breaker?
4. Is the circuit breaker suitable for the equipment in which it is installed? Have other protective functions such as GFCI or AFCI been provided as required by the *NEC*?
5. Is the temperature rating of the circuit breaker suitable for the application?

The UL Marking Guide for Molded Case Circuit Breakers is a valuable resource to understand circuit breaker markings that may further explain these and other markings in detail. If you have questions about CB markings not answered here, consult the Marking Guide or the manufacturer to assist in an *NEC*-compliant installation.

Mr. Larsen, P. E., is the manager, Industry Standards for Circuit Protection for Square D Company / Schneider Electric. Mr. Larsen has served in various positions over the past 32 years. He is a member of several UL, IEEE and NEMA technical committees. His other memberships include NFPA, IAEI and CANENA.

What Do the Markings on Circuit Breakers Mean?

by Ed Larsen, P. E.

Have you ever been confused about what the markings on circuit breakers mean? Understanding the markings on electrical equipment is a fundamental need to ensure a safe and reliable electrical installation. Circuit breaker marking requirements are established by the requirements found in the *NEC* and the UL 489 product standard. This article will discuss the most common markings and where they can be found.

The UL 489 product standard for Molded Case Circuit Breakers specifies the information to be marked on circuit breakers and where it is to be located, so let's discuss what information needs to be marked on the circuit breaker and the location where you will find those markings. Keep in mind the UL® standard specifies minimum requirements. Circuit breaker manufacturers may provide additional information or provide information in a more convenient location.

Markings Visible without Removing Trims or Covers

UL 489 requires that some markings be visible without removing trims or covers. This location is typically referred to as the handle escutcheon (see photo 1).

Markings Visible with Trims or Covers Removed

UL 489 requires other markings be visible on an installed circuit breaker with trims or covers removed. This location is typically referred to as the face of the circuit breaker (see photos 2–4).

Other markings which should be visible with trims or covers removed are:

Independent trip – Multi-pole circuit breakers are constructed with either a common trip, where all poles are mechanically tripped when one of the poles trips, or an independent trip construction where only the pole that is involved with the overcurrent condition trips. If a 2-pole circuit breaker does not have an internal com-

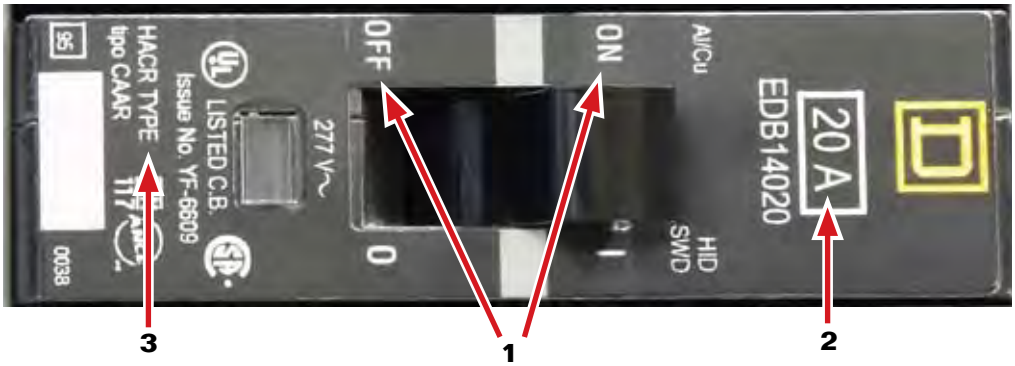

Photo 1. Markings Visible with Trims or Covers in Place

1. ON and OFF – The ON and OFF (closed and open) positions of the handle must be marked (*NEC* 240.81). These positions may also be marked with the internationally recognized "I" and "O" symbols, although this is not a UL requirement. If these markings are not visible when a motor operator is installed over the circuit breaker markings, then they must appear on the motor operator. Motor operators may be found in applications where remote or automatic operation of a circuit breaker is required.

2. Ampere rating (if 100 A or less) – The ampere rating may be located on the handle escutcheon or on the handle itself (*NEC* 240.83(B)). Circuit breakers that are rated more than 100 A may have their ampere rating marked in a position that is not visible with trims or covers in place.

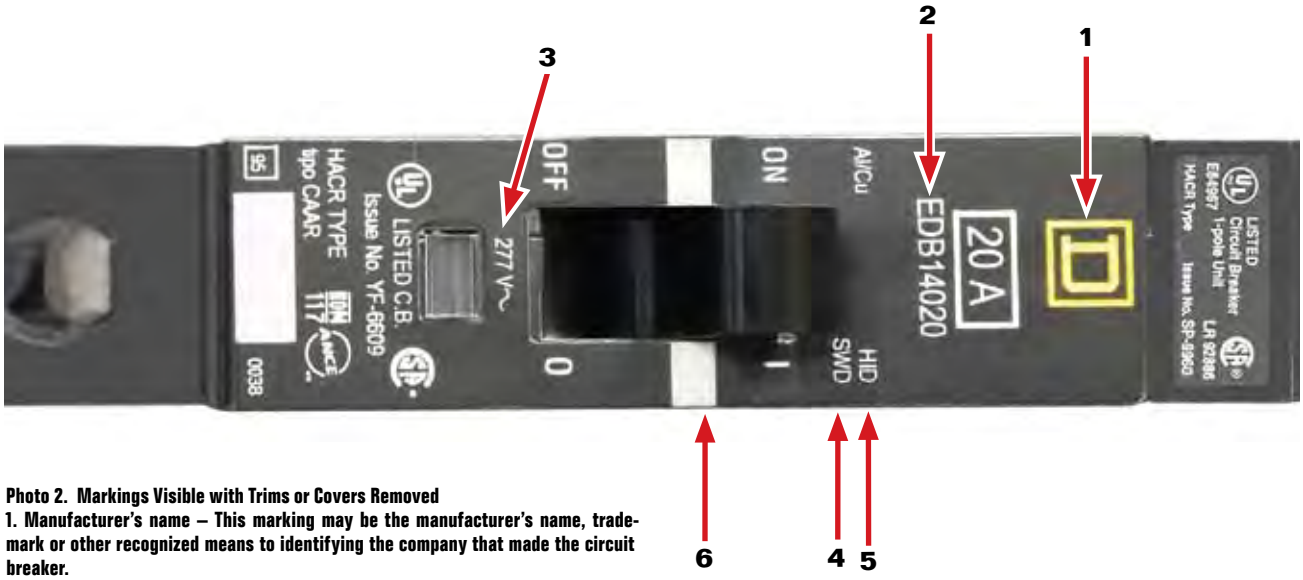

Photo 2. Markings Visible with Trims or Covers Removed

1. Manufacturer's name – This marking may be the manufacturer's name, trademark or other recognized means to identifying the company that made the circuit breaker.

2. Type designation – All circuit breakers are marked with a type designation, which may be a catalog number prefix or a separate designation. Equipment labels, such as on panelboards, will list the circuit breaker types suitable for use. Note that the word "type" may or may not be used on the circuit breaker or equipment labels. It is important to review the markings on the equipment, such as a panelboard, to make sure the circuit breaker designations on the equipment match the marking on the circuit breaker.

3. Voltage rating – All circuit breakers must be marked with a voltage rating. If the rating is not marked "ac" or "dc," then it is suitable for both. 120/240 V rated circuit breakers are suitable for use on single and three-phase 4-wire systems where the line-to-ground voltage does not exceed 120 V. Wye rated circuit breakers such as those rated 480Y/277 V, are suitable for use on three-phase 4-wire systems where the voltage to ground does not exceed 277 V. Special attention needs to be given to high leg or corner-grounded delta systems to insure that the circuit breaker has the appropriate rating. A review to see that the circuit breakers installed have a voltage rating suitable for the application is paramount for a code-compliant installation (*NEC* 240.83(E)).

4. SWD – 15- or 20-A circuit breakers rated 347 V or less may be marked "SWD," meaning that they are suitable for switching fluorescent lighting loads on a regular basis (*NEC* 240.83(D)). These circuit breakers are evaluated for high endurance use, since they will be used similar to a light switch.

5. HID – 50 A or less circuit breakers rated 480 V or less may be marked "HID," meaning they are suitable for switching high intensity discharge or fluorescent lighting loads on a regular basis. These circuit breakers may employ a different construction than a standard SWD circuit breaker in order to address the high inrush current resulting from the lower power factor created by the HID lighting (*NEC* 240.83(D)). These circuit breakers also undergo additional endurance evaluation to demonstrate their ability to perform the switching duty.

6. Trip and reset – Circuit breaker handles typically assume an intermediate position when tripped. This position must either be marked on the circuit breaker or on the equipment into which it is to be installed. If these markings are not visible when a motor operator is installed, then a "tripped" marking may appear on the motor operator.

mon trip feature, then it must be marked "Independent Trip" or "No Common Trip." *NEC* 240.20(B) is the foundational requirement for a common trip function in a circuit breaker; however, it also goes on to explain where independent trip is permitted.

For Replacement Use Only not-CTL – The Class CTL (circuit limiting) panelboard has only been in existence for about 25 years, even though the lighting and appliance branch circuit panelboard has been in the *NEC* for decades. CTL panelboards have a rejection means designed to reject more than the appropriate number of circuit breakers that can be installed in the panel. The marking "For replacement Use Only Not CTL Assemblies" means that the circuit breaker does not have CTL rejection provisions and is intended for replacement in older equipment pre-dating the CTL requirements for circuit breakers and panelboards. Circuit breakers with this designation should not be installed in a panelboard marked "Class CTL Panelboard" since that would be a violation of the listing of the assembly [*NEC* 110.3(B)].

Markings Found in Other Locations

The markings we will discuss below may appear in any location except the back of the circuit breaker. These markings include:

40°C – This marking indicates the maximum ambient temperature in which the circuit breaker can be applied at its marked ampere rating without rerating the ampacity of the circuit breaker. This marking is required for thermal-magnetic circuit breakers and is optional for electronic trip circuit breakers unless they are only suitable for a 25°C ambient, in which case they must be marked 25°C. When the ambient temperature rises above 40°C, the designer may need to consult the manufacturer to obtain rerating information (see item 4 in photo 3).

Class CTL – Circuit breakers marked Class CTL have a rejection means designed into the circuit breaker. Class CTL panelboards or assemblies, in conjunction with Class CTL circuit breakers, prevent more circuit breaker poles from being installed than the number for which the equipment is rated.

Photo 3. Markings Visible with Trims or Covers Removed

1. Line and load designation – Circuit breakers marked with "line" and "load" designations are not suitable for reverse connection. Circuit breakers with interchangeable trip units must be marked "line" and "load" unless there is no risk of shock when changing the trip unit.

2. Interrupting ratings – All circuit breakers with an interrupting rating more than 5000 A must be marked with an interrupting rating (*NEC* 240.83(C)). Interrupting ratings are stated in RMS symmetrical amperes. If the short-circuit current rating of the equipment in which the circuit breaker is installed is less than the interrupting rating of the circuit breaker, then the lesser rating applies. Circuit breakers should be reviewed after installation to ensure they have an interrupting rating suitable for the application. This marking may be found in any location except the back of circuit breakers that are 1-½ inches wide per pole or less due to the size constraint.

3. Ampere rating (if more than 100 A) – The ampere rating of a circuit breaker larger than 100 A may be found in a location that is visible after the cover or trim is removed. This marking requirement also applies to interchangeable trip units (*NEC* 240.83(A)).

5. Terminations (Cu-Al wire) – Circuit breakers must be marked with the type material (Cu-Al) and size of wire for which their terminals are suitable for use. If suitable for use with only copper or only aluminum, then the word "only" must be used. The abbreviations "CU" and "AL" are generally found on circuit breakers as permitted by the product standard. If only solid 10–14 AWG wire can be used, then that information must be noted. The number of wires per terminal will also be noted if more than one wire per terminal is permitted (*NEC* 110.14(A)).

6. Tightening torque – The nominal torque for all field-wiring terminals must be marked. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be found in any location except on the back.

7. Wire temperature ratings – Circuit breakers rated 125 A or less may be marked as suitable for use with 60°C, 60/75°C or 75°C only wire. Circuit breakers rated more than 125 A are rated for use with 75°C wire; the marking is optional. It is always permissible to use wire with a higher temperature rating, but it must be sized in accordance with the temperature marking on the circuit breaker and *NEC* Table 310.16. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be in any location except on the back (*NEC* 110.14(C)1).

8. HACR type – This marking indicates the circuit breaker is suitable for use with the group motor installations typically found in heating, air conditioning and refrigeration equipment. The *NEC* 2005 no longer has this marking requirement. The electrical industry determined that circuit breakers are considered suitable for use with such equipment without any further testing, therefore, the HACR marking is no longer required on air conditioning and refrigeration equipment or on circuit breakers for use in these applications. The requirement for this marking has also been removed from the UL 1995 product standard for HVAC equipment (see item 3 in photo 1).

Maximum wire size – Circuit breakers are typically marked with a wire range, however that marking is not mandatory. If the circuit breaker cannot accept the next larger wire size required for the ampere rating, then the maximum wire size must be marked in any location except the back (see item 5 in photo 3).

Separately shipped connectors –If connectors are not factory installed on a circuit breaker, then it must be marked with the proper connectors or terminal kits required in any location except the back (see item 8 in photo 3).

Ground-Fault Protection for People

The GFCI function, as part of a circuit breaker, provides ground-fault protection for people and has a number of unique marking and instruction requirements.

Test function – The GFCI has a test function that requires action upon installation and on a monthly basis. GFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate monthly testing.

Photo 4. 1Ø – 3Ø Marking
1. 1Ø – 3Ø marking – A 2-pole circuit breaker used to protect a 3-phase load on a corner-grounded delta system must be rated and marked for such an installation. Circuit breakers marked "1-phase – 3-phase" or "1Ø – 3Ø "are suitable for use on 3-phase corner-grounded delta or single-phase circuits (*NEC* 240.85).

Suitable for continuous operation at 100% of ampere rating only if used in a recognized enclosure 52 in. (1321 mm) by 20 in. (508 mm) x 7 1/2 in. (190 mm) deep or larger. Use only with 90° rated wire sized per the ampacity of 75° rated wire.

Figure 1. 100% Rated Marking
100 percent continuous rated – Circuit breakers are typically intended for use at not more than 80% of rated current where the load is considered continuous, or will continue for 3 hours or more (*NEC* 210.20). However, some circuit breakers are rated for continuous use at 100% of their current rating. These circuit breakers must be so marked in any location except on the back. Enclosure information such as a specific type or specific volume must also be marked. A requirement for the use of 90°C insulated wire sized to the 75°C column in *NEC* Table 310.16 and specific ventilation requirements may also be marked on the circuit breaker or equipment (*NEC* 210.20(A) and 215.3).

"Class A" marking – A "Class A" ground-fault device is intended to protect people. The Class A marking indicates that the trip threshold of the GFCI is between 4 mA and 6 mA. This marking may be in any location except the back.

Instructions – All GFCI circuit breakers must include instructions for the installer plus instructions on the use of the test function. A hangtag or self-adhesive label must also be provided, instructing the user to test the GFCI at least monthly. Inspectors should check to see that the tag or label has been properly installed.

Ground-Fault Protection for Equipment

Circuit breakers may also include a ground-fault protection for equipment (GFPE) function that, like GFCIs, has a number of unique marking and instruction requirements.

Test function – GFPE circuit breakers may have a test button or switch that may be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Trip level – GFPE circuit breakers must be marked with their trip threshold in milliamperes in a location accessible without removing trims or covers.

Instructions – All GFPE circuit breakers must include instructions for the installer.

Arc-Fault Protection

Circuit breakers may also include arc-fault protection (AFCI) that, like GFCIs, also has a number of unique marking and instruction requirements.

Device identification – AFCIs must also be identified appropriately. Branch/feeder or Combination type AFCIs must be so marked in a location visible when the trims or covers are removed. This is an important marking to note as we move into 2008, as *NEC*-2005 requires Combination AFCIs in bedrooms effective January 1, 2008 (*NEC* 210.12).

Test function – AFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Instructions – All AFCI circuit breakers must include instructions for the installer.

Circuit Breaker Markings Ensure a Safe Electrical Installation

So why are all of these markings on circuit breakers? Without them, it would be nearly impossible to install or inspect an installation for the appropriate performance ratings and fundamental electrical connections. When designing or completing an installation, key items to review are:

1. Are the voltage, continuous current, and interrupting ratings appropriate for the application?
2. Does the application require SWD or HID ratings?
3. Is the wire type and size appropriate for the circuit breaker?
4. Is the circuit breaker suitable for the equipment in which it is installed? Have other protective functions such as GFCI or AFCI been provided as required by the *NEC*?
5. Is the temperature rating of the circuit breaker suitable for the application?

The UL Marking Guide for Molded Case Circuit Breakers is a valuable resource to understand circuit breaker markings that may further explain these and other markings in detail. If you have questions about CB markings not answered here, consult the Marking Guide or the manufacturer to assist in an *NEC*-compliant installation.

Mr. Larsen, P. E., is the manager, Industry Standards for Circuit Protection for Square D Company / Schneider Electric. Mr. Larsen has served in various positions over the past 32 years. What Do the Markings on Circuit Breakers Mean?

by Ed Larsen, P. E.

Have you ever been confused about what the markings on circuit breakers mean? Understanding the markings on electrical equipment is a fundamental need to ensure a safe and reliable electrical installation. Circuit breaker marking requirements are established by the requirements found in the *NEC* and the UL 489 product standard. This article will discuss the most common markings and where they can be found.

The UL 489 product standard for Molded Case Circuit Breakers specifies the information to be marked on circuit breakers and where it is to be located, so let's discuss what information needs to be marked on the circuit breaker and the location where you will find those markings. Keep in mind the UL® standard specifies minimum requirements. Circuit breaker manufacturers may provide additional information or provide information in a more convenient location.

Markings Visible without Removing Trims or Covers

UL 489 requires that some markings be visible without removing trims or covers. This location is typically referred to as the handle escutcheon (see photo 1).

Markings Visible with Trims or Covers Removed

UL 489 requires other markings be visible on an installed circuit breaker with trims or covers removed. This location is typically referred to as the face of the circuit breaker (see photos 2–4).

Other markings which should be visible with trims or covers removed are:

Independent trip – Multi-pole circuit breakers are constructed with either a common trip, where all poles are mechanically tripped when one of the poles trips, or an independent trip construction where only the pole that is involved with the overcurrent condition trips. If a 2-pole circuit breaker does not have an internal com-

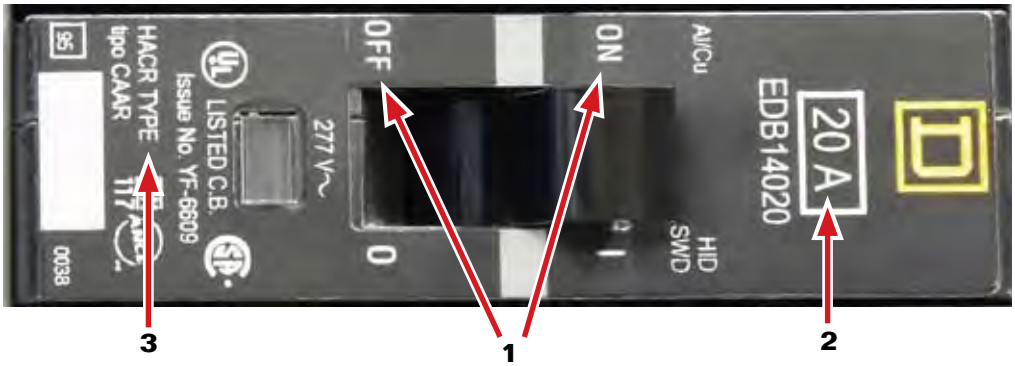

Photo 1. Markings Visible with Trims or Covers in Place

1. ON and OFF – The ON and OFF (closed and open) positions of the handle must be marked (*NEC* 240.81). These positions may also be marked with the internationally recognized "I" and "O" symbols, although this is not a UL requirement. If these markings are not visible when a motor operator is installed over the circuit breaker markings, then they must appear on the motor operator. Motor operators may be found in applications where remote or automatic operation of a circuit breaker is required.

2. Ampere rating (if 100 A or less) – The ampere rating may be located on the handle escutcheon or on the handle itself (*NEC* 240.83(B)). Circuit breakers that are rated more than 100 A may have their ampere rating marked in a position that is not visible with trims or covers in place.

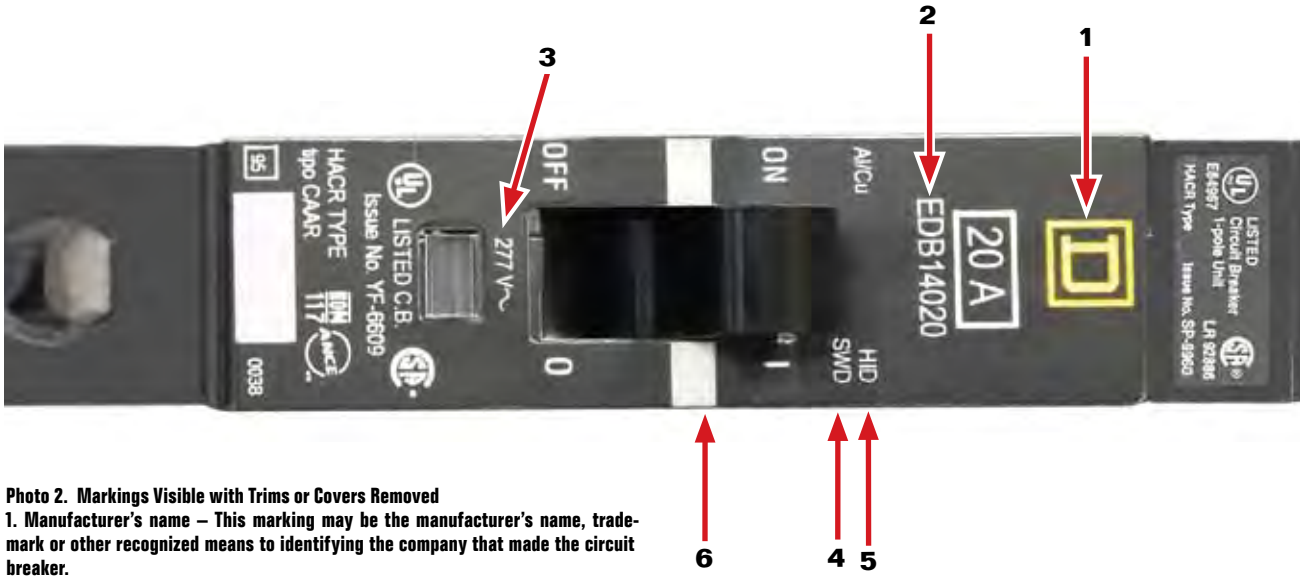

Photo 2. Markings Visible with Trims or Covers Removed

1. Manufacturer's name – This marking may be the manufacturer's name, trademark or other recognized means to identifying the company that made the circuit breaker.

2. Type designation – All circuit breakers are marked with a type designation, which may be a catalog number prefix or a separate designation. Equipment labels, such as on panelboards, will list the circuit breaker types suitable for use. Note that the word "type" may or may not be used on the circuit breaker or equipment labels. It is important to review the markings on the equipment, such as a panelboard, to make sure the circuit breaker designations on the equipment match the marking on the circuit breaker.

3. Voltage rating – All circuit breakers must be marked with a voltage rating. If the rating is not marked "ac" or "dc," then it is suitable for both. 120/240 V rated circuit breakers are suitable for use on single and three-phase 4-wire systems where the line-to-ground voltage does not exceed 120 V. Wye rated circuit breakers such as those rated 480Y/277 V, are suitable for use on three-phase 4-wire systems where the voltage to ground does not exceed 277 V. Special attention needs to be given to high leg or corner-grounded delta systems to insure that the circuit breaker has the appropriate rating. A review to see that the circuit breakers installed have a voltage rating suitable for the application is paramount for a code-compliant installation (*NEC* 240.83(E)).

4. SWD – 15- or 20-A circuit breakers rated 347 V or less may be marked "SWD," meaning that they are suitable for switching fluorescent lighting loads on a regular basis (*NEC* 240.83(D)). These circuit breakers are evaluated for high endurance use, since they will be used similar to a light switch.

5. HID – 50 A or less circuit breakers rated 480 V or less may be marked "HID," meaning they are suitable for switching high intensity discharge or fluorescent lighting loads on a regular basis. These circuit breakers may employ a different construction than a standard SWD circuit breaker in order to address the high inrush current resulting from the lower power factor created by the HID lighting (*NEC* 240.83(D)). These circuit breakers also undergo additional endurance evaluation to demonstrate their ability to perform the switching duty.

6. Trip and reset – Circuit breaker handles typically assume an intermediate position when tripped. This position must either be marked on the circuit breaker or on the equipment into which it is to be installed. If these markings are not visible when a motor operator is installed, then a "tripped" marking may appear on the motor operator.

mon trip feature, then it must be marked "Independent Trip" or "No Common Trip." *NEC* 240.20(B) is the foundational requirement for a common trip function in a circuit breaker; however, it also goes on to explain where independent trip is permitted.

For Replacement Use Only not-CTL – The Class CTL (circuit limiting) panelboard has only been in existence for about 25 years, even though the lighting and appliance branch circuit panelboard has been in the *NEC* for decades. CTL panelboards have a rejection means designed to reject more than the appropriate number of circuit breakers that can be installed in the panel. The marking "For replacement Use Only Not CTL Assemblies" means that the circuit breaker does not have CTL rejection provisions and is intended for replacement in older equipment pre-dating the CTL requirements for circuit breakers and panelboards. Circuit breakers with this designation should not be installed in a panelboard marked "Class CTL Panelboard" since that would be a violation of the listing of the assembly [*NEC* 110.3(B)].

Markings Found in Other Locations

The markings we will discuss below may appear in any location except the back of the circuit breaker. These markings include:

40°C – This marking indicates the maximum ambient temperature in which the circuit breaker can be applied at its marked ampere rating without rerating the ampacity of the circuit breaker. This marking is required for thermal-magnetic circuit breakers and is optional for electronic trip circuit breakers unless they are only suitable for a 25°C ambient, in which case they must be marked 25°C. When the ambient temperature rises above 40°C, the designer may need to consult the manufacturer to obtain rerating information (see item 4 in photo 3).

Class CTL – Circuit breakers marked Class CTL have a rejection means designed into the circuit breaker. Class CTL panelboards or assemblies, in conjunction with Class CTL circuit breakers, prevent more circuit breaker poles from being installed than the number for which the equipment is rated.

Photo 3. Markings Visible with Trims or Covers Removed

1. Line and load designation – Circuit breakers marked with "line" and "load" designations are not suitable for reverse connection. Circuit breakers with interchangeable trip units must be marked "line" and "load" unless there is no risk of shock when changing the trip unit.

2. Interrupting ratings – All circuit breakers with an interrupting rating more than 5000 A must be marked with an interrupting rating (*NEC* 240.83(C)). Interrupting ratings are stated in RMS symmetrical amperes. If the short-circuit current rating of the equipment in which the circuit breaker is installed is less than the interrupting rating of the circuit breaker, then the lesser rating applies. Circuit breakers should be reviewed after installation to ensure they have an interrupting rating suitable for the application. This marking may be found in any location except the back of circuit breakers that are 1-½ inches wide per pole or less due to the size constraint.

3. Ampere rating (if more than 100 A) – The ampere rating of a circuit breaker larger than 100 A may be found in a location that is visible after the cover or trim is removed. This marking requirement also applies to interchangeable trip units (*NEC* 240.83(A)).

5. Terminations (Cu-Al wire) – Circuit breakers must be marked with the type material (Cu-Al) and size of wire for which their terminals are suitable for use. If suitable for use with only copper or only aluminum, then the word "only" must be used. The abbreviations "CU" and "AL" are generally found on circuit breakers as permitted by the product standard. If only solid 10–14 AWG wire can be used, then that information must be noted. The number of wires per terminal will also be noted if more than one wire per terminal is permitted (*NEC* 110.14(A)).

6. Tightening torque – The nominal torque for all field-wiring terminals must be marked. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be found in any location except on the back.

7. Wire temperature ratings – Circuit breakers rated 125 A or less may be marked as suitable for use with 60°C, 60/75°C or 75°C only wire. Circuit breakers rated more than 125 A are rated for use with 75°C wire; the marking is optional. It is always permissible to use wire with a higher temperature rating, but it must be sized in accordance with the temperature marking on the circuit breaker and *NEC* Table 310.16. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be in any location except on the back (*NEC* 110.14(C)1).

8. HACR type – This marking indicates the circuit breaker is suitable for use with the group motor installations typically found in heating, air conditioning and refrigeration equipment. The *NEC* 2005 no longer has this marking requirement. The electrical industry determined that circuit breakers are considered suitable for use with such equipment without any further testing, therefore, the HACR marking is no longer required on air conditioning and refrigeration equipment or on circuit breakers for use in these applications. The requirement for this marking has also been removed from the UL 1995 product standard for HVAC equipment (see item 3 in photo 1).

Maximum wire size – Circuit breakers are typically marked with a wire range, however that marking is not mandatory. If the circuit breaker cannot accept the next larger wire size required for the ampere rating, then the maximum wire size must be marked in any location except the back (see item 5 in photo 3).

Separately shipped connectors –If connectors are not factory installed on a circuit breaker, then it must be marked with the proper connectors or terminal kits required in any location except the back (see item 8 in photo 3).

Ground-Fault Protection for People

The GFCI function, as part of a circuit breaker, provides ground-fault protection for people and has a number of unique marking and instruction requirements.

Test function – The GFCI has a test function that requires action upon installation and on a monthly basis. GFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate monthly testing.

Photo 4. 1Ø – 3Ø Marking
1. 1Ø – 3Ø marking – A 2-pole circuit breaker used to protect a 3-phase load on a corner-grounded delta system must be rated and marked for such an installation. Circuit breakers marked "1-phase – 3-phase" or "1Ø – 3Ø "are suitable for use on 3-phase corner-grounded delta or single-phase circuits (*NEC* 240.85).

Suitable for continuous operation at 100% of ampere rating only if used in a recognized enclosure 52 in. (1321 mm) by 20 in. (508 mm) x 7 1/2 in. (190 mm) deep or larger. Use only with 90° rated wire sized per the ampacity of 75° rated wire.

Figure 1. 100% Rated Marking
100 percent continuous rated – Circuit breakers are typically intended for use at not more than 80% of rated current where the load is considered continuous, or will continue for 3 hours or more (*NEC* 210.20). However, some circuit breakers are rated for continuous use at 100% of their current rating. These circuit breakers must be so marked in any location except on the back. Enclosure information such as a specific type or specific volume must also be marked. A requirement for the use of 90°C insulated wire sized to the 75°C column in *NEC* Table 310.16 and specific ventilation requirements may also be marked on the circuit breaker or equipment (*NEC* 210.20(A) and 215.3).

"Class A" marking – A "Class A" ground-fault device is intended to protect people. The Class A marking indicates that the trip threshold of the GFCI is between 4 mA and 6 mA. This marking may be in any location except the back.

Instructions – All GFCI circuit breakers must include instructions for the installer plus instructions on the use of the test function. A hangtag or self-adhesive label must also be provided, instructing the user to test the GFCI at least monthly. Inspectors should check to see that the tag or label has been properly installed.

Ground-Fault Protection for Equipment

Circuit breakers may also include a ground-fault protection for equipment (GFPE) function that, like GFCIs, has a number of unique marking and instruction requirements.

Test function – GFPE circuit breakers may have a test button or switch that may be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Trip level – GFPE circuit breakers must be marked with their trip threshold in milliamperes in a location accessible without removing trims or covers.

Instructions – All GFPE circuit breakers must include instructions for the installer.

Arc-Fault Protection

Circuit breakers may also include arc-fault protection (AFCI) that, like GFCIs, also has a number of unique marking and instruction requirements.

Device identification – AFCIs must also be identified appropriately. Branch/feeder or Combination type AFCIs must be so marked in a location visible when the trims or covers are removed. This is an important marking to note as we move into 2008, as *NEC*-2005 requires Combination AFCIs in bedrooms effective January 1, 2008 (*NEC* 210.12).

Test function – AFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Instructions – All AFCI circuit breakers must include instructions for the installer.

Circuit Breaker Markings Ensure a Safe Electrical Installation

So why are all of these markings on circuit breakers? Without them, it would be nearly impossible to install or inspect an installation for the appropriate performance ratings and fundamental electrical connections. When designing or completing an installation, key items to review are:

1. Are the voltage, continuous current, and interrupting ratings appropriate for the application?
2. Does the application require SWD or HID ratings?
3. Is the wire type and size appropriate for the circuit breaker?
4. Is the circuit breaker suitable for the equipment in which it is installed? Have other protective functions such as GFCI or AFCI been provided as required by the *NEC*?
5. Is the temperature rating of the circuit breaker suitable for the application?

The UL Marking Guide for Molded Case Circuit Breakers is a valuable resource to understand circuit breaker markings that may further explain these and other markings in detail. If you have questions about CB markings not answered here, consult the Marking Guide or the manufacturer to assist in an *NEC*-compliant installation.

Mr. Larsen, P. E., is the manager, Industry Standards for Circuit Protection for Square D Company / Schneider Electric. Mr. Larsen has served in various positions over the past 32 years. He is a member of several UL, IEEE and NEMA technical committees. His other memberships include NFPA, IAEI and CANENA.

What Do the Markings on Circuit Breakers Mean?

by Ed Larsen, P. E.

Have you ever been confused about what the markings on circuit breakers mean? Understanding the markings on electrical equipment is a fundamental need to ensure a safe and reliable electrical installation. Circuit breaker marking requirements are established by the requirements found in the *NEC* and the UL 489 product standard. This article will discuss the most common markings and where they can be found.

The UL 489 product standard for Molded Case Circuit Breakers specifies the information to be marked on circuit breakers and where it is to be located, so let's discuss what information needs to be marked on the circuit breaker and the location where you will find those markings. Keep in mind the UL® standard specifies minimum requirements. Circuit breaker manufacturers may provide additional information or provide information in a more convenient location.

Markings Visible without Removing Trims or Covers

UL 489 requires that some markings be visible without removing trims or covers. This location is typically referred to as the handle escutcheon (see photo 1).

Markings Visible with Trims or Covers Removed

UL 489 requires other markings be visible on an installed circuit breaker with trims or covers removed. This location is typically referred to as the face of the circuit breaker (see photos 2–4).

Other markings which should be visible with trims or covers removed are:

Independent trip – Multi-pole circuit breakers are constructed with either a common trip, where all poles are mechanically tripped when one of the poles trips, or an independent trip construction where only the pole that is involved with the overcurrent condition trips. If a 2-pole circuit breaker does not have an internal com-

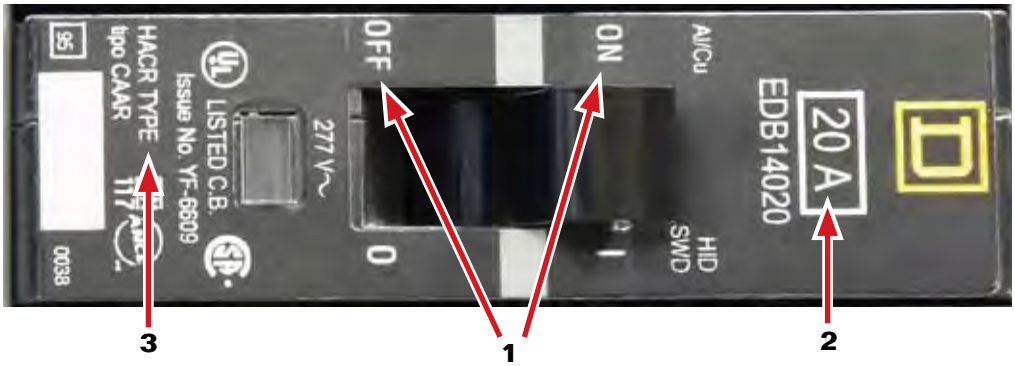

Photo 1. Markings Visible with Trims or Covers in Place

1. ON and OFF – The ON and OFF (closed and open) positions of the handle must be marked (*NEC* 240.81). These positions may also be marked with the internationally recognized "I" and "O" symbols, although this is not a UL requirement. If these markings are not visible when a motor operator is installed over the circuit breaker markings, then they must appear on the motor operator. Motor operators may be found in applications where remote or automatic operation of a circuit breaker is required.

2. Ampere rating (if 100 A or less) – The ampere rating may be located on the handle escutcheon or on the handle itself (*NEC* 240.83(B)). Circuit breakers that are rated more than 100 A may have their ampere rating marked in a position that is not visible with trims or covers in place.

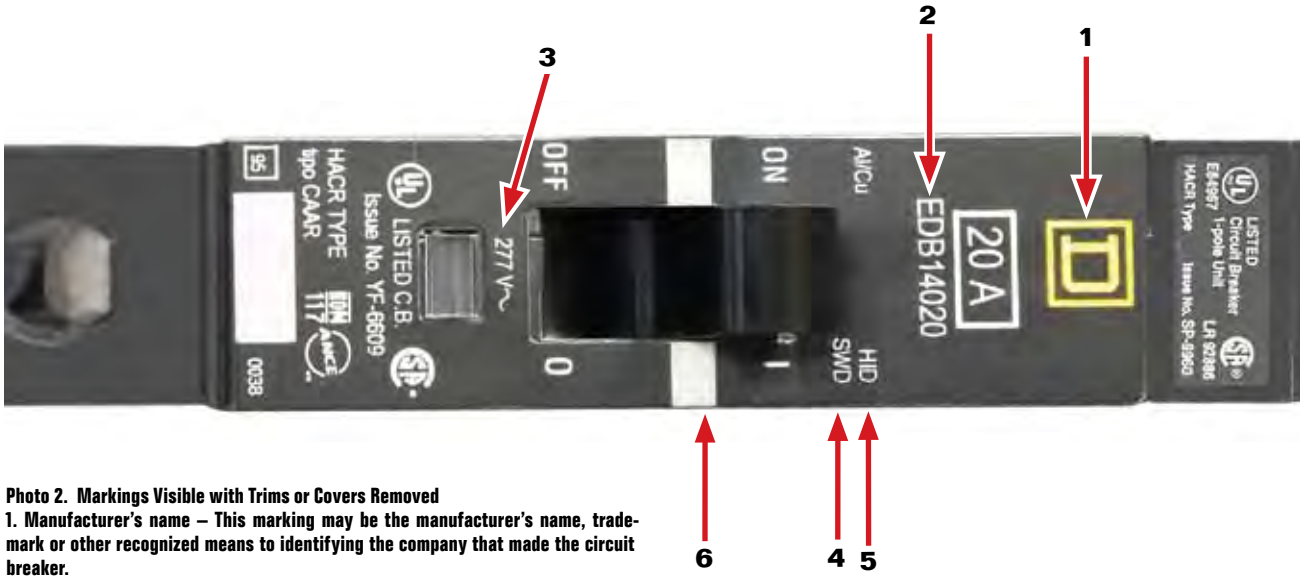

Photo 2. Markings Visible with Trims or Covers Removed

1. Manufacturer's name – This marking may be the manufacturer's name, trademark or other recognized means to identifying the company that made the circuit breaker.

2. Type designation – All circuit breakers are marked with a type designation, which may be a catalog number prefix or a separate designation. Equipment labels, such as on panelboards, will list the circuit breaker types suitable for use. Note that the word "type" may or may not be used on the circuit breaker or equipment labels. It is important to review the markings on the equipment, such as a panelboard, to make sure the circuit breaker designations on the equipment match the marking on the circuit breaker.

3. Voltage rating – All circuit breakers must be marked with a voltage rating. If the rating is not marked "ac" or "dc," then it is suitable for both. 120/240 V rated circuit breakers are suitable for use on single and three-phase 4-wire systems where the line-to-ground voltage does not exceed 120 V. Wye rated circuit breakers such as those rated 480Y/277 V, are suitable for use on three-phase 4-wire systems where the voltage to ground does not exceed 277 V. Special attention needs to be given to high leg or corner-grounded delta systems to insure that the circuit breaker has the appropriate rating. A review to see that the circuit breakers installed have a voltage rating suitable for the application is paramount for a code-compliant installation (*NEC* 240.83(E)).

4. SWD – 15- or 20-A circuit breakers rated 347 V or less may be marked "SWD," meaning that they are suitable for switching fluorescent lighting loads on a regular basis (*NEC* 240.83(D)). These circuit breakers are evaluated for high endurance use, since they will be used similar to a light switch.

5. HID – 50 A or less circuit breakers rated 480 V or less may be marked "HID," meaning they are suitable for switching high intensity discharge or fluorescent lighting loads on a regular basis. These circuit breakers may employ a different construction than a standard SWD circuit breaker in order to address the high inrush current resulting from the lower power factor created by the HID lighting (*NEC* 240.83(D)). These circuit breakers also undergo additional endurance evaluation to demonstrate their ability to perform the switching duty.

6. Trip and reset – Circuit breaker handles typically assume an intermediate position when tripped. This position must either be marked on the circuit breaker or on the equipment into which it is to be installed. If these markings are not visible when a motor operator is installed, then a "tripped" marking may appear on the motor operator.

mon trip feature, then it must be marked "Independent Trip" or "No Common Trip." *NEC* 240.20(B) is the foundational requirement for a common trip function in a circuit breaker; however, it also goes on to explain where independent trip is permitted.

For Replacement Use Only not-CTL – The Class CTL (circuit limiting) panelboard has only been in existence for about 25 years, even though the lighting and appliance branch circuit panelboard has been in the *NEC* for decades. CTL panelboards have a rejection means designed to reject more than the appropriate number of circuit breakers that can be installed in the panel. The marking "For replacement Use Only Not CTL Assemblies" means that the circuit breaker does not have CTL rejection provisions and is intended for replacement in older equipment pre-dating the CTL requirements for circuit breakers and panelboards. Circuit breakers with this designation should not be installed in a panelboard marked "Class CTL Panelboard" since that would be a violation of the listing of the assembly [*NEC* 110.3(B)].

Markings Found in Other Locations

The markings we will discuss below may appear in any location except the back of the circuit breaker. These markings include:

40°C – This marking indicates the maximum ambient temperature in which the circuit breaker can be applied at its marked ampere rating without rerating the ampacity of the circuit breaker. This marking is required for thermal-magnetic circuit breakers and is optional for electronic trip circuit breakers unless they are only suitable for a 25°C ambient, in which case they must be marked 25°C. When the ambient temperature rises above 40°C, the designer may need to consult the manufacturer to obtain rerating information (see item 4 in photo 3).

Class CTL – Circuit breakers marked Class CTL have a rejection means designed into the circuit breaker. Class CTL panelboards or assemblies, in conjunction with Class CTL circuit breakers, prevent more circuit breaker poles from being installed than the number for which the equipment is rated.

Photo 3. Markings Visible with Trims or Covers Removed

1. Line and load designation – Circuit breakers marked with "line" and "load" designations are not suitable for reverse connection. Circuit breakers with interchangeable trip units must be marked "line" and "load" unless there is no risk of shock when changing the trip unit.

2. Interrupting ratings – All circuit breakers with an interrupting rating more than 5000 A must be marked with an interrupting rating (*NEC* 240.83(C)). Interrupting ratings are stated in RMS symmetrical amperes. If the short-circuit current rating of the equipment in which the circuit breaker is installed is less than the interrupting rating of the circuit breaker, then the lesser rating applies. Circuit breakers should be reviewed after installation to ensure they have an interrupting rating suitable for the application. This marking may be found in any location except the back of circuit breakers that are 1-½ inches wide per pole or less due to the size constraint.

3. Ampere rating (if more than 100 A) – The ampere rating of a circuit breaker larger than 100 A may be found in a location that is visible after the cover or trim is removed. This marking requirement also applies to interchangeable trip units (*NEC* 240.83(A)).

5. Terminations (Cu-Al wire) – Circuit breakers must be marked with the type material (Cu-Al) and size of wire for which their terminals are suitable for use. If suitable for use with only copper or only aluminum, then the word "only" must be used. The abbreviations "CU" and "AL" are generally found on circuit breakers as permitted by the product standard. If only solid 10–14 AWG wire can be used, then that information must be noted. The number of wires per terminal will also be noted if more than one wire per terminal is permitted (*NEC* 110.14(A)).

6. Tightening torque – The nominal torque for all field-wiring terminals must be marked. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be found in any location except on the back.

7. Wire temperature ratings – Circuit breakers rated 125 A or less may be marked as suitable for use with 60°C, 60/75°C or 75°C only wire. Circuit breakers rated more than 125 A are rated for use with 75°C wire; the marking is optional. It is always permissible to use wire with a higher temperature rating, but it must be sized in accordance with the temperature marking on the circuit breaker and *NEC* Table 310.16. If the width of the circuit breaker is 1-½ inches per pole or less, then this marking may be in any location except on the back (*NEC* 110.14(C)1).

8. HACR type – This marking indicates the circuit breaker is suitable for use with the group motor installations typically found in heating, air conditioning and refrigeration equipment. The *NEC* 2005 no longer has this marking requirement. The electrical industry determined that circuit breakers are considered suitable for use with such equipment without any further testing, therefore, the HACR marking is no longer required on air conditioning and refrigeration equipment or on circuit breakers for use in these applications. The requirement for this marking has also been removed from the UL 1995 product standard for HVAC equipment (see item 3 in photo 1).

Maximum wire size – Circuit breakers are typically marked with a wire range, however that marking is not mandatory. If the circuit breaker cannot accept the next larger wire size required for the ampere rating, then the maximum wire size must be marked in any location except the back (see item 5 in photo 3).

Separately shipped connectors –If connectors are not factory installed on a circuit breaker, then it must be marked with the proper connectors or terminal kits required in any location except the back (see item 8 in photo 3).

Ground-Fault Protection for People

The GFCI function, as part of a circuit breaker, provides ground-fault protection for people and has a number of unique marking and instruction requirements.

Test function – The GFCI has a test function that requires action upon installation and on a monthly basis. GFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate monthly testing.

Photo 4. 1Ø – 3Ø Marking
1. 1Ø – 3Ø marking – A 2-pole circuit breaker used to protect a 3-phase load on a corner-grounded delta system must be rated and marked for such an installation. Circuit breakers marked "1-phase – 3-phase" or "1Ø – 3Ø "are suitable for use on 3-phase corner-grounded delta or single-phase circuits (*NEC* 240.85).

Suitable for continuous operation at 100% of ampere rating only if used in a recognized enclosure 52 in. (1321 mm) by 20 in. (508 mm) x 7 1/2 in. (190 mm) deep or larger. Use only with 90° rated wire sized per the ampacity of 75° rated wire.

Figure 1. 100% Rated Marking
100 percent continuous rated – Circuit breakers are typically intended for use at not more than 80% of rated current where the load is considered continuous, or will continue for 3 hours or more (*NEC* 210.20). However, some circuit breakers are rated for continuous use at 100% of their current rating. These circuit breakers must be so marked in any location except on the back. Enclosure information such as a specific type or specific volume must also be marked. A requirement for the use of 90°C insulated wire sized to the 75°C column in *NEC* Table 310.16 and specific ventilation requirements may also be marked on the circuit breaker or equipment (*NEC* 210.20(A) and 215.3).

"Class A" marking – A "Class A" ground-fault device is intended to protect people. The Class A marking indicates that the trip threshold of the GFCI is between 4 mA and 6 mA. This marking may be in any location except the back.

Instructions – All GFCI circuit breakers must include instructions for the installer plus instructions on the use of the test function. A hangtag or self-adhesive label must also be provided, instructing the user to test the GFCI at least monthly. Inspectors should check to see that the tag or label has been properly installed.

Ground-Fault Protection for Equipment

Circuit breakers may also include a ground-fault protection for equipment (GFPE) function that, like GFCIs, has a number of unique marking and instruction requirements.

Test function – GFPE circuit breakers may have a test button or switch that may be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Trip level – GFPE circuit breakers must be marked with their trip threshold in milliamperes in a location accessible without removing trims or covers.

Instructions – All GFPE circuit breakers must include instructions for the installer.

Arc-Fault Protection

Circuit breakers may also include arc-fault protection (AFCI) that, like GFCIs, also has a number of unique marking and instruction requirements.

Device identification – AFCIs must also be identified appropriately. Branch/feeder or Combination type AFCIs must be so marked in a location visible when the trims or covers are removed. This is an important marking to note as we move into 2008, as *NEC*-2005 requires Combination AFCIs in bedrooms effective January 1, 2008 (*NEC* 210.12).

Test function – AFCI circuit breakers must have a test button or switch that must be labeled in a location accessible without removing trims or covers in order to facilitate testing.

Instructions – All AFCI circuit breakers must include instructions for the installer.

Circuit Breaker Markings Ensure a Safe Electrical Installation

So why are all of these markings on circuit breakers? Without them, it would be nearly impossible to install or inspect an installation for the appropriate performance ratings and fundamental electrical connections. When designing or completing an installation, key items to review are:

1. Are the voltage, continuous current, and interrupting ratings appropriate for the application?
2. Does the application require SWD or HID ratings?
3. Is the wire type and size appropriate for the circuit breaker?
4. Is the circuit breaker suitable for the equipment in which it is installed? Have other protective functions such as GFCI or AFCI been provided as required by the *NEC*?
5. Is the temperature rating of the circuit breaker suitable for the application?

The UL Marking Guide for Molded Case Circuit Breakers is a valuable resource to understand circuit breaker markings that may further explain these and other markings in detail. If you have questions about CB markings not answered here, consult the Marking Guide or the manufacturer to assist in an *NEC*-compliant installation.

Multiband and Silicon Integrated Antennas for Wireless Sensor Networks

by

Joan Gemio Valero

Ph.D. Dissertation

Supervisor: Josep Parrón Granados

Antenna and Microwave Systems Group
Department of Telecommunications and Systems Engineering

Universitat Autònoma de Barcelona

Barcelona, July 2011

Abstract

Wireless technologies have triggered an important revolution in the world of telecommunication networks and services. New systems, such as the latest generation mobile phones or wireless LANs, have appeared being enthusiastically accepted by people. In particular, applications related to remote sensor networks are growing rapidly (for temperature monitoring, the detection of free parking spaces, etc.).

This thesis is focused on antenna design for distributed wireless sensor networks. The remote sensors we are considering are connected to a central unit using a wireless link in the 5.8 GHz ISM band and the central unit transmits the collected information to the Internet via a WLAN connection.

In the central unit multiband antennas are necessary to cover several frequency bands with a single radiating element. Two solutions to obtain this multiband performance are proposed: fractal-based ground planes and resonator loaded monopoles. Several novel antennas that easily meet the system requirements are manufactured and measured.

For remote sensors small dimensions and low costs are desired. The use of silicon integrated antennas fabricated with standard CMOS technology is a good choice to achieve these requirements. First, the main problems of antenna integration are discussed and, then a possible solution to improve the antenna efficiency is presented together with a study of the effects of other elements integrated in the same chip with the antenna. The measurements of the manufactured prototypes demonstrate that antenna integration at 5.8 GHz is feasible, and that system ranges of some meters can be obtained even when the antenna is fabricated together with other elements integrated in the same chip.

The possibility of having some of the sensors implanted inside the body will be a reality in the near future, for this reason the particular case of implanted antennas is also analyzed. The last part of this thesis is devoted to study the body effects on antenna performance and evaluate the additional propagation losses introduced by the body tissues.

Agraïments

En aquesta vida tot té un inici i un final. Ara ha arribat un dels moments més esperats d'aquesta tesis, el moment d'escriure els agraïments, fet que indica que aquest treball ha arribat a la seva culminació. A més és l'ocasió perfecte per donar les gràcies a totes aquelles persones que m'han acompanyat durant aquests 4 anys.

Gràcies Josep (director d'aquesta tesis) per donar-me l'oportunitat de realitzar aquest treball i per poder gaudir de la teva ajuda sempre que l'he necessitat. Gràcies també als altres membres del grup AMS (Pedro, Oscar, Gary), per totes les aportacions que heu fet durant aquest període. Ramón, tot i que ja no estàs en el grup, no m'oblido pas de tu. Jordi Soler, et vull agrair tots els comentaris que has anat fent per millorar el treball realitzat. Felix i Jordi, gràcies per totes les antenes fabricades. Gràcies a tots els professors de la ETSE, ja que sense el que ells em van ensenyar no hauria pogut fer aquesta tesis.

També vull agrair l'ajuda rebuda per part de membres d'altres institucions: a Jose Maria González Arbesú (UPC) per ajudar-me a fer les mesures dels diagrames de radiació i a Jordi Sacristán (CNM) i Toni Baldi (CNM), per fer possible que pogués fabricar les antenes integrades en silici.

Gràcies a tots els company del despatx (Mónica, Jordi, Eden, Rafa, Mercedes, Verdú) i als que no esteu en el despatx (Jose, Toni) per haver fet més entretinguts els dies que ens hem passat aquí tancats treballant. Algun@s de vosaltres heu estat molt més que simples company@s de feina, i espero que aquesta amistat perduri en el futur.

A tota la gent que fora de la universitat m'ha donat suport i m'ha ajudat a gaudir d'aquest període, també els vull dir gràcies. Gràcies Monica, Oscar, Jordi, Laia, i gràcies també a tots els del "Patinet" (Anna, August, Canari, David, Jaume, Jordi, ...) per haver compartit amb mi molts caps de setmana, ja sigui sobre dues o quatre rodes.

Pare, mare i avis, a vosaltres us deixo pel final. Vosaltres em vareu motivar a iniciar aquesta tesis i sempre heu estat presents en aquest llarg camí. Heu suportat el meu mal humor quan les coses no anaven com jo volia i sempre heu estat allà, animant-me a tirar endavant i a arribar al final d'aquest camí que vaig iniciar ja fa un bon temps. Moltes gràcies per tot, i recordeu que aquesta tesis va dedicada a vosaltres !!!!

Joan Gemio Valero, Juliol 2011

This work has been supported by the Spanish Ministry of Science and Innovation through grants **TEC2006-13248-C04-01** and **TEC2009-13897-C03-02**, and by the Spanish Ministry of Education through the **FPU program**.

Silicon integrated antennas were manufactured in the integrated clean room for micro and nano manufacturing of Instituto de Microelectrónica de Barcelona - Centro Nacional de Microelectrónica (IMB-CNM) supported by the Spanish Ministry of Science and Innovation through the **GICSERV program ref. 2009-NGG 151** and **ref. 2010-NGG 183**.

Radiation pattern measurements were carried out at the anechoic chamber of the Antenna Lab group of the Universitat Politecnica de Catalunya.

2.26 Schematic representation of a trap dipole antenna [66]. 39

2.27 Monopole antenna loaded with two double layer magnetic resonators DL-CLL [67] of identical dimensions fabricated on Rogers RO4003C [68] double sided 0.508 mm substrate ($\epsilon_r = 3.38$, $tan\delta = 0.0021$). 40

2.28 Parametric study of the variation of the input reflection coefficient S_{11} with respect to (a) the monopole length L_M, (b) the resonator width R_W, (c) the length of the resonator capacitor strip R_{CL}. 41

2.29 Parametric study of the variation of the input reflection coefficient S_{11} with respect to (a) the monopole width W_M and (b) the resonator offset position R_O. 42

2.30 Simulated and measured S_{11} parameters of the prototype antenna with the dimensions shown in table 2.3. 44

2.31 Simulated current distributions at 2.45 GHz, 4.9 GHz and 5.875 GHz. Each image is individually normalized and displayed on a 30 dB scale. 44

2.32 Simulated radiation patterns of the prototype antenna whose dimensions are shown in table 2.3. Black dotted lines are used for the copolar components. Crosspolar components are too low to be plotted with the current axis configuration. 45

2.33 Radiation efficiency and total efficiency of the prototype whose dimensions are shown in table 2.3. Efficiency measurements were carried out using the method presented in [69]. 46

2.34 SRR geometry and impinging plane wave for computation of the monostatic radar cross section. The SRR is supported on Rogers RO4003C 0.508 mm substrate ($\varepsilon_r = 3.38$, $\tan\delta = 0.0027$). $L_1 = 8.2$ mm, $L_2 = 6.6$ mm, $w_1 = w_2 = 0.5$ mm, $g_1 = g_2 = 1.5$ mm, $t = 0.3$ mm. 47

2.35 Computed monostatic radar cross section in free space for the SRR of figure 2.34. Solid line: stand alone outer open ring. Dashed line: stand alone inner open ring. Dotted line: SRR. 48

2.36 Simulated current distributions. Each image is individually normalized and displayed on a 20 dB scale. Arrows are scaled according to the normalized current levels. 48

2.37 SRR loaded monopole. The structure was fabricated on Rogers RO4003C 0.508 mm substrate ($\varepsilon_r = 3.38$, $\tan\delta = 0.0027$). $L_m = 22$ mm, $w_m = 6$ mm, $L_0 = 1$ mm, $w_0 = 1$ mm, $h = 2.5$ mm, $s = 0.3$ mm. SRRs dimensions are the same as in figure 2.34. 49

2.38 Simulations comparing the stand alone monopole and the SRR loaded monopole. 50

2.39 Simulated radiation efficiency of the stand alone monopole and the SRR loaded monopole. 51

2.40 SRR loaded monopole prototype antenna. (a) Prototype antenna mounted on a large ground plane. (b) Simulated and measured S_{11} parameters. (c) Simulated and measured radiation efficiency. 51

2.41 Measured normalized radiation patterns of the SRR loaded monopole. Each cut has been normalized with reference to its maximum. Black dotted lines are used for the copolar component; red dashed lines are used for the crosspolar component. 53

2.42 Fabricated prototype. In the rear side a conductor strip is used to reduce the resonance frequency of the large resonator. 54

2.43 Parametric study of the variation of the S_{11} parameter with respect to (a) the length of the monopole L_M, (b) the width of the monopole W_M, (c) (d) the height of the resonators H_{R1}, H_{R2}, (e) the length of the rear side strip L_S and (f) the width of the resonators W_R. 55

2.44 Simulated current distributions at the S_{11} minimums. Each image is individually normalized and displayed on a 30 dB scale. 56

2.45 Measured and simulated S_{11} parameter of the asymmetric loaded monopole antenna. Blue solid line shows simulated results, and red dashed line shows measured results. 57

2.46 Measured and simulated results for the radiation efficiency and the total efficiency. Total efficiency takes into account the mismatch loss. 58

2.47 Measured radiation patterns of the asymmetric loaded monopole in the three operating bands. Each cut has been normalized with reference to its maximum. Black dotted lines are used for the copolar component; red dashed lines are used for the crosspolar component. 58

3.1 Example of intra-chip communication system. (a) Conceptual system illustration of intra-chip wireless interconnected system for clock signal distribution. (b) 0.18 μm clock transmitter and receiver with zigzag dipole antennas [78]. 64

3.2 Examples of integrated antennas operating at frequencies higher than 60 GHz. (a) Array antenna fabricated on high resistivity silicon presented by Buechler in 1986 [79]. (b) Folded slot antenna designed at 79 GHz [80]. (c) and (d) 60 GHz on-chip Yagi antennas [81, 82]. 65

3.3 Integrated antenna presented by Lin in [83]. (a) Layout of the 2 mm zigzag dipole. (b) Antenna measurement setup with a signal generator and a spectrum analyzer. (c) Antenna pair gain as a function of the distance in three different environments at 24 GHz. The inset shows the 2 mm zigzag dipole antenna radiation pattern. 66

3.4 Fully integrated transmitter with an on-chip dipole antenna at 24 GHz [91]. (a) Photomicrograph of the fully integrated transmitter and frequency synthesizer. (b) Reception of the signal generated by a transmitter IC with an on-chip antenna using a 20 dBi gain horn antenna. 67

3.5 Antenna pair gain as a function of the distance of a 5.8 GHz monopole and a 24 GHz dipole antenna. The antennas are located 52 cm and 5 mm above the ground [75]. 67

3.6 Simplified metal/dielectric layer structure of the fabricated prototypes. It is equivalent to a standard 0.18 μm RF CMOS technology. 69

3.7 Antenna input parameters and radiation efficiency with and without the SiO_2 layer. The silicon conductivity is $\sigma = 5$ S/m. The antenna is a meandered dipole and the chip dimensions are 5.25 mm x 1.9 mm. 70

3.8 Effects of the silicon conductivity in antenna parameters. Input reflection coefficient, input impedance and efficiency are shown. The antenna is a meandered dipole and chip dimensions are 5.25 mm x 1.9 mm. 71

3.9 Silicon antennas measurement setup. (a) A 1 cm PVC support was used to separate the antenna from the metallic chuck. (b) The differential dipole antennas were fed with a Picoprobe GSGSG probe. 72

3.10 Propagation measurement setup used for the gain measurement of the fabricated prototypes. Gain measurements were carried out in the 5.8 GHz ISM band. 73

3.11 Different components used for the propagation measurements. (a) Signal generator with a balun. (b) Receiving patch antenna fabricated on Rogers RO4003C substrate ($\varepsilon_r = 3.38$, $\tan\delta = 0.0027$). 74

3.12 Input parameters of a meandered dipole antenna fabricated on silicon. Solid line shows the simulated results. Dashed lines show the measured results of the same antenna fabricated on different wafers. A 100 Ω impedance was used as differential reference impedance. 75

3.13 Topologies included in the miniaturization study. 76

3.14 Measured and simulated results of a meandered dipole (figure 3.13) with $N = 8$ meanders, conductor width = 100 μm and $L_1 = 9.2$ mm. 76

3.15 Antennas with different miniaturization techniques. The chip dimensions are 12.5 mm x 2 mm. 77

3.16 Results of the miniaturization study in the probe station scenario. (a) Measured miniaturization factor (MF). (b) Simulated total efficiency of the different topologies. N is the number of meanders. The dimensions of the other variables (defined in figure 3.13) are in mm. The reference antenna for the MF calculation is a simple flat dipole with $F_{flat-dipole} = 68$ GHz·mm. 78

3.17 Results of the miniaturization study in a free space scenario. (a) Simulated miniaturization factor (MF) (b) Simulated total efficiency of the different topologies. N is the number of meanders. The dimensions of the other variables (defined in figure 3.13) are in mm. The reference antenna for the MF calculation is a simple flat dipole with $F_{flat-dipole} = 89$ GHz·mm. . . . 79

3.18 Results of the miniaturization study in the probe station scenario when antennas are fabricated on a low-loss substrate (RO3010, $\varepsilon_r = 10.2,\ tan\delta = 0.0023$). (a) Simulated miniaturization factor (MF). (b) Simulated radiation efficiency of the different topologies. N is the number of meanders. The dimensions of the other variables (defined in figure 3.13) are in mm. The reference antenna for the MF calculation is a simple flat dipole with $F_{flat-dipole} = 75.5$ GHz·mm. 80

3.19 Design of the fabricated prototype antennas. (a) Image of the fabricated meandered dipole antenna. (b) Schematic representation of the etching patterns used for the micromachining process. Black rectangles indicate the areas where silicon is etched. 82

3.20 Prototype antennas with micromachining. (a) Top view of one of the antennas. (b) Rear view of some of the antennas. 83

3.21 Simulated input reflection coefficient. (a) Different etching configurations are applied. The etching depth is 450 μm. (b) Different etching depths (μm) are applied. The M2 pattern is used for the micromachining process. The wafers thickness is 500 μm. WM = Without Micromachining. 84

3.22 Simulated radiation parameters when micromachining techniques are applied. (a) Radiation efficiency as a function of frequency. The etching depth is 450 μm. (b) and (c) radiation efficiency and gain improvement as a function of the etching depth. The operating frequency is 5.8 GHz and the wafers thickness is 500 μm. The reference gain for the gain improvement plot is the gain of the antenna without micromachining (−18.95 dB). WM = Without Micromachining. 85

3.23 Simulated gain improvement as a function of the etched area position. (a) Pattern used in the micromachining process. (b) Gain improvement plot. The reference gain is the gain of the antenna without micromachining (−18.95 dB). 87

3.24 Performance improvement due to micromachining in a free space scenario. (a) Simulated input reflection coefficient. The etching depth is 450 μm. (b) Gain improvement as a function of the etching depth. The operating frequency is 5.8 GHz and the wafers thickness is 500 μm. WM = Without Micromachining. 88

3.25 Fabricated prototype antenna for the evaluation of the coil effects on the RF link. The chip dimensions are 3.8 mm x 5.2 mm. 89

3.26 Prototype antennas. The chip dimensions are 3.8 mm x 5.2 mm. The distances d between the RF antenna and the coil are 320 μm, 570 μm, 820 μm, 1.07 mm, 1.32 mm and 1.57 mm. 89

3.27 Measured input reflection coefficient of an integrated antenna fabricated together with a coil for an inductive link (figure 3.25). The distance between the antenna and the coil is d = 320 μm. 90

3.28 Radiation parameters as a function of the distance d between the RF antenna and the coil. (a) Antenna gain. The simulated gain without the coil is -17.7 dB. (b) Gain degradation. The reference gain is the gain when the coil is at $d = 1.57$ mm. Operating frequency $f = 5.8$ GHz. 90

3.29 Simulated gain degradation in a free space scenario as a function of the distance d between the RF antenna and the coil. The reference gain (-25.5 dB) is the gain when the coil is at $d = 1.57$ mm. Operating frequency $f = 5.8$ GHz. 92

Chapter 1

Introduction

1.1 Wireless communication systems: New trends and use of the ISM bands

1.1.1 New trends

Over recent years, wireless communication systems have spread widely and new communication services have been enthusiastically adopted by people around the world. Mobile communication systems have had a massive growth, firstly with voice services, and recently, with the latest generation of mobile data services that allow for high data transmission rates. Nowadays, it is quite common to find people reading their electronic mail, reading the last news in an online newspaper or updating their Facebook page in the train during their journey to the office.

The proliferation of computers and wireless communications has evolved into an era of wireless networking. Wireless Local Area Networks (WLANs) have replaced the traditional LANs in a huge number of applications because WLANs introduce benefits such as improved flexibility, mobility and ease of installation. Furthermore, the most modern commercial devices [1–4] are starting to use the latest generation mobile phone systems together with the WLAN systems to improve the user experience, providing access to the network inside and outside the office and taking advantage of the higher performance of WLANs when the user is inside.

Mobile phones and WLANs are probably the most popular wireless systems, but over recent years the use of other wireless devices has also increased. For instance remote sensor networks can be used to detect the free spaces in a parking lot and send this information to

the people that are looking for parking space [5–7]; or to precisely control the temperature at different points of a room or a building and adjust the air conditioner according to the sensors measurements [8].

In sensor networks a group of sensors are spatially distributed and, using a wireless link, they transmit the information collected to a central unit which can process it or retransmit it around the world over the Internet. In these applications sensor size and cost are key factors to ensure system viability. For this reason, the integration of the RF front-end together with the sensor elements can help obtain really small and cheap devices. Due to the increasing use of these systems, multiple commercial transceiver modules for these applications can be found [9]. However, the radiating element is usually an external antenna that increases the system size. Furthermore, costs are also increased by the need for a physical connection between the antenna and the integrated front-end. The integration of the whole system (including the antenna and the sensor) in a single chip can be advantageous and avoid the need for external connections.

Another field where the use of wireless devices is increasing is in medical applications, which can be understood as a specific case of sensor networks. The aim of these systems is to improve the life quality of patients, improving their mobility during treatment and the subsequent monitoring period. These systems can be also extremely useful for the treating of chronic diseases. As an example, wireless implantable glucose monitoring systems can improve the life and mobility of people with diabetes related problems. Moreover, these systems could also increase safety by alerting the emergency services when a problem is detected.

1.1.2 Use of the ISM bands

In recent years there has been a significant increase in the number of systems and devices that operate in the Industrial, Scientific and Medical (ISM) applications frequency bands. According to the Code of Federal Regulations (CFR) of the Federal Communications Commission (FCC) [10] and the International Telecommunications Union (ITU) regulations [11], the ISM bands are for operation of "equipment or appliances designed to generate and use locally RF energy for industrial, scientific, medical, domestic or similar purposes". Typical ISM applications are the production of physical, biological, or chemical effects such as heating, ionization of gases, mechanical vibrations, hair removal or acceleration of charged particles. Specific examples of the previous applications are domestic microwave ovens, jewelry cleaners for home use or ultrasonic humidifiers. Table 1.1 shows a summary of the frequency bands defined by the FCC for ISM

Table 1.1: *Frequency bands for ISM applications defined by the Federal Communications Commission (FCC) [12].* [1] *The use of these frequency bands for ISM applications shall be subject to special authorization.* [2] *Only in Region 2.*

Frequency Range	Center frequency
13553 - 13567 kHz	13560 kHz
26957 - 27283 kHz	27120 kHz
40.66 - 40.70 MHz	40.68 MHz
433.05 - 434.79 MHz	433.92 MHz[1]
902 - 928 MHz	915 MHz[2]
2400 - 2500 MHz	2450 MHz
5725 - 5875 MHz	5800 MHz
24 - 24.25 GHz	24.125 GHz
61 - 61.5 GHz	61.25 GHz[1]
122 - 123 GHz	122.5 GHz[1]
244 - 246 GHz	245 GHz[1]

applications, also known as ISM frequency bands.

The previous definition states that ISM bands were not originally specified for telecommunication services, but the FCC mentions that these bands can also be used for this kind of services [13]. However, the radio communication services operating within these frequency bands must accept harmful interference which may be caused by the other ISM applications. The FCC has several rules and regulations that must be satisfied by these communication systems to ensure their correct operation and avoid undesirable interferences to other systems [13].

Multiple license free communication systems that use some of the ISM bands have appeared in the last years. WLANs under the IEEE (Institute of Electrical and Electronic Engineers) 802.11b standard [14], one of the most widespread standards, use the 2.45 GHz ISM band for data transmission. Other examples can be found in Bluetooth systems [15], a wireless technology standard for exchanging data over short distances from fixed and mobile devices, or Zigbee systems [16]. Apart from these communication systems, different examples where the ISM bands are used in sensor networks can be also found in literature [17, 18].

Implantable devices could also operate in the ISM bands. Originally, the Medical Implantable Communications Services (MICS) 402 - 405 MHz frequency band was defined for these devices [19]. Some of the first examples of communication systems in implantable devices can be found in wireless links for pacemakers in order to monitor the pacemaker state [20]. Pacemakers are big devices, but in new applications, like implantable glucose monitoring systems, smaller devices are necessary. For that reason, the 2.45 GHz and

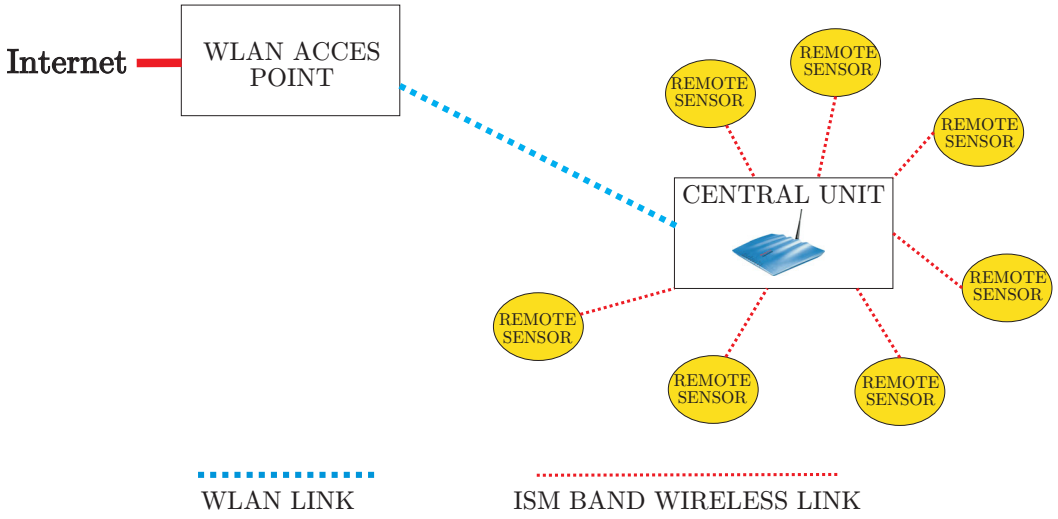

Figure 1.1: *Sensor network with a central unit that collects the sensors information and sends it to the Internet using a WLAN connection. The central unit and the remote sensors are connected using a wireless link working in the 2.45 GHz or 5.8 GHz ISM bands.*

5.8 GHz ISM bands could be considered to reduce the system dimensions.

1.2 Motivation and focus of this thesis

1.2.1 Thesis motivation and system description

This thesis is focused on the antenna design for a wireless remote sensor network with a central unit connected to the Internet through a WLAN access point (figure 1.1).

According to figure 1.1 all the sensors will be connected to a central unit and this unit will be connected to the Internet through a WLAN access point. Using the WLAN connection the central unit will be able to send the sensors information to anyplace around the world. In order to assure maximum coverage and compatibility with the latest standards, the central unit will use the 2.45 GHz and the 5 GHz bands defined by the 802.11 standards. With this dual band operation, the typical 802.11 a/b/g standards can be used, and furthermore the system will be also compatible with the most modern versions of the 802.11 standards, such as the 802.11n.

The remote sensors and the central unit will be connected through a wireless link using the ISM bands. To achieve small devices, the 5.8 GHz frequency band is advisable, but in some applications, such as implantable sensors, lower frequencies like the 2.45 GHz ISM

band can be desirable. Therefore the central unit must be able to simultaneously receive information from sensors operating in both bands.

The use of a central unit that collects the information instead of having the sensors directly connected to the Internet will allow for smaller and simpler sensors. Moreover, the distance between the sensors and the central unit will be smaller than the distance between the sensors and the WLAN access point, thus allowing for low power sensors that transmit tiny power levels, reducing power consumption and increasing the sensors battery life.

A particular case of the previous system is when one of the remote sensors is implanted inside the human body. An example of application with implanted sensors could be in a hospital, where they could be used to monitor the patients health status. Sensors would be connected to the central unit that could be a small receiver located on the patient bed or table. This central unit would be connected to the hospital network using the nearest WLAN access point, allowing the authorized doctors and nurses to access the patient information from any computer in the hospital. It is true that the central unit could be connected with a cable to the hospital network, but a WLAN connection has advantages, like the fact that the patient could be moved from one room to another (for instance for a special diagnostic operation) while keeping open the connection to the hospital network.

Multiple small variations could be introduced to the described system in order to modify its functionality. For instance a portable central unit with a Bluetooth connection could use the patient mobile phone to send the collected information to the Internet when away from a WLAN access point. Another option could be to use the new WiMAX (IEEE 802.16 [14]) systems to transmit the information to the Internet.

1.2.2 Focus of the thesis and objectives

The aim of this thesis is the design of antenna solutions to cover the needs of the sensor network presented in the previous section. The requirements of the central unit antenna and the sensors antenna are quite different; therefore both problems will be analyzed separately.

According to the above system description, the central unit must be able to use the 2.45 GHz and 5 GHz bands defined by the 802.11 standards, as well as the 5.8 GHz ISM band. One possible option could be to use a different antenna for each band; but this is not an optimal solution. Multiband radiators that can give service to several bands with a single radiating element are desirable. For this reason an important part of the work

presented in this thesis will be devoted to the design of multiband antennas to try to optimize performance while keeping to reduced dimensions. Among the possible solutions to achieve this multiband functionality, we will consider fractal geometries and resonator loaded structures. Our study will be focused on monopole antennas because, as can be seen in figure 1.1, the central unit will be similar to an ADSL router and monopole antennas are typically used in this kind of devices.

In remote sensors, small and cheap antennas are necessary. The integration of the RF front-end together with the sensors can be of interest to obtain small devices. However, the radiating element is usually an off-chip antenna thus increasing the system size and cost due to the need for a physical connection between the antenna and the RF front-end. A good choice to obtain really small systems is the use of system-on-chip solutions [21], where antenna and circuits are integrated together in the same chip. For this reason one chapter of this thesis will focus on the design of small antennas fabricated with standard CMOS silicon technologies. Furthermore, antenna performance degradation due to the presence of other components will be also analyzed.

The special case of a sensor implanted inside the human body will be considered. In implantable devices the human body effects on the antenna performance must be taken into account. Human tissues near the antenna will produce losses that will degrade the antenna performance; this being one of the most important limiting factors of the systems using implantable devices.

Therefore, the three main objectives of this thesis can be summarized as:

- Design of monopole multiband antennas for the central unit.
- Design of silicon integrated antennas for remote sensors.
- Study of the body effects when one of the sensors is implanted inside the human body.

Finally, we want to point out that the purpose of this thesis is not only to give a particular solution for a specific problem but to carry out a thorough study of the proposed topologies and its operating principles as well. Design guidelines will be given to assure that the topologies and results presented can also be applied in other systems with similar requirements.

1.3 Thesis organization

This thesis is divided into five chapters to gradually cover the aforementioned objectives.

Chapter 1, is the chapter that you are reading at this moment. It gives a brief introduction to the modern wireless communication systems and to the ISM bands. This chapter also presents our motivation and goals, showing the system architecture that has inspired and motivated this thesis. The results obtained during this thesis have permitted the author to publish and contribute to several papers which are detailed at the end of this chapter.

To satisfy the central unit requirements, high performance antennas with multiband behavior are necessary. For this reason, chapter 2 will focus on the design of multiband antennas covering the WLAN and ISM bands. Firstly a briefly introduction to multiband antennas will be given. Then, the chapter is divided in two sections. The first section analyzes multiband antennas inspired by fractal shapes. Some novel designs where fractals are used in the ground plane will be shown, and we will take advantage of the combination of the fractal shape in the ground plane and in the monopole element to improve antenna performance. In the second section, multiband behavior will be obtained using monopole structures loaded with resonators. Different novel topologies will be presented with a thorough analysis of their operating principles. Firstly the monopole will be loaded with a simple resonator and, next, it will be loaded with a dual resonator to introduce more operating bands. Finally, asymmetric structures will be also considered to improve multiband performance.

Chapter 3 will focus on the design of antennas for remote sensors. This chapter will analyze the design, fabrication and measurement of miniature integrated antennas fabricated with standard CMOS technologies. Firstly the performance offered by classical miniaturization technique when they are applied to antennas fabricated on a silicon substrate will be analyzed. Next, micromachining techniques will be suggested as a way to improve antenna performance and finally, the degradation introduced by other elements when they are fabricated together with the antenna will be studied.

In chapter 4 implantable antennas will be analyzed, focusing on the study of the propagation losses introduced by the human body. Furthermore, some of the results will be tested with measurements carried out using tissue simulating liquids.

Finally, chapter 5 includes the conclusions of this thesis and some guidelines for future work.

1.4 List of Author's Contributions

This section shows the contributions of the author to international journals and conferences during the period of development of this thesis. A distinction is made between those contributions related to the work of this thesis and those that are the result of the collaboration with other researchers but not directly related to the thesis content.

Chapter 2

Multiband antennas for the central unit

This chapter will focus on the design of multiband antennas for the central unit of the remote sensor network. As it has been said in the introduction, multiband performance is necessary to serve the ISM and WLAN frequency bands with a single radiating element.

Firstly a brief introduction to the concept of multiband antennas will be given and previous works related to multiband radiators will be shown. Next, two options to solve our problem will be analyzed: fractal shapes and resonator loaded structures. Some novel antenna designs will be presented for each option. Although this chapter is focused on monopole configurations, the same ideas could also be applied in the design of other kinds of antennas, such as dipoles or PIFA antennas.

2.1 Introduction to multiband antennas

Some of the classic antennas that can be found in literature, like straight dipoles or horns, have a behavior highly dependent on frequency [22–24], which means that they only work properly at the design frequency. However, it would be desirable to have antennas that could work simultaneously at multiple frequencies. For this reason multifrequency antennas are required.

There are two types of multifrequency antennas: multiband and broadband antennas. While a multiband characteristic is related to a discrete set of frequency bands where the antenna parameters are similar [25], broadband behavior is associated with an antenna whose parameters are similar within one large frequency band [22].

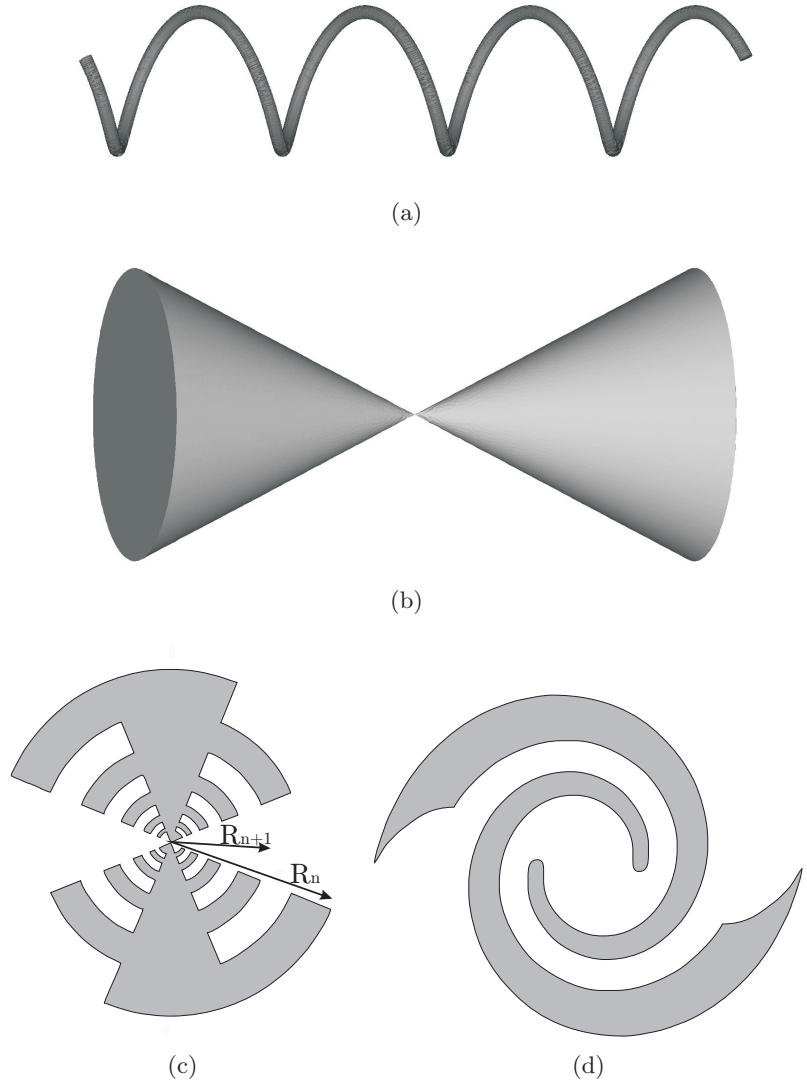

Figure 2.1: *Classic broadband and multiband antennas. (a) Helix antenna. (b) Biconical antenna. (c) Log-periodic antenna. (d) Spiral antenna.*

Different basic topologies have been used to obtain multiband or broadband behavior. Some well known antennas with broadband behavior are the helix (figure 2.1(a)) and the biconical antennas (figure 2.1(b)). To simplify the fabrication process, some geometrical approximation to the biconical antenna, like the triangular monopole or the bow tie dipole, can also be used [22].

The self scalable principle of antennas states that the input and radiation parameters of an antenna are invariant to a change of its physical dimensions if a similar change is also made in the operating frequency [22]. Based on this idea, DuHamel [26] introduced the concept of log-periodic antennas. An example of a real implementation can be seen in

figure 2.1(c), where the geometric ratio (τ) is defined as

$$\tau = \frac{R_n}{R_{n+1}} = \frac{f_{m+1}}{f_m} \tag{2.1}$$

being f_m and f_{m+1} the frequency of two consecutive operating bands of the antenna. In this kind of antennas, the geometric ratio (τ) observed in the geometry also defines the antenna log-periodic behavior in frequency.

Based on the same idea, in 1957 Rumsey [27] introduced the frequency independent antennas. He said that the behavior of an antenna that could be fully described by angles would be frequency independent. This is a theoretical concept, nevertheless there are some real implementations, like the spiral antenna of figure 2.1(d), that come close to this idea.

These are just a few examples of classical topologies used for broadband and multiband antennas. They were presented half century ago, but they are still in use, and some of them have been the base for the development of modern multiband antennas, such as the fractal antennas that will be analyzed later in this chapter.

Over the past few years an important effort has been put into the design of new multiband antennas for multiple system coverage in order to satisfy the needs of the market, which demands high performance small radiators with multiband behavior. Multiple examples of multiband antennas can be found, with designs that range from those based on monopoles with stub tuning [28, 29], sleeve dipoles [30] or multi-branch [31], to those based on dielectric resonators [32, 33]. Recently, the use of PIFA antennas [34–36] for mobile and portable terminals has been increasing due to their compact size and ease of integration inside the mobile terminal. Figure 2.2 shows some examples of the aforementioned solutions.

Top-loading techniques are another interesting option to achieve multiband behavior. These techniques have been typically used to reduce antenna dimensions [22]. For instance the introduction of a top capacitive load in a monopole antenna increases its electrical length, reducing the operating frequency without increasing the monopole height. However, top-loading techniques can also be applied to some antenna geometries, such as a triangular monopole or a Sierpinski monopole, in order to obtain multiband radiators [37]. From figure 2.3 it is seen that when loads are introduced to the antenna geometry, new current paths are created thus adding new resonances to the antenna response.

It is advisable to use these antennas at even resonances because relative changes in the input resistance are smaller than at odd resonances, but these resistance values differ from 50 Ω and hence the matching levels are poor. As was suggested in [37] the input resistance can be adjusted by modifying the antenna geometry. Figure 2.4 shows a modified version

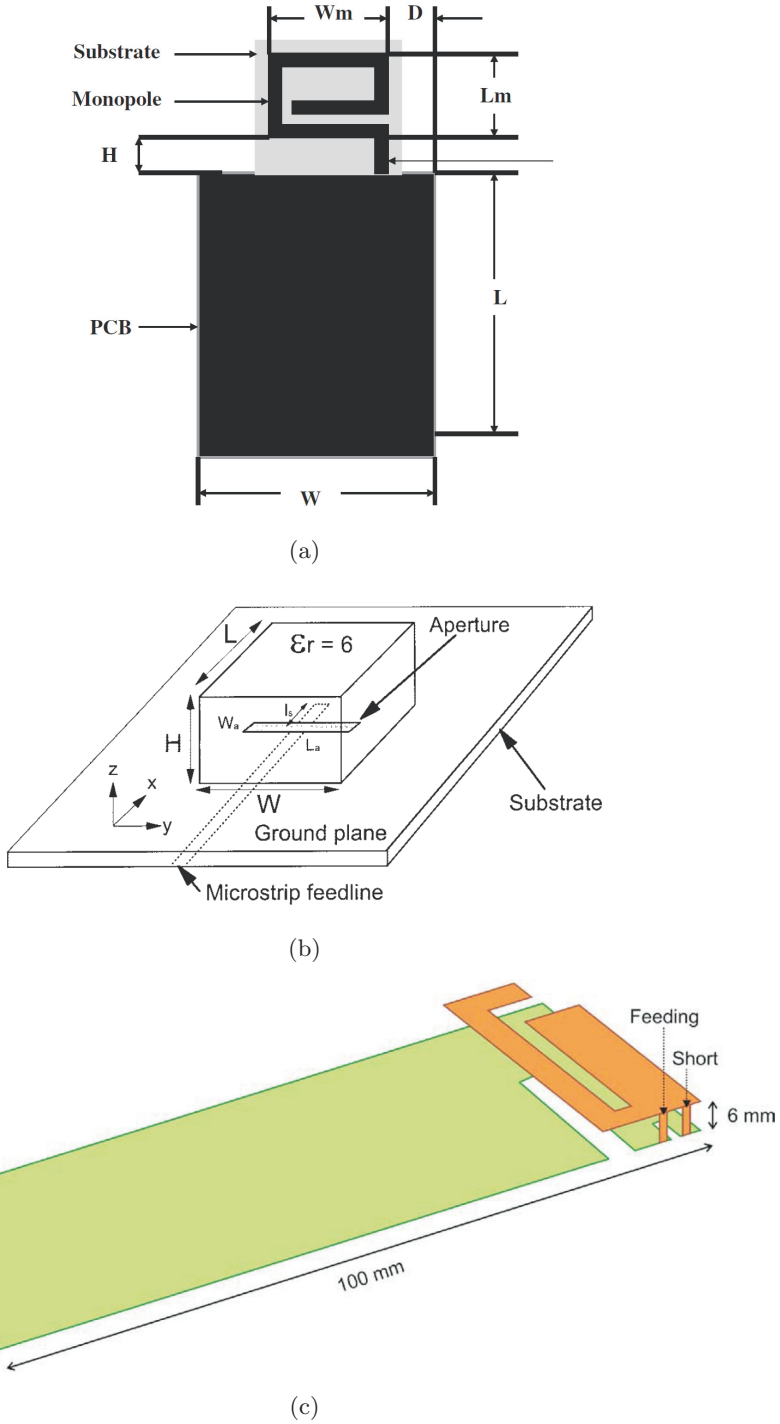

Figure 2.2: *Multiband antennas presented in recent years. (a) Monopole with stub tuning [28]. (b) Antenna based on dielectric resonators [32]. (c) PIFA Antenna [35].*

of the triangular monopole antenna where the width w has been increased to reduce input resistance at even resonances and improve matching levels. Input reflection coefficients better than -10 dB are achieved in the four antenna matching bands.

It is important to point out that, in the framework of this thesis, similar input parameters in all the bands will not be the only design requirement for our multiband antennas. Similar radiation patterns will also be necessary.

2.2 Multiband antennas inspired by fractal geometries

In this section, it will be shown that fractal shapes can improve multiband antenna performance when they are used either in the monopole element or in the ground plane generation process. Several antenna designs suitable for the central unit of the wireless sensor network will be presented.

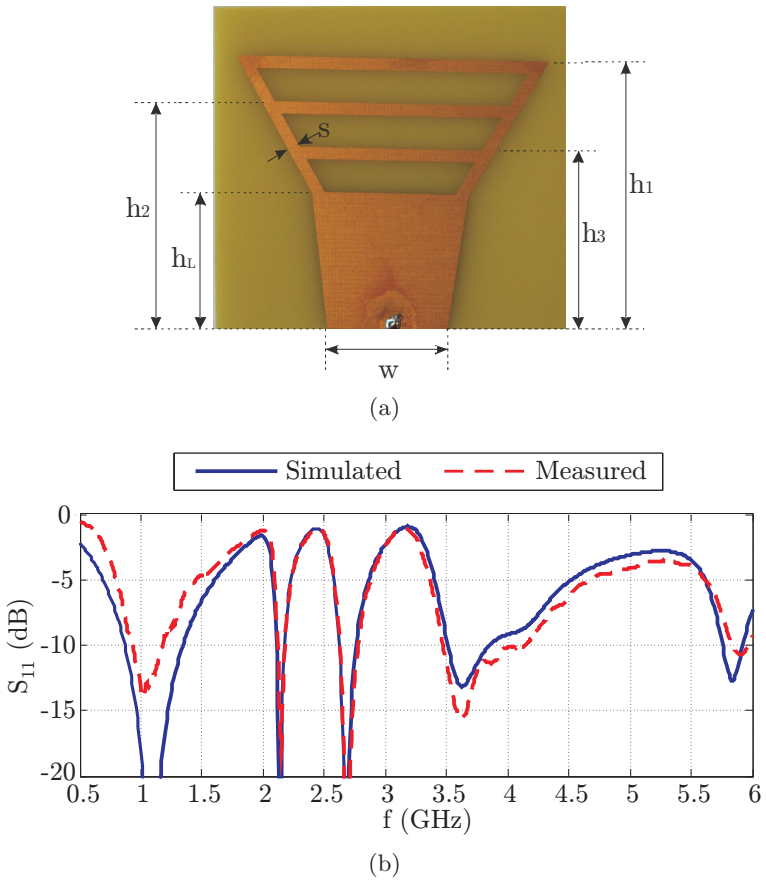

Figure 2.4: *Modified top-loaded triangular monopole. The width w has been increased to improve the matching levels. (a) Fabricated prototype. h_1 = 50 mm, h_2 = 41.7 mm, h_3 = 33.3 mm, h_l = 25 mm, s = 2 mm, w = 25 mm. (b) Measured and simulated input reflection coefficient.*

2.2.1 Introduction to the use of fractal shapes in antenna design

The definition of fractal is not a clear concept. The most important properties that characterize a fractal are its fractal dimension and its self similarity property [38–41]. Mandelbrot gave the following definition: "A fractal is by definition a set for which the Hausdorff dimension strictly exceeds the topological dimension", which he later replaced with: "A fractal is a shape made of parts similar to the whole in some way" [39–41]. In [39] it is said that the condition that must be accomplished to define an object as a fractal is that its fractal dimension exceeds its topological dimension.

One of the main ideas behind the fractal concept is that most fractal objects have self similarity at different scale levels, which means that a fractal object is composed of small but similar copies of itself. An example of a self similar fractal shape in nature is the

cauliflower (figure 2.5). If it is analyzed at different scale levels, the same shape is observed. In nature, other examples of fractal shapes can be found in trees, leaves, snowflakes or the coastline, to mention just a few examples.

Fractal shapes can be generated with an iterative process where each iteration is created using multiple rotated and/or scaled copies of the previous iteration. As can be seen in figure 2.6(a), the Sierpinski gasket generation process starts with a solid triangle. In each iteration, the new geometry is generated using three copies scaled by a factor of 2 of the previous iteration. Figure 2.6(a) shows the evolution of the geometry when the number of iterations is increased. The fractal shape is the geometry obtained after an infinite number of iterations. The generation process of other fractals, like the Sierpinski carpet or the Koch curve, is also shown in figure 2.6.

Strictly speaking, fractal shapes can not be physically built since they are a mathematical abstraction which includes an infinite number of elements. However, some real structures inspired by these ideal fractals are typically used. These real implementations are usually known as truncated fractals, prefractals or fractals with a finite number of iterations [39].

The use of fractal shapes is widespread in antenna design. One interesting property of some fractals, like the Koch or the Hilbert curves, is the space filling property which says that they can have an infinite length and be fitted in a finite area. This property is useful to reduce the antenna dimensions [42, 43], because when the number of fractal iterations is increased, the total antenna length is also increased, reducing the resonance frequency

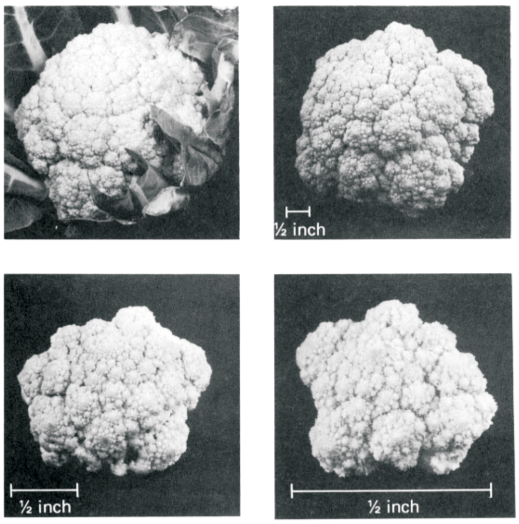

Figure 2.5: *An example of fractal shape in nature: Cauliflower [38].*

without a significant change in the area.

The self similarity property of some fractals makes these structures very suitable for multiband antennas. One of the first reported examples of a multiband fractal-based antenna was the Sierpinski antenna shown in [44, 45], where the Sierpinski gasket was used to obtain a multiband monopole. Since these initial references, further works have been presented in order to improve the Sierpinski monopole performance and have more control in the allocation of the operating bands [46–53].

Most of the aforementioned examples are based on dipole or monopole configurations; however similar ideas can be applied to other types of antenna. For instance in [54–56] the Sierpinski gasket (or a modified version of it) is used in the design of multiband patch antennas.

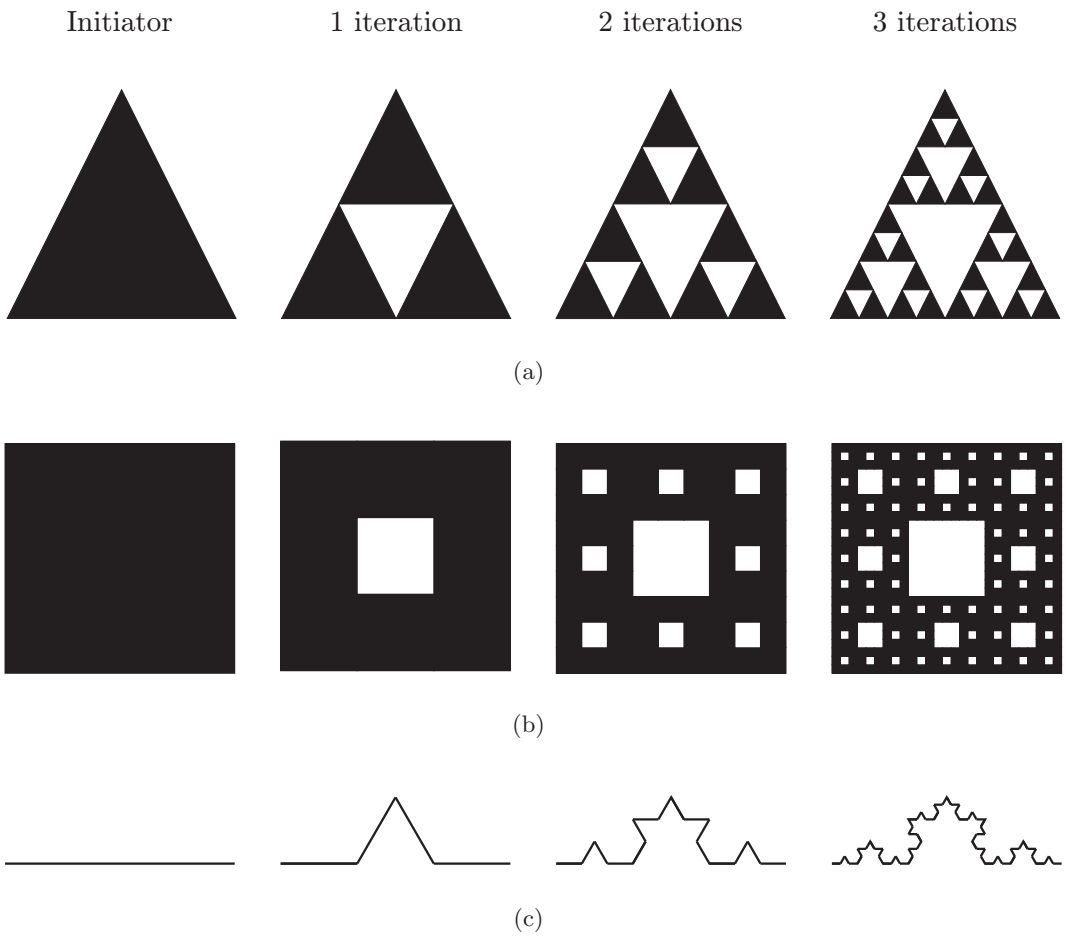

Figure 2.6: *Generation of different fractal shapes using an iterative process. (a) Sierpinski gasket. (b) Sierpinski carpet. (c) Koch curve.*

2.2.2 The Sierpinski monopole

In this section the performance of the Sierpinski monopole will be further analyzed because some of the new antennas presented in this thesis will be based on this structure. In the Sierpinski monopole the number of fractal iterations is directly related to the antenna multiband behavior. When additional fractal iterations are applied to the geometry, new resonances are introduced to its response.

According to figure 2.7 when the number of iterations is equal to two, three pairs of resonances can be clearly seen at low frequencies (0 - 6 GHz). When the number of iterations is increased to three, a new pair of resonances appears at higher frequencies (8 - 12 GHz). This tendency goes on as more fractal iterations are included in the antenna geometry. Good matching levels are obtained at the odd resonances when the reference impedance is 50 Ω, therefore the position of the operating bands will be mainly defined by the odd resonances of the structure. Moreover, if radiation patterns at the odd resonances are analyzed, acceptable similarity between them is obtained, and hence the Sierpinski monopole can be considered a multiband radiator [45].

The Sierpinski monopole multiband behavior is related to the self similarity property at different scale levels of this geometry and it can be easily understood analyzing the current distributions of the antenna (figure 2.8). When the frequency increases, currents are concentrated in a smaller part of the antenna, thus the antenna active area (area where currents are important) scales with frequency. If we zoom in on the active area, the shape of the current distributions at the different resonances is the same but scaled. This similarity in the current distributions allows for the antenna multiband behavior, offering similar input and radiation parameters in multiple operating bands. In the particular case of figure 2.8 the antenna will present a frequency log-periodic behavior, with a period equal to 2, due to the fact that the geometry has been created with a scale factor of 2. It is important to point out that the first resonance behavior will be slightly different due to the truncation effects related to the finite dimensions of the real antenna [44, 45].

The antenna of figure 2.7 is the basic Sierpinski monopole, however multiple perturbations can be applied to the original geometry to change and adjust the position of the bands, the periodicity among them and the radiation patterns shape. In the Sierpinski monopole the resonance frequencies are associated to the monopole edge length rather than to its height [48]. For a fixed height, when the flare angle α is increased, the edge length is also increased and the resonances will be shifted to lower frequencies. Another important factor is that the flare angle also modifies the radiation pattern shape. According to figure 2.9 when the flare angle $\alpha = 90^{o}$ the monopole offers a bidirectional radiation

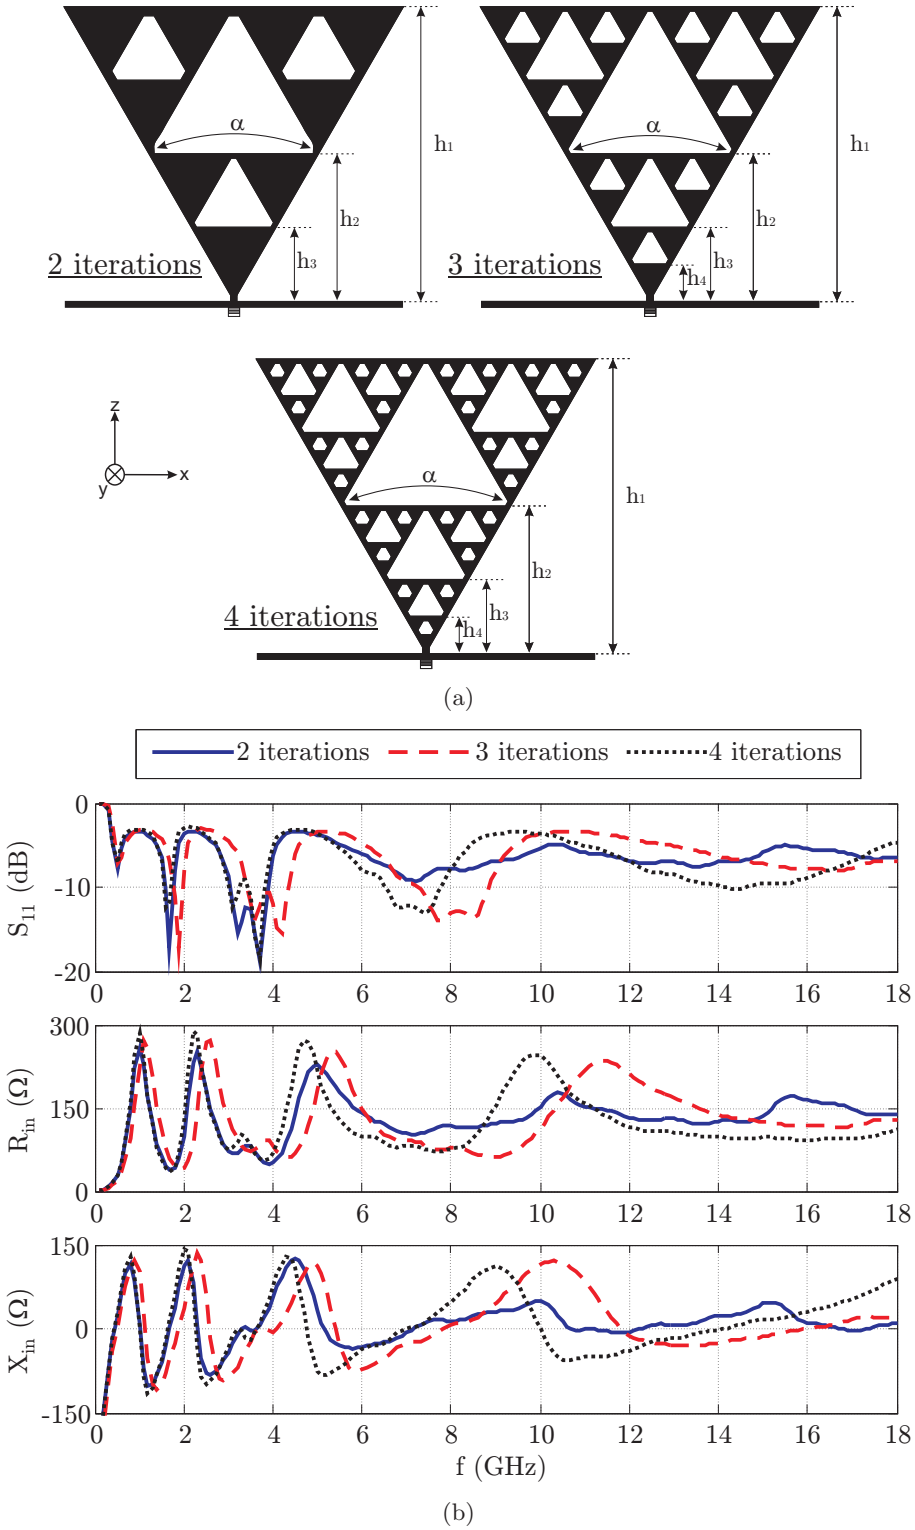

Figure 2.7: *Sierpinski monopole antenna with different numbers of iterations.* $h_1 = 100$ *mm,* $\alpha = 60^o$ *and* $h_{n+1} = h_n/2$.

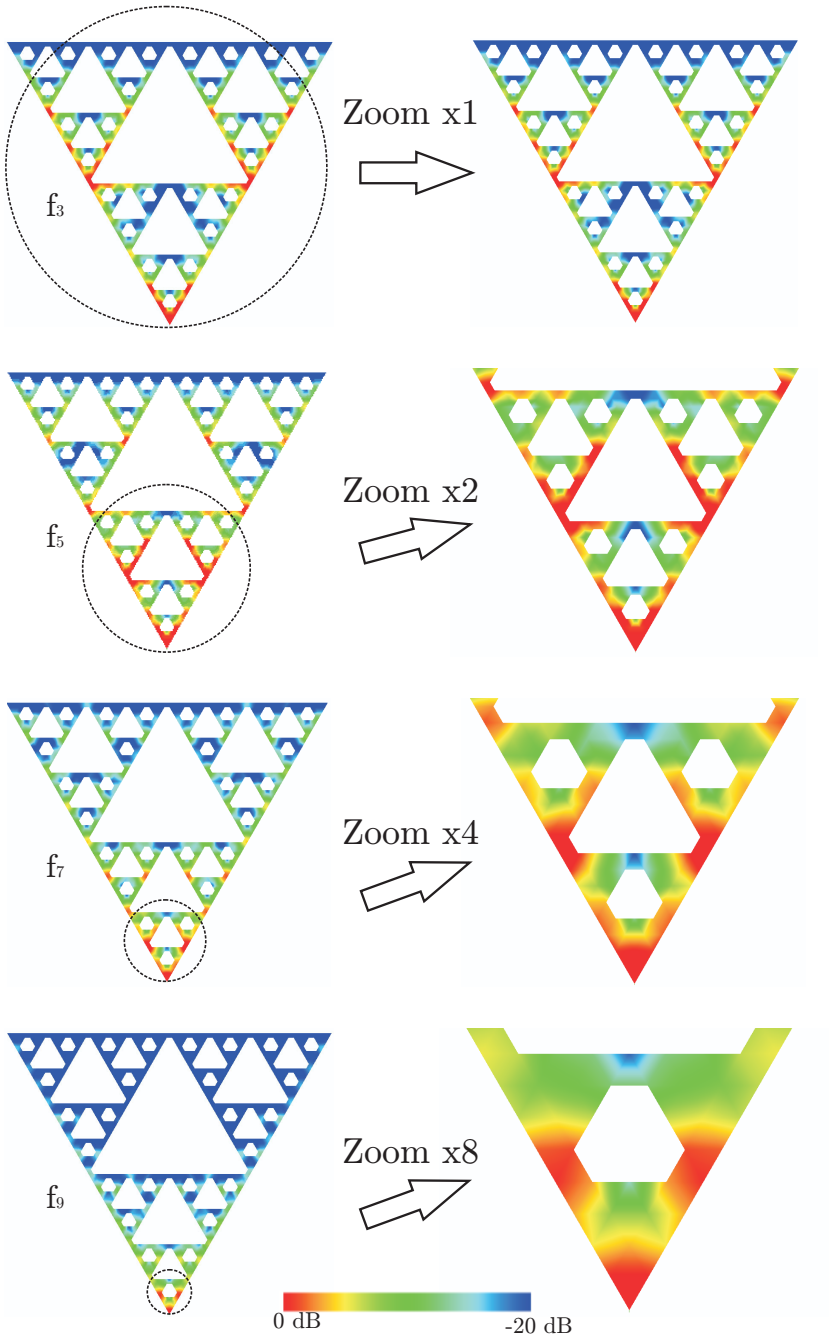

Figure 2.8: *Normalized current distributions at the odd resonances of a Sierpinski monopole with 4 fractal iterations.*

patterns, whereas if this angle is increased to $\alpha = 110^{o}$ radiation patterns become quad-directional. Therefore, depending on the application, the flare angle can be changed to adapt the radiation patterns to the specific application requirements.

Flare angle and antenna height can control, the radiation patterns and the operating bands position while keeping the same frequency spacing. The frequency spacing can be adjusted by changing the scale factor of the fractal geometry (figure 2.10(a)) [46]. Another option is the structure known as Mod-p (figure 2.10(b)), where multiple bands and sub-bands can be defined [49, 50].

As is shown in figure 2.11, the Sierpinski monopole can be combined with the aforementioned top-loading techniques with the aim of improving its multiband behavior [57]. Top-loading resonances are added at low frequencies and can be used to adjust the frequency spacing between the two first bands which does not agree with the scale factor because of the truncation effect of the fractal geometry. At high frequencies the top-loading effects will be less important because the antenna currents self scale with frequency approaching the antenna feeding point.

Furthermore asymmetric structures can increase the design flexibility, due to the fact that the whole structure resonances will combine resonances of both halves. As an example, figure 2.11 shows an asymmetric antenna based on two halves of top-loaded Sierpinski monopoles of different heights [57]. The asymmetric antenna reactance and the reactance of the isolated halves are plotted in figure 2.12. At low frequencies the input impedance of the asymmetric structure is equal to the parallel of the impedance of both isolated halves. For this reason the odd resonances of the asymmetric structure approximately coincide with the odd resonances of the two separated halves.

The relative variations in the real part of the impedance are generally smaller in even resonances than in odd resonances. Therefore to obtain multiband behavior the use of even resonances is advisable because it will allow us to obtain good matching levels simultaneously in the different bands if the average value of the input resistance at these resonances is used as reference impedance. Good antenna matching is achieved when the reference impedance is 170 Ω (figure 2.13).

According to figure 2.14, radiation patterns at even resonances are not equal in all the bands, but it could be useful because two different patterns are obtained. At the first three resonances the typical monopole-like pattern is obtained. This pattern could be suitable for terrestrial communications. At the fourth and fifth even resonances, the radiation levels for higher elevation angles increase, and this is useful for satellite communications. These results open the possibility of using the symmetric antenna as a solution for terrestrial

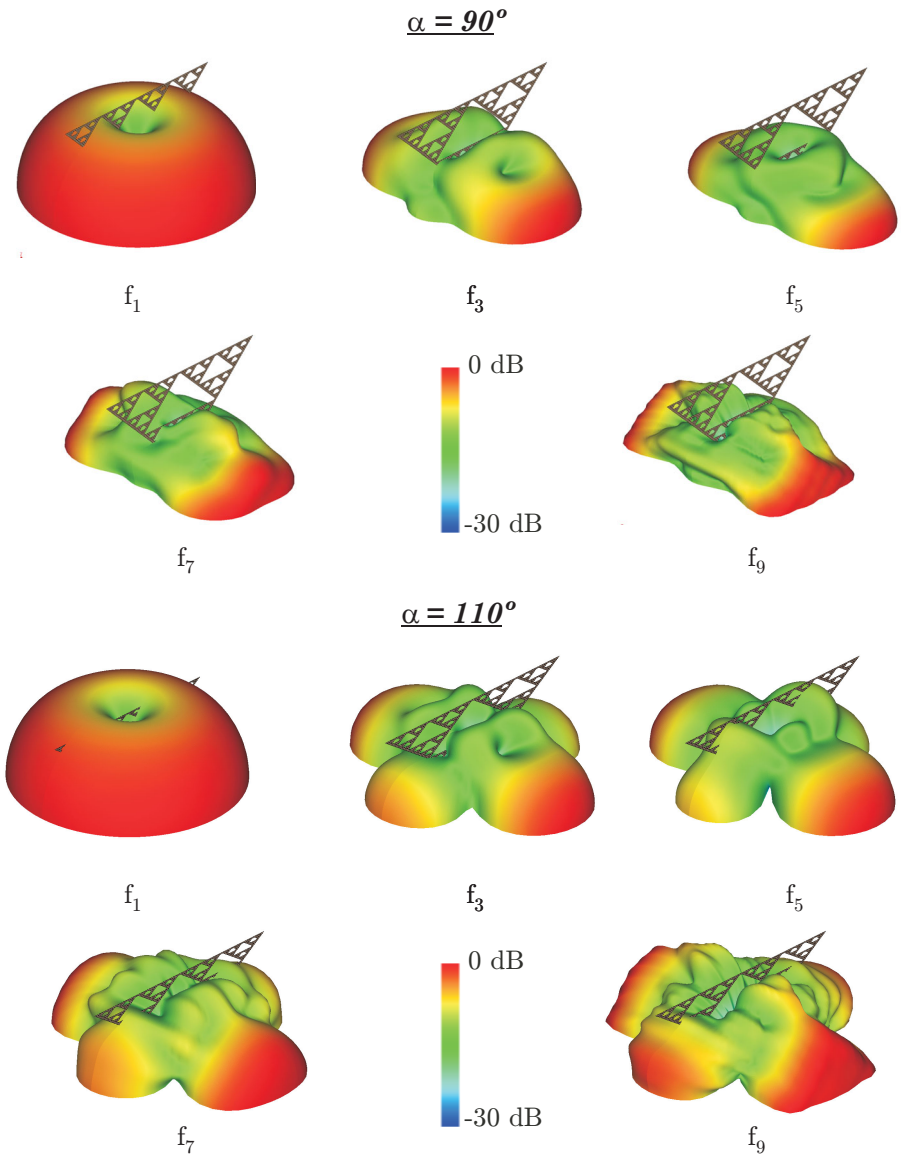

Figure 2.9: *Radiation patterns at the odd resonances of the Sierpinski monopole with different flare angles* α.

and satellite services with a single radiating element.

In the sensor network these radiation patterns could also be of interest. For instance in an outdoor sensor network where there is no WLAN or mobile phone system coverage, the low frequency bands could be used to collect information from the sensors, and this information could be transmitted to the Internet using a satellite communication system operating in high frequency bands. In this scenario, the satellite communication system would replace the WLAN connection of the original system. Another possible application could be in indoor scenarios where different frequency bands could be used to receive information from sensors at different elevation angles. However, in order to use this antenna in the sensor network, the antenna geometry should be adjusted to correctly allocate the operating bands according to the system requirements.

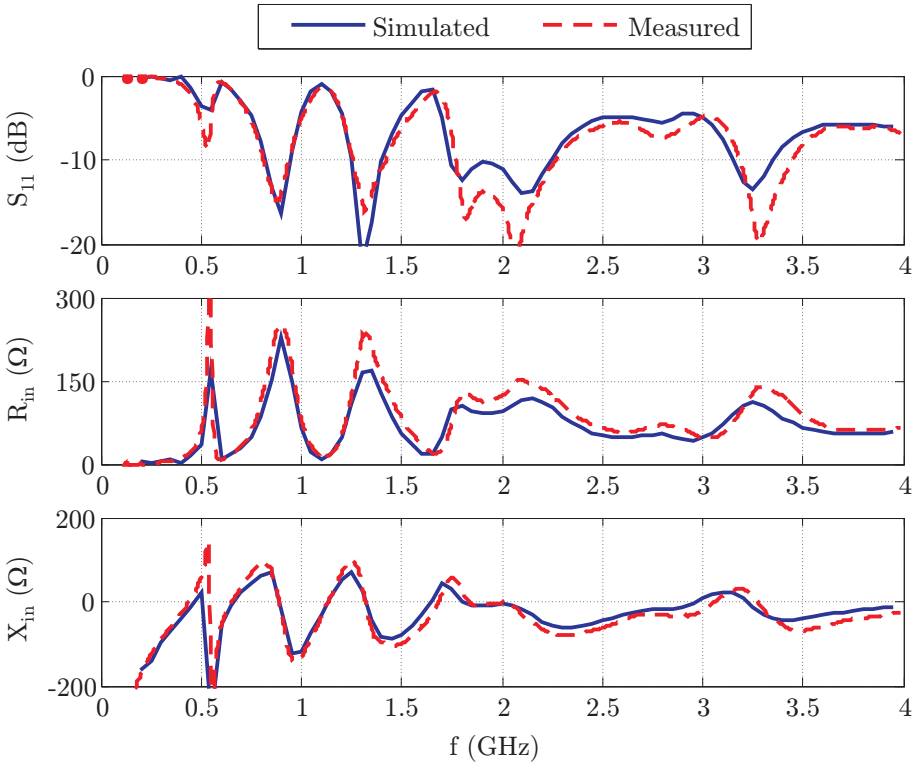

Figure 2.13: *Input parameters of an asymmetric top-loaded Sierpinski monopole (scaled prototype with h_{11} = 90 mm). The reference impedance for the S_{11} parameter calculation is 170 Ω instead of 50 Ω.*

2.2.3 Use of the Sierpinski gasket in the ground plane

In the previous section, and in most of the previous works presented in literature, the Sierpinski gasket is used in dipoles or monopoles with solid ground planes. In this section the fractal shape will be used in a different way, as part of the antenna ground plane.

If not properly taken into consideration, a ground plane with finite dimensions can introduce undesirable effects and degrade antenna performance. Nevertheless, it will be shown that we can make good use of the finite dimensions ground planes effects to improve antenna performance. In particular we will use a finite ground plane inspired by the Sierpinski gasket to improve the multiband behavior of the whole radiating structure.

The ground plane resonances will be used to reinforce the monopole resonances, improve the matching levels and bandwidths, and even introduce new operating bands. Several examples that use the ground plane effects to improve antenna performance can be found in literature [35, 58–63], but in these references the ground plane is not based on fractal shapes, which is one of the main novelties presented in this thesis.

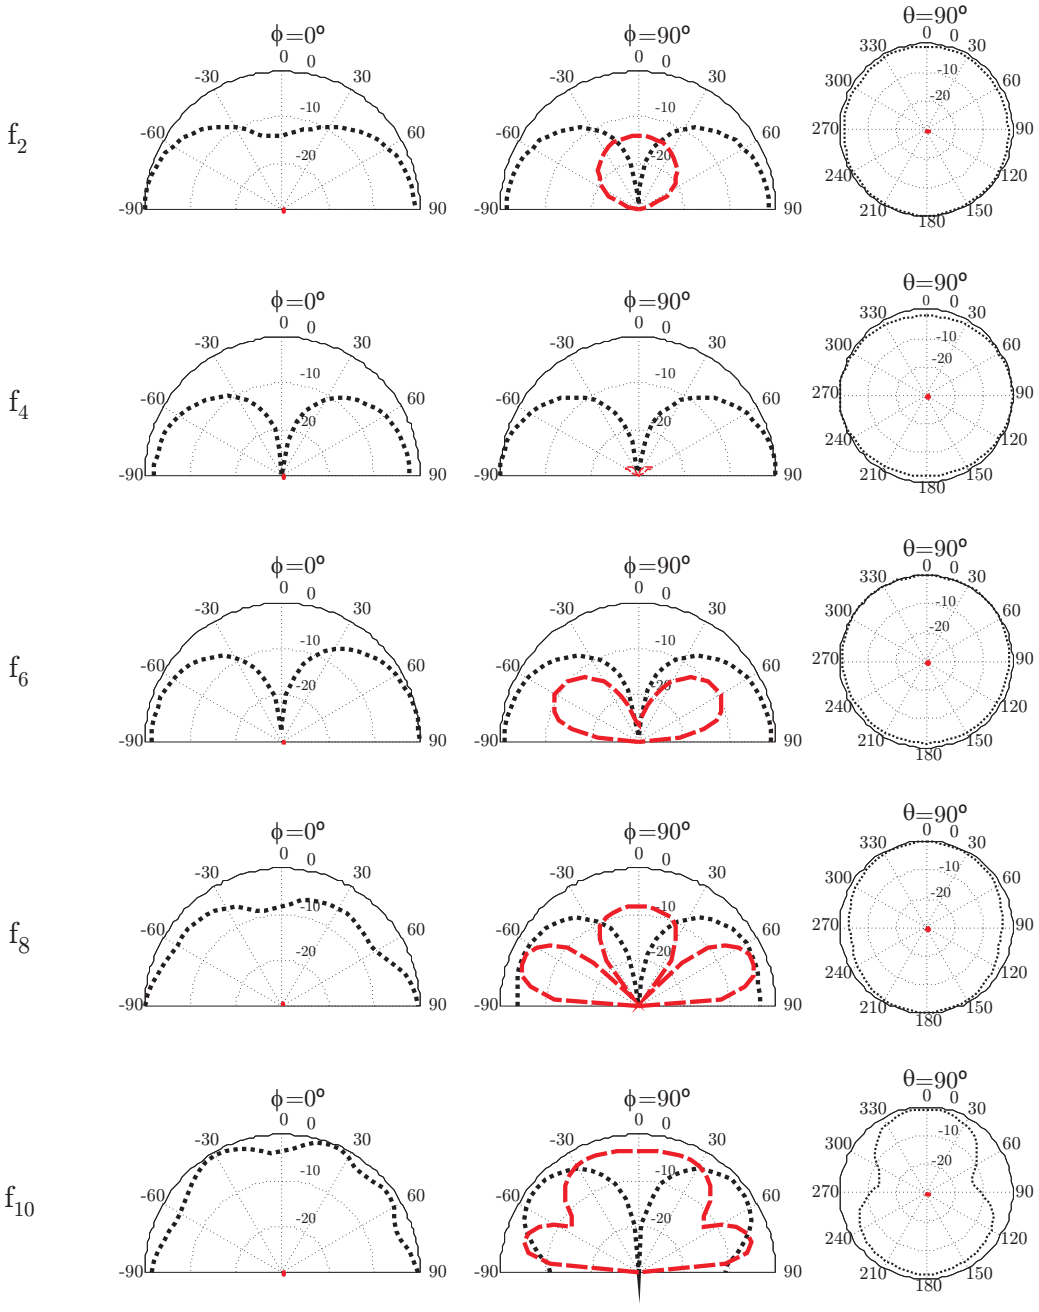

Figure 2.14: *Radiation patterns at the even resonances of an asymmetric top-loaded Sierpinski monopole (figure 2.11). Black dotted lines are used for the copolar component; red dashed lines are used for the crosspolar component.*

The triangular monopole height is 50 mm and the ground plane dimensions are 200 mm x 200 mm.*

Effects of using a fractal-based ground plane

The fractal-based ground plane is created using four copies of a Sierpinski gasket rotated 90º to each other. In the ground plane generation process a different number of fractal iterations can be used obtaining the geometries shown in figure 2.15. In this figure it can be seen that the generated ground plane keeps the self similarity property of the original Sierpinski gasket, and hence it is predictable that the ground plane will also exhibit multiband behavior with multiple controlled resonances.

Figure 2.16 shows that new resonances are introduced when the number of ground plane fractal iterations is increased. This is because the whole structure resonances are a combination of the monopole element resonances and the ground plane resonances. Moreover, the position of the ground plane resonances is similar to the position of the resonances obtained if the Sierpinski gasket used in the ground plane generation process is used as monopole element. Only a small frequency shift is observed due to the mutual loading effects between the different copies of the Sierpinski gaskets that make up the ground plane. Furthermore, good matching levels are obtained in the odd resonance when

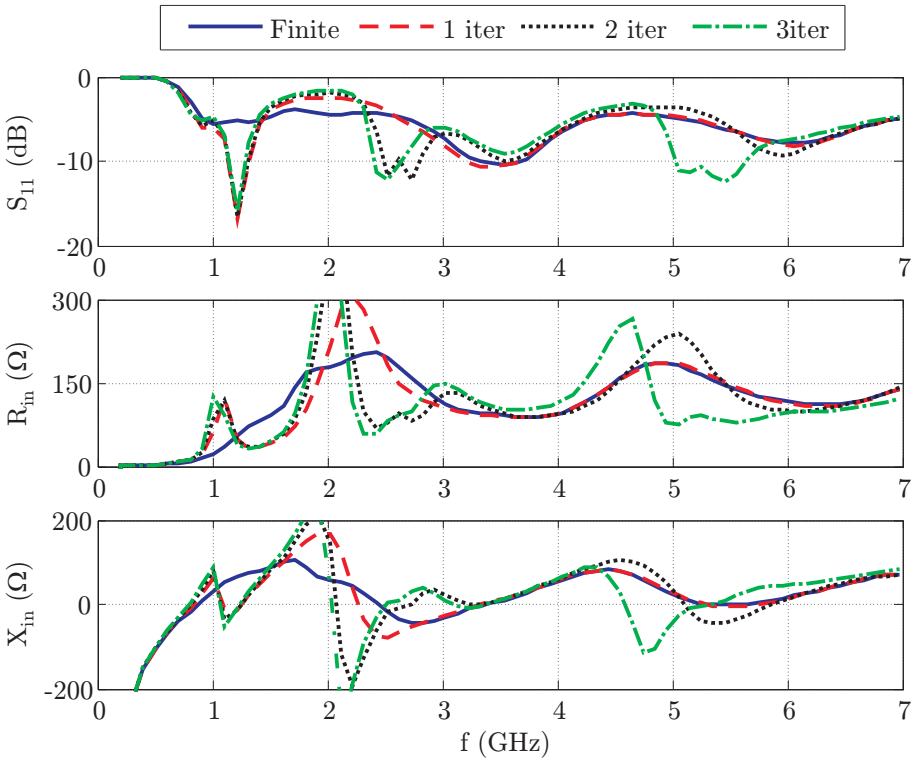

Figure 2.16: *Input parameters of a triangular monopole on a fractal-based ground plane with different number of iterations (figure 2.15).*

the reference impedance is 50 Ω. It is important to point out that the aforementioned perturbations applied to the Sierpinski monopole, like the use of different scale factors, can also be applied to the ground plane in order to adjust the position of its resonances.

Dual band triangular monopole antenna on a fractal-based ground plane

In this section an equilateral triangular monopole will be mounted on a fractal-based ground plane (figure 2.17) to obtain a multiband antenna that covers the needs of the central unit.

The design process is as follows. The triangular monopole height h_m is set in order to obtain 50 Ω matching in the lower part of the 5 GHz band when it is on a solid ground plane. In the generation of the Sierpinski gasket for the ground plane, two fractal iterations with a scale factor of 2 were initially used, with the objective of obtaining three operating bands with frequency spacing around 2. However, the spacing between the two lower bands is larger than 2 due to the truncation effects of the real finite ground plane. Moreover, the first band is not well matched to 50 Ω, therefore, this band will not be considered in our design, setting $h_1 = 2h_2$ just to avoid the truncation effect (mismatch) for the second

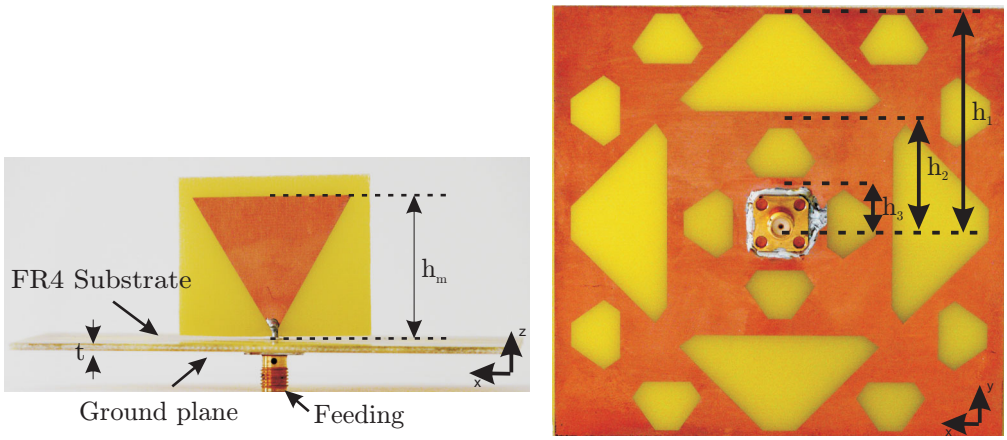

Figure 2.17: *Triangular monopole on a fractal-based ground plane. (a) Monopole element. (b) Modified ground plane inspired by the Sierpinski gasket.*

band.

The heights h_2 and h_3 have to be adjusted to allocate the 2.45 GHz and 5 GHz WLAN bands. For this reason the scale factor of the second iteration is increased to 2.36 to obtain the desired frequency spacing. The final design (figure 2.17) has the following dimensions: $h_m = 30$ mm, $h_1 = 52$ mm, $h_2 = 26$ mm, and $h_3 = 11$ mm. These dimensions take into account the effects of the low cost FR4 1.55 mm substrate ($\epsilon_r = 4.5$, $tan\delta = 0.02$) used to support the antenna metallic parts.

In order to demonstrate the improved performance of the antenna with the modified ground plane, it will be compared with the results obtained when the triangular monopole is mounted on a solid ground plane with the same dimensions. The input impedance and return losses of both configurations are plotted in figure 2.18, and table 2.1 summarizes the operating bands and their bandwidth, taking into account that an input reflection coefficient better than -10 dB is desired.

For the triangular monopole on the solid ground plane there are two possible operating bands. However, the matching levels of the first one are poor and therefore it may not be useful. The second one, with a center frequency of 5.1 GHz, is well matched and has a relative bandwidth of 17.2 %. In the case of the fractal-based ground plane, new resonances appear due to the fractal shape, obtaining good 50 Ω matching at 2.475 GHz, with a relative bandwidth of 6.3 %. Moreover, the 5 GHz band has been improved, increasing its relative bandwidth to 28.6 %. This is due to the fact that dimensions have been adjusted to obtain the third resonance introduced by the ground plane at a frequency slightly higher than the monopole resonance. The combination of both resonances is responsible for the

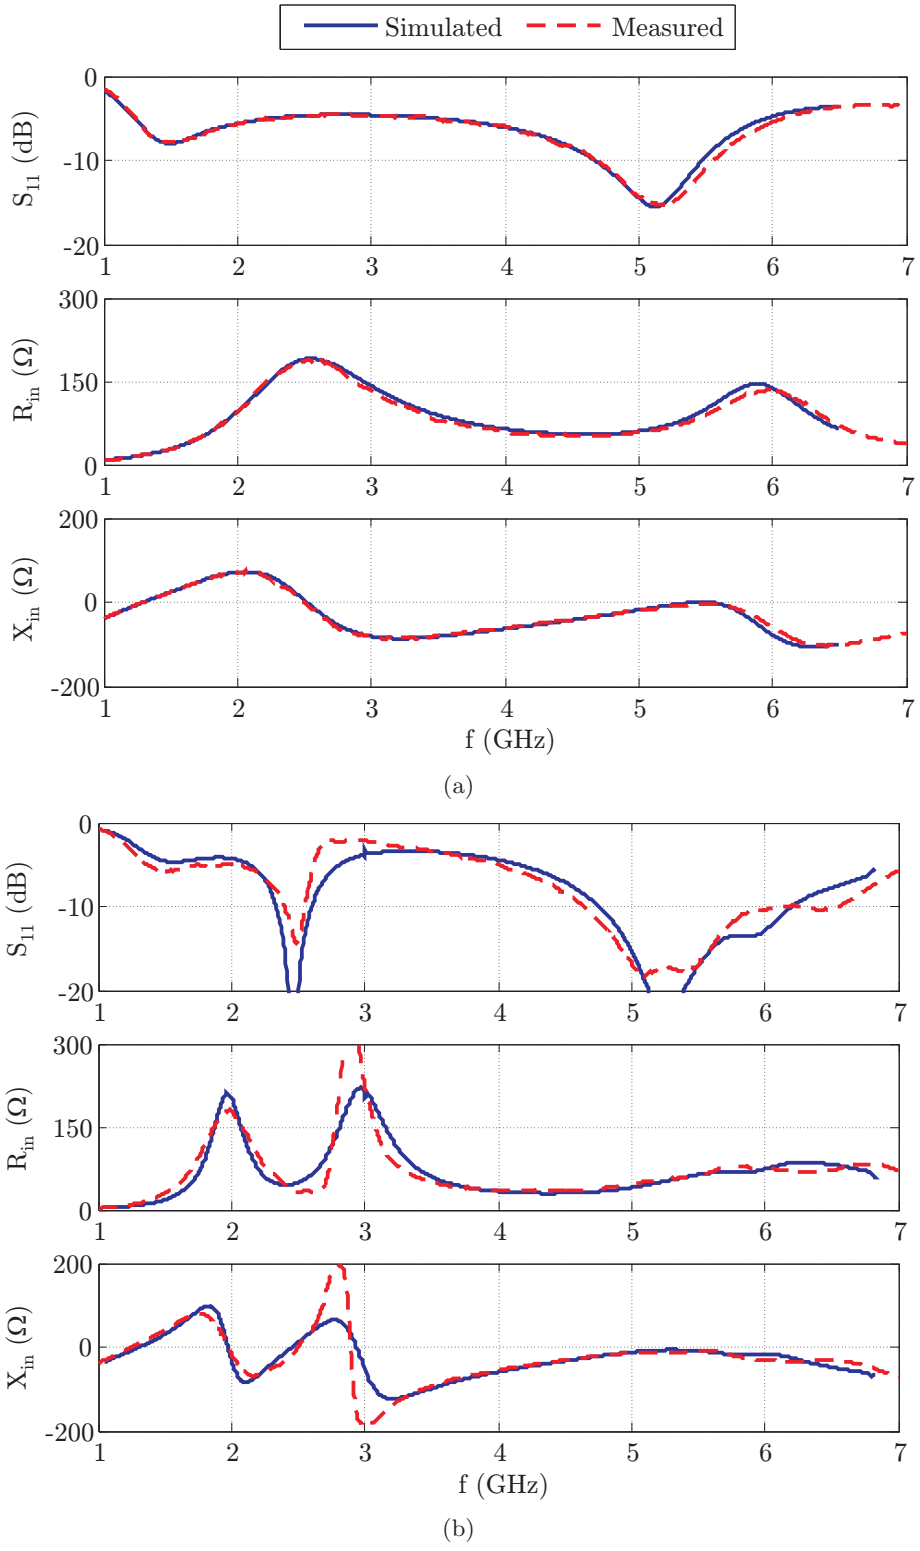

Figure 2.18: *Antenna input parameters. (a) Triangular monopole on a solid ground plane. (b) Triangular monopole on a fractal-based ground plane.*

Table 2.1: *Measured operating bands of the triangular monopole on the different ground plane configurations.*

Solid ground plane		
Operating band (GHz)	Center frequency (GHz)	Relative bandwidth(%)
4.675 - 5.556	5.1	17.2

Fractal-based ground plane		
Operating band (GHz)	Center frequency (GHz)	Relative bandwidth(%)
2.397 - 2.552	2.475	6.3
4.645 - 6.194	5.4	28.6

bandwidth increase.

The simulated copolar and crosspolar components of both configurations are shown in figure 2.19. Good similarity between the two bands and reduced crosspolar levels are obtained. The radiation patterns keep the same properties when the solid ground plane is replaced by the fractal-based ground plane, proving that the fractal ground plane allows the introduction of new operating bands without significantly degrading the radiation parameters of the original monopole antenna. The simulated directivity with the solid ground plane is 3.4 dB for the first band and 4.6 dB for the second one, whereas the directivity with the fractal-based ground plane is 4.1 dB for the first one and 5.1 dB for the latter.

Back radiation could be considered significant. However, this is not due to the use of a fractal-based ground plane but to the small ground plane dimensions, because similar back radiation levels are obtained with both ground plane configurations. These back radiation levels could be improved by using larger ground planes. The simulated radiation efficiency is over 90% in the frequency range under consideration for both cases.

Figure 2.20 shows the current distributions in the fractal-based ground plane in both operating bands. It can be seen as frequency increases, currents are located in a smaller region of the ground plane. Due to the self similarity property of the fractal geometry, current distributions at the different bands are similar with different scale factors, and this allows us to obtain the multiband performance of the antenna.

This antenna offers good matching levels, good similarity in radiation patterns and good efficiency levels in both frequency bands, and thus it could be perfectly well used as antenna for the central unit.

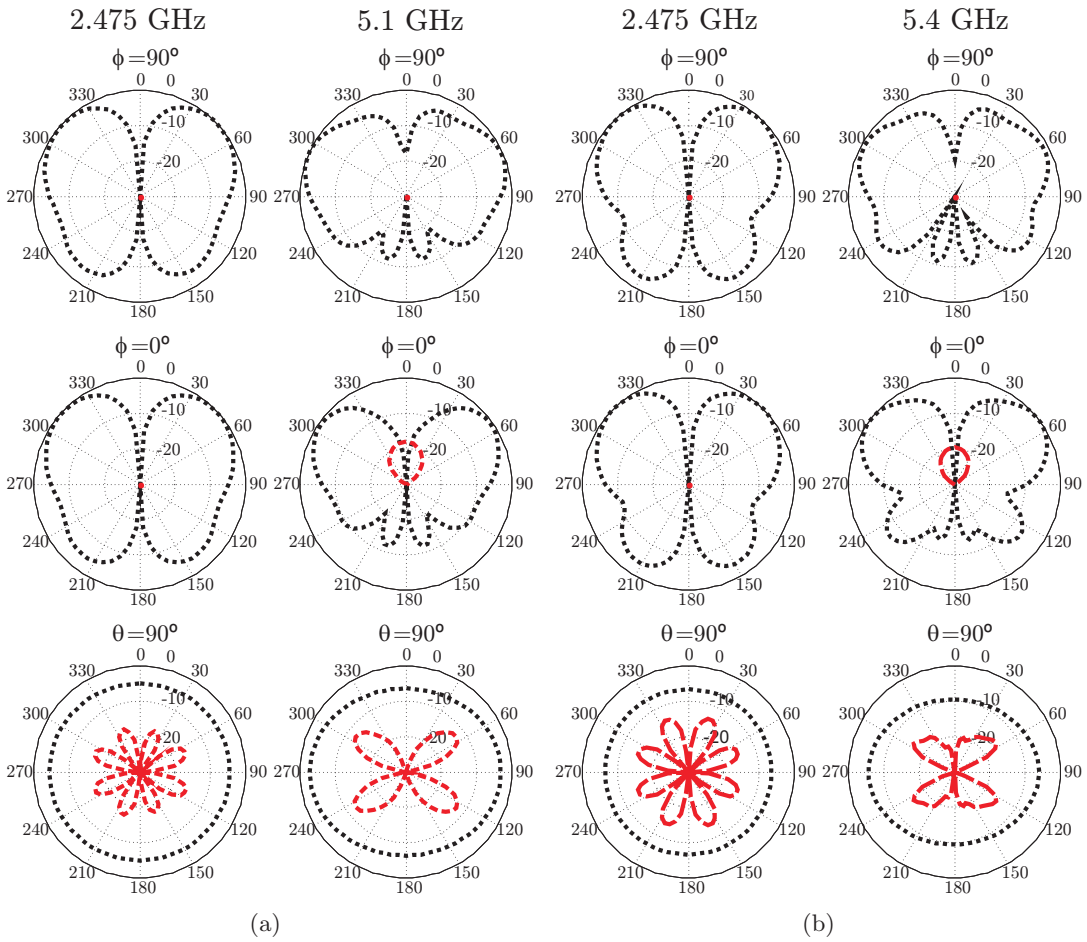

Figure 2.19: *Simulated normalized radiation patterns. Black dotted lines are used for the copolar component, red dashed lines are used for the crosspolar component. (a) Triangular monopole on a solid ground plane. (b) Triangular monopole on a fractal-based ground plane.*

Dual band Sierpinski monopole antenna on a fractal-based ground plane

In the previous section the fractal shape was only used in the ground plane in order to introduce new operating bands to a triangular monopole. In this section, the Sierpinski gasket will be used in both elements to increase design flexibility. The fractal-based ground plane will reinforce the resonances of a Sierpinski monopole improving the matching levels and bandwidths.

The ground plane is similar to the one presented in figure 2.17(b), but dimensions are slightly different with $h_1 = 50$ mm and a scale factor equal to two. The monopole is based on a Sierpinski gasket with the same scale factor. As can be seen in figure 2.21, several monopoles with various flare angles α were fabricated.

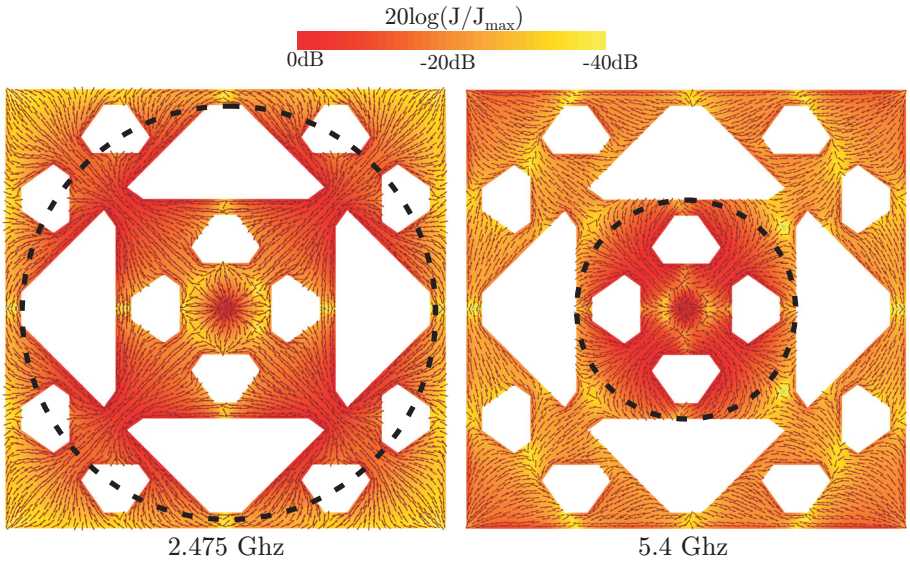

Figure 2.20: *Current distributions in the ground plane. The area with higher current density levels (active area) has been marked with a dashed circle.*

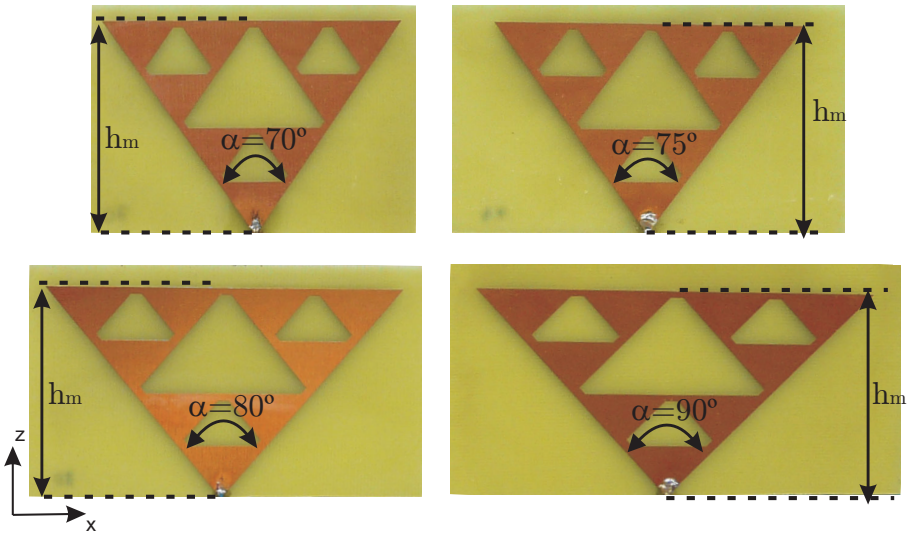

Figure 2.21: *The monopole element is a two iteration Sierpinski gasket with different flare angles α. Antennas were fabricated on a low cost FR4 substrate (ϵ_r = 4.5, tanδ = 0.02). h_m = 50 mm.*

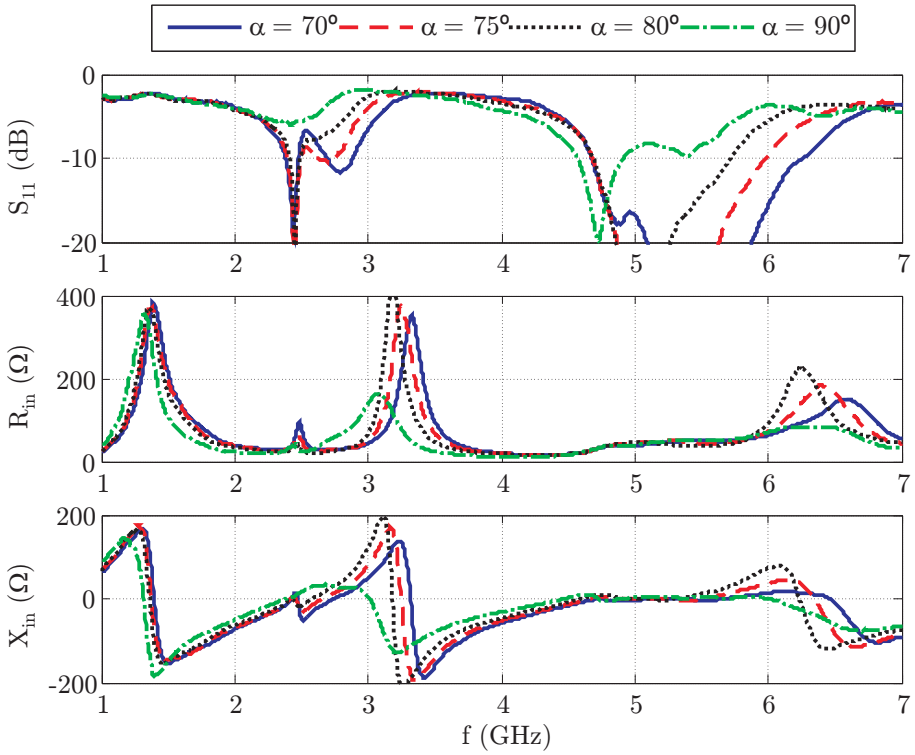

Figure 2.22: *Measured input parameters of a Sierpinski monopole with different flare angles α on a fractal-based ground plane.*

If the Sierpinski gasket used as monopole and the Sierpinski gasket used in the ground plane generation process are the same, both will have approximately the same resonance frequencies, reinforcing the resonances of the whole structure. However, the antenna performance can be improved if the monopole is modified in order to separate the resonances of both elements and increase the available bandwidth.

Antenna measurements of figure 2.22 show that double resonances appear near the operating bands when the monopole flare angle is not 90º. Since the flare angle α of the monopole is different from the flare angle of the Sierpinski gasket used in the ground plane, resonance frequencies of both elements are not the same, creating double resonances in the response of the whole antenna that help to improve the bandwidths. Similar results could be obtained by changing the monopole height h_m instead of the flare angle α.

As the flare angle decreases, monopole resonance frequencies slightly increase and the frequency separation between resonances also increases improving the bandwidth. The problem is that if the monopole flare angle is smaller than $\alpha = 75^{\circ}$, the monopole resonances and the fractal-based ground plane resonances are separated too far and the first band (2.45 GHz) splits into two bands with a reduced bandwidth.

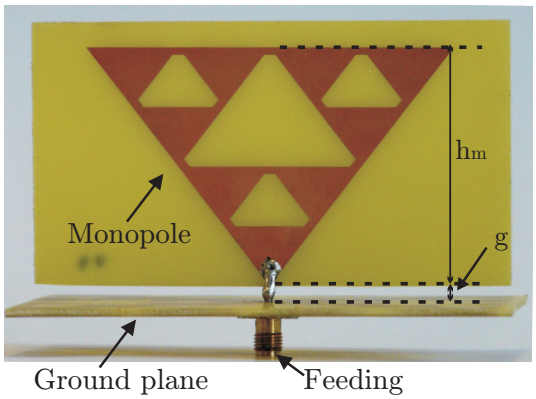

Figure 2.23: *A small gap g between the ground plane and the monopole can be used to optimize the antenna performance and improve the matching levels.*

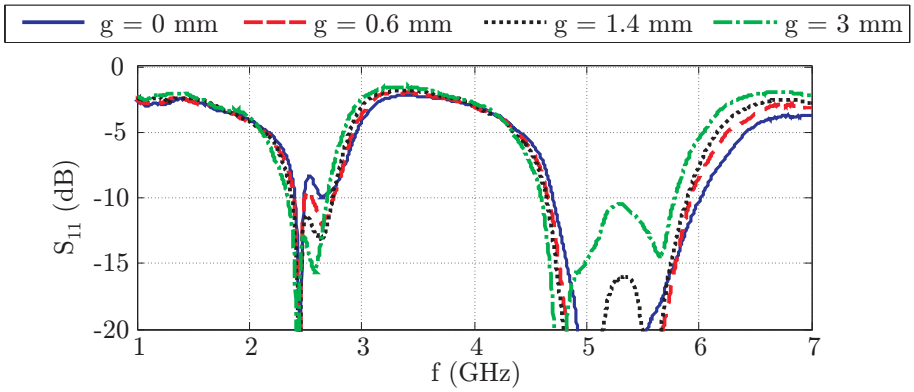

Figure 2.24: *Measured input parameters of a Sierpinski monopole with $\alpha = 75^o$ mounted on a fractal-based ground plane with different gap sizes g (figure 2.23).*

Once the flare angle is set to $\alpha = 75^o$, a fine tuning process to optimize the matching levels can be carried out by adjusting the height of the monopole (g) above the ground plane (figure 2.23). Measured return losses for different values of g are plotted in figure 2.24. As the height g increases, the insertion losses at the first band decrease while the second band is slightly degraded. The optimum choice of g in order to maximize the $S_{11} < -10$ dB bandwidth in both bands is $g = 1.4$ mm. With this configuration the operating bands are 2.37 GHz - 2.74 GHz and 4.64 GHz - 5.9 GHz, with relative bandwidths of 14.5 % and 23.9 % respectively. Table 2.2 summarizes the information about the operating bands with and without the fractal-based ground plane.

If we compare these results with those presented in the previous section where a triangular monopole was used, we can see that the use of the fractal shape simultaneously in the monopole and in the ground plane allows us to increase the first band bandwidth without significantly degrading the second band.

Table 2.2: *Measured operating bands of the Sierpinski monopole on the different ground plane configurations.*

Solid ground plane		
Operating band (GHz)	Center frequency (GHz)	Relative bandwidth(%)
2.58 - 2.73	2.65	5.6
4.75 - 5.23	5	9.6

Fractal-based ground plane		
Operating band (GHz)	Center frequency (GHz)	Relative bandwidth(%)
2.37 - 2.74	2.55	14.5
4.64 - 5.90	5.27	23.9

Simulated copolar and crosspolar components of the radiation patterns for the optimized design are shown in figure 2.25(b). For comparative purposes, figure 2.25(a) shows the radiation patterns obtained when the same Sierpinski monopole is mounted on a solid ground plane with the same dimensions as the fractal ground plane. By comparing figures 2.25(a) and 2.25(b) it can be concluded that the fractal ground plane does not introduce important changes in the radiation patterns and that low crosspolar levels are obtained. The simulated directivity is around 4.2 dB for the first band and 5.8 dB for the second. Although low cost FR4 dielectric losses are high, simulated efficiency levels are over 70 % in both bands.

As in the previous section, the presented antenna offers good multiband performance, and it could be used for the central unit.

2.3 Resonator loaded multiband monopole antennas

In this section, a new kind of antenna suitable for the central unit will be analyzed: monopoles loaded with resonators. The resonators effects will be used to improve the antenna multiband behavior.

2.3.1 Introduction to resonator loaded antennas

Recently, it has been demonstrated that loading a dipole/monopole with 'particles' can also facilitate dual band operation [64, 65]. These 'particles' are resonators that couple via the magnetic field produced by currents flowing along the dipole. In effect, such resonators load the dipole element at specifically chosen locations with a reactance that is determined by the resonant properties of the particular 'particle' geometry. The effects of these resonators

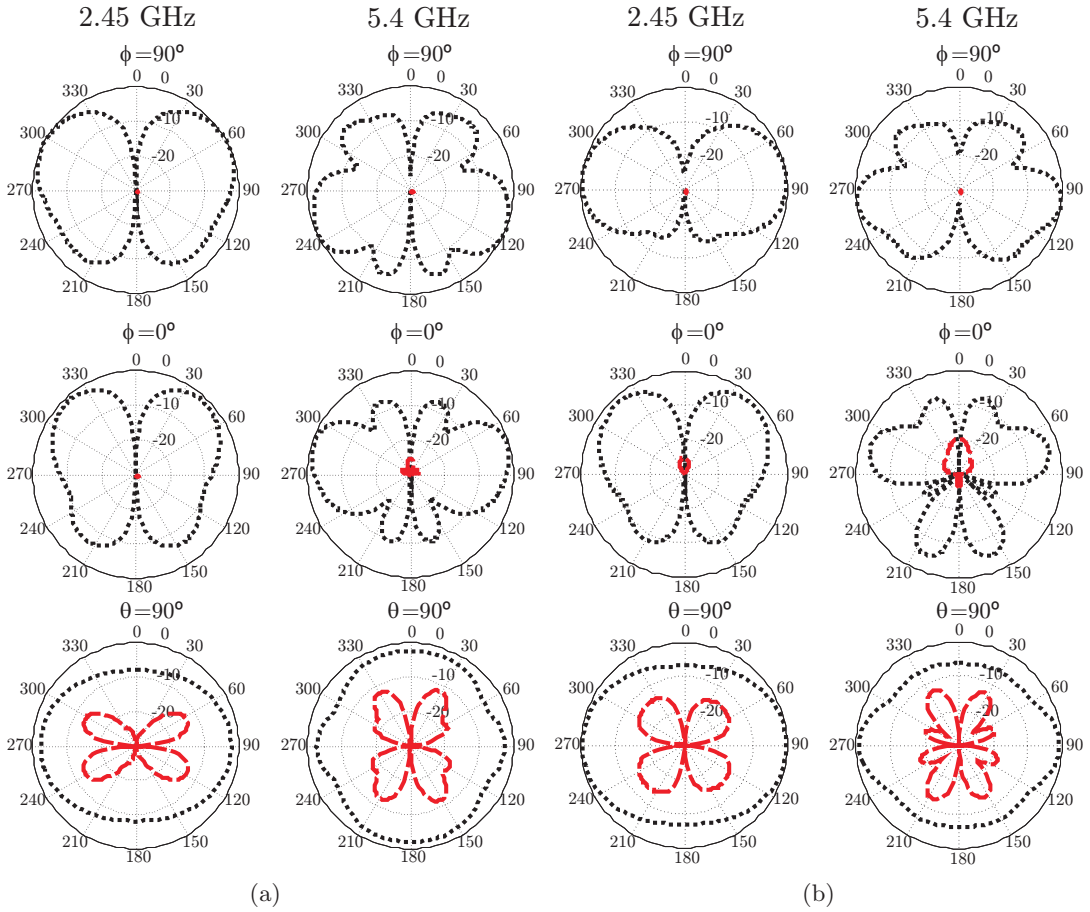

Figure 2.25: *Simulated normalized radiation patterns. Black dotted lines are used for the copolar component, red dashed lines are used for the crosspolar component. (a) Sierpinski monopole on a solid ground plane. (b) Sierpinski monopole on a fractal-based ground plane.*

can introduce new matching bands to the antenna.

Amateur radio enthusiasts have used a similar principle in trap antennas operating in HF bands for many years [66]. For operating in a number of bands, such as those between 3.5 MHz and 30 MHz, it is impractical for most amateurs to use a separate antenna for each band, for this reason multiband antennas are also necessary in this frequency range. As an example, in [66] a trap antenna with the structure shown in figure 2.26 for the 3.5 MHz and 7 MHz bands is presented.

A trap in an antenna can perform two different functions depending on whether or not it is resonant at the operating frequency. A typical use is a resonant parallel trap. Let us assume that each LC combination is resonant in the 7 MHz band. Because of this parallel resonance, the trap presents high impedance at this point of the antenna. The electrical

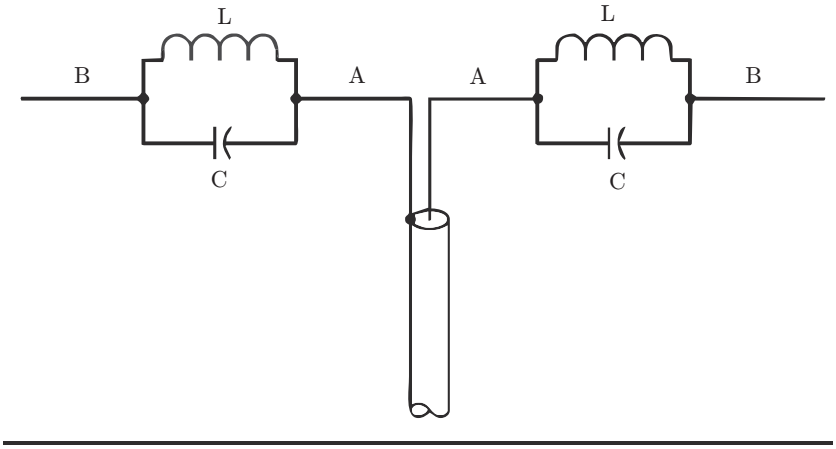

Figure 2.26: *Schematic representation of a trap dipole antenna [66].*

effect at 7 MHz is that the trap behaves as an insulator, an open circuit that 'cuts' the antenna at this point, separating the B sections from the antenna. The result is that we have an antenna system that is resonant in the 7 MHz band, taking into account that each section A represents $\lambda/4$ at this frequency. One of the problems of this configuration is that the trap losses at the resonance frequency can reduce the antenna efficiency.

At the other operating band, where the trap is not resonant, the LC resonators acts as an electric load. If the operating frequency is below the trap resonance, the trap acts as an inductor; if above, as a capacitor. Inductive loading will electrically lengthen the antenna, and capacitive loading will electrically shorten the antenna. In the example we are considering, the traps behave as inductors when operation takes place at 3.5 MHz, electrically lengthening the antenna. This means that the total length of sections A and B may be something less than a physical $\lambda/4$ at 3.5 MHz. Thus, we have a dual band antenna that is shorter than a resonant dipole in the lower frequency band.

In the previous example, traps were resonant at one of the two frequencies of operation. However, the same band coverage can be obtained with resonant traps at a frequency between both operating bands, for instance, 5 MHz. With proper selection of the LC ratio and the dimensions of A and B sections, the traps will act to electrically shorten the antenna at 7 MHz and electrically lengthen it at 3.5 MHz. Thus, an antenna that is intermediate in physical length between a resonant dipole at 3.5 MHz and a resonant dipole at 7 MHz can cover both bands, even though the trap is not resonant at these frequencies. Note that these traps have less RF current flowing in the trap components in the operating bands, and hence trap losses are lower. The use of a trap resonating at a frequency quite apart from the antenna operating bands is also known as off-resonance loading.

Based on these concepts and operating principles, different antenna topologies with multiband behavior suitable for the central unit of the sensor network will be presented and we will also give some guidelines for the antenna design process. In the frequency bands used by the sensor network, traps will be implemented in a distributed way instead of using discrete components, introducing some advantages such as the fact that the additional physical path created by the resonators can be used to tune the position of the straight monopole resonances.

2.3.2 Dual band resonator loaded monopole antenna

In this section the off-resonance loading principle will be employed in a design that avoids resonator losses using magnetic resonators whose natural frequency lies between the lower and upper WLAN bands.

Antenna design

The basic geometry of the antenna consists of two identical capacitively loaded magnetic resonators attached to a uniform width monopole (figure 2.27). The magnetic resonators

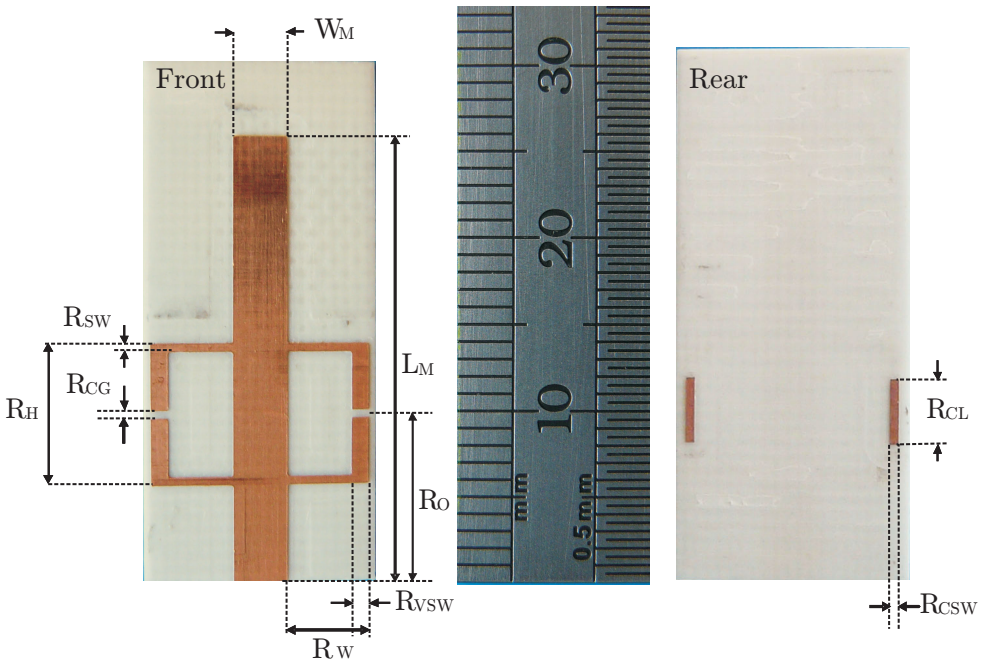

Figure 2.27: *Monopole antenna loaded with two double layer magnetic resonators DL-CLL [67] of identical dimensions fabricated on Rogers RO4003C [68] double sided 0.508 mm substrate (ϵ_r = 3.38, tanδ = 0.0021).*

are based on a double layer capacitive loaded loop (DL-CLL) [67].

The monopole length L_M affects both operating bands (figure 2.28(a)), so the design begins with L_M approximately equal to a quarter wavelength at 2.45 GHz. A small adjustment of this parameter must then be carried out to fine tune the first band position.

According to figure 2.28(b) the resonator width R_W simultaneously shifts the second and the third S_{11} minimums without significantly affecting the first. The second S_{11} minimum shifts because the resonator inductance changes with R_W. The third S_{11} minimum position is also affected by the resonator width because, as will be shown in figure 2.31, at frequencies near this S_{11} minimum currents tend to follow the perimeter

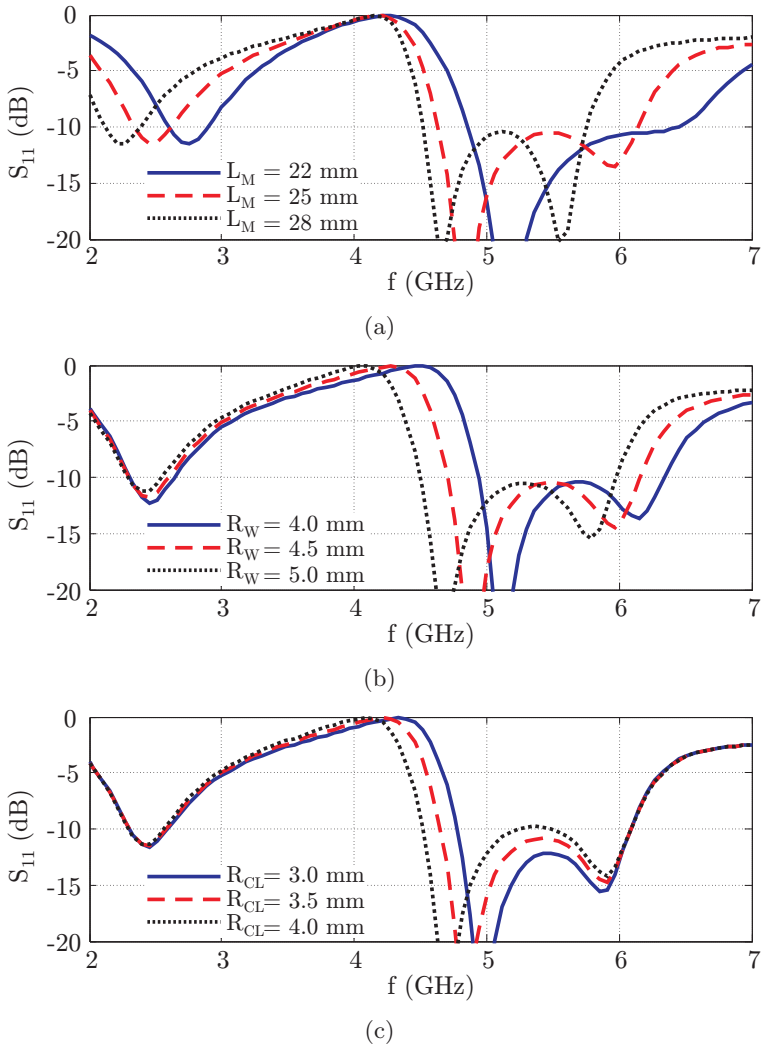

Figure 2.28: *Parametric study of the variation of the input reflection coefficient S_{11} with respect to (a) the monopole length L_M, (b) the resonator width R_W, (c) the length of the resonator capacitor strip R_{CL}.*

of the structure. Consequently, the resonator external width R_W is chosen based on the wavelength λ_2 corresponding to the upper frequency of the second band defined by the 802.11 standard (5.8 GHz) such that

$$L_M + 2R_W \approx \frac{3\lambda_2}{4} \tag{2.2}$$

The second S_{11} minimum is mainly controlled by the resonance frequency of the resonator (figure 2.28(c)). The resonator dimensions are set to obtain a resonance frequency lower than 4.9 GHz. This can be achieved by changing the resonator height R_H (modifying the inductance), the loop gap R_{CG}, and the rear strip dimensions R_{CL}, R_{CSW} (modifying the capacitance). The separation between the second and the third S_{11} minimums affects the second band bandwidth and matching levels. A clear trade-off between both parameters exists: when the separation is increased, bandwidth is improved, but center band matching is degraded.

The resonator quality factor will also affect the bandwidth of the impedance match over the 5 GHz band. The bandwidth can be increased by decreasing its capacitance and increasing the resonator height R_H in order to increase the inductance. The resonator loop strip width R_{SW} is chosen as 0.4 mm based on fabrication considerations.

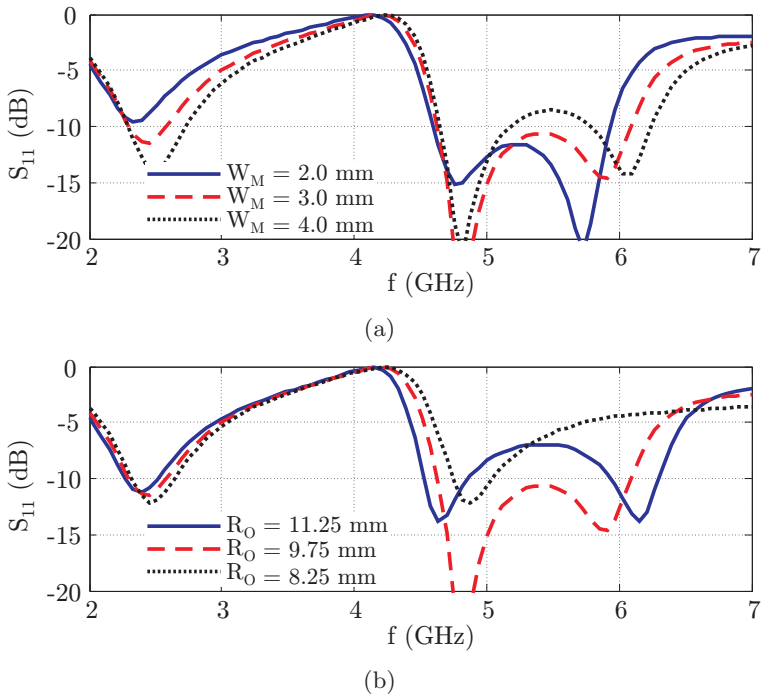

Figure 2.29: *Parametric study of the variation of the input reflection coefficient S_{11} with respect to (a) the monopole width W_M and (b) the resonator offset position R_O.*

The match over both operating bands can be optimized by adjusting the monopole width W_M and the resonator position offset R_O (figure 2.29(a) and 2.29(b)). Furthermore, the offset parameter controls the resonator loading position, and the adjustment of this parameter allows for the separation of the minimum efficiency point, due to resonator losses at the resonance frequency, from the match band (off-resonance loading principle).

After the initial design, a fine tuning process of the aforementioned parameters is necessary to allocate the operating bands according to the system requirements.

Prototype antenna: Fabrication and measurement

Figure 2.27 shows the prototype antenna fabricated on Rogers RO4003C [68] 0.508 mm substrate ($\epsilon_r = 3.38$, $tan\delta = 0.0021$) using a LPKF ProtoMat S62 circuit board plotter. Prototype dimensions are shown in table 2.3. The capacitor formed by overlapping strips on both faces is the most tolerance critical part of the fabrication process. The alignment tolerance was relaxed by making the front strip twice as wide as the rear strip. The prototype presented here is the second of two that were built on double-sided substrate, the first one covered 802.11 a/b/g/h WLAN bands and the second one, the universal 802.11 a/b/g/h/j WLAN bands that include Japan.

The input reflection coefficient of the fabricated prototype is plotted in figure 2.30. The available relative bandwidths (table 2.4) are enough to cover the WLAN and ISM bands requirements. In the 2.45 GHz band the relative bandwidth is 11.7 %. In the 5 GHz band, the combination of the second resonance of the straight monopole near 6 GHz and

Table 2.3: *Dimensions of the dual band WLAN monopole antenna.*

0.9 mm	0.5 mm	9.75 mm	3.6 mm	0.45 mm

Table 2.4: *Measured operating bands of the dual band resonator loaded monopole antenna (figure 2.27) with the dimensions of table 2.3.*

Resonator loaded monopole antenna		
Operating band (GHz)	Center frequency (GHz)	Relative bandwidth(%)
2.26 - 2.54	2.4	11.7
4.74 - 6.12	5.4	25.4

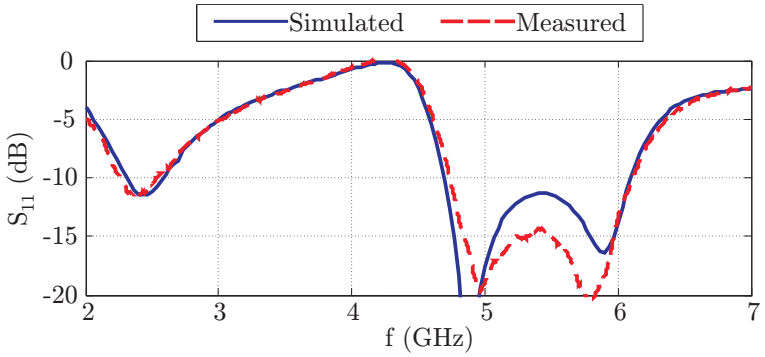

Figure 2.30: *Simulated and measured S_{11} parameters of the prototype antenna with the dimensions shown in table 2.3.*

the S_{11} minimum introduced by the resonator effects near 5 GHz, is used to improve the available bandwidth, achieving a relative bandwidth of over 25 %.

The normalized current distributions (figure 2.31) show a $\lambda/4$ standing wave at 2.45 GHz where currents in the resonator arms are practically zero, a $\lambda/4$ standing wave at 4.9 GHz where the resonator effectively isolates the top half of the monopole, and a $3\lambda/4$ standing wave at 5.875 GHz over a path that includes the monopole top and bottom strips and the resonator arms. This explains why the first S_{11} minimum position is mainly defined by the monopole length, the second S_{11} is mainly defined by the properties of the

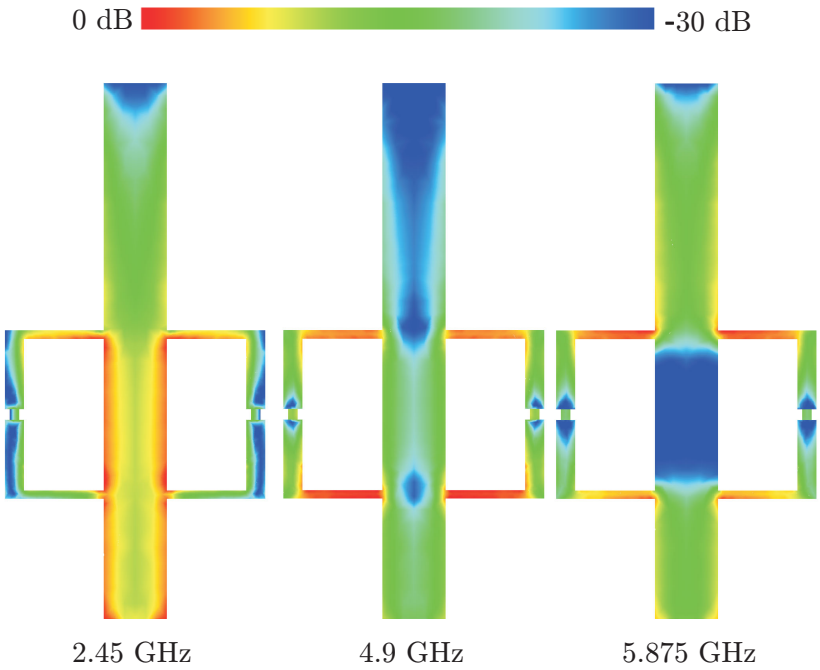

Figure 2.31: *Simulated current distributions at 2.45 GHz, 4.9 GHz and 5.875 GHz. Each image is individually normalized and displayed on a 30 dB scale.*

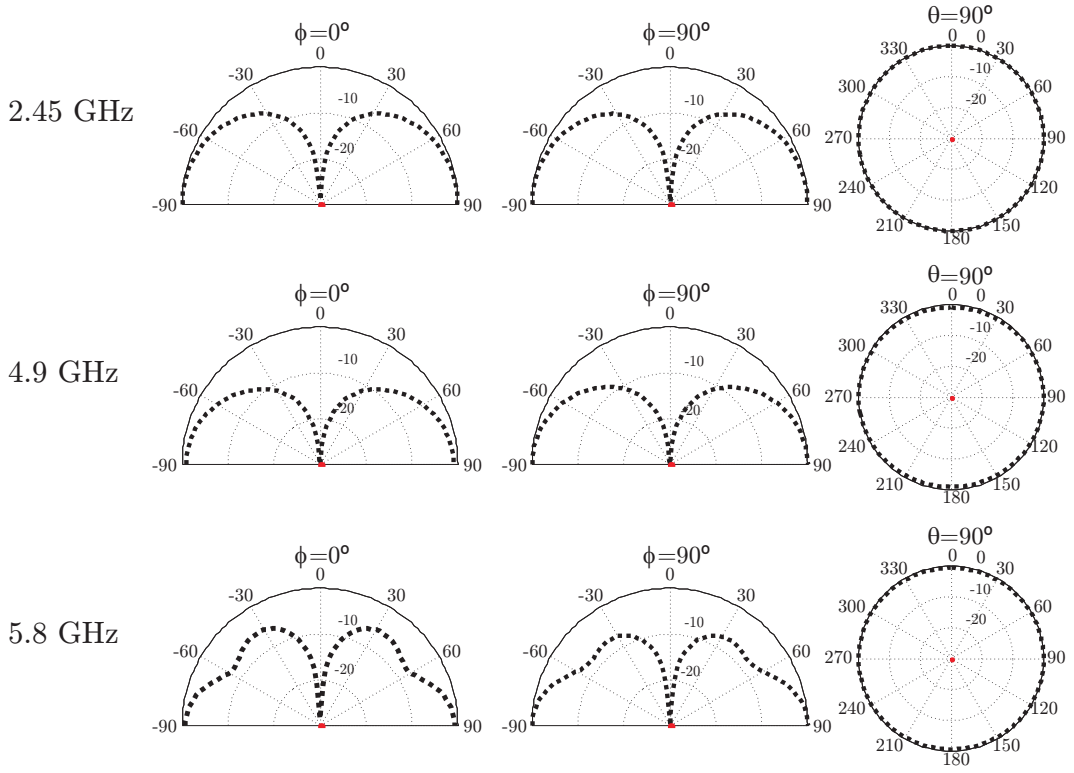

Figure 2.32: *Simulated radiation patterns of the prototype antenna whose dimensions are shown in table 2.3. Black dotted lines are used for the copolar components. Crosspolar components are too low to be plotted with the current axis configuration.*

monopole and the resonator, and the third S_{11} minimum is mainly defined by the length of the external perimeter of the structure (including the resonator arms).

Figure 2.32 shows the radiation patterns.There is little variation in the shape of the 2.45 GHz radiation patterns, so only one is shown in this frequency band. The patterns at 4.9 GHz are characteristic of a quarter wavelength monopole, while, as expected, those at 5.8 GHz show a three quarter wavelength monopole pattern. The H-plane radiation patterns are essentially omnidirectional with less than 1 dB variation over both bands. Due to the antenna symmetry, the simulated maximum crosspolar levels are exceptionally low. The gain ranges from a maximum of 7.1 dB to a minimum of 5.8 dB.

The radiation and total efficiencies of the fabricated prototype are plotted in figure 2.33. Measurements were carried out using the method presented in [69] and FEKO [70] was used for the simulations. The minimum efficiency occurs at the resonator resonance of 4.25 GHz, some 650 MHz below the band edge frequency of 4.9 GHz. The in-band radiation efficiency is practically unaffected by the resonators thanks to the use of the off-resonance loading principle where the resonator resonance is out of the antenna operating bands. Measured

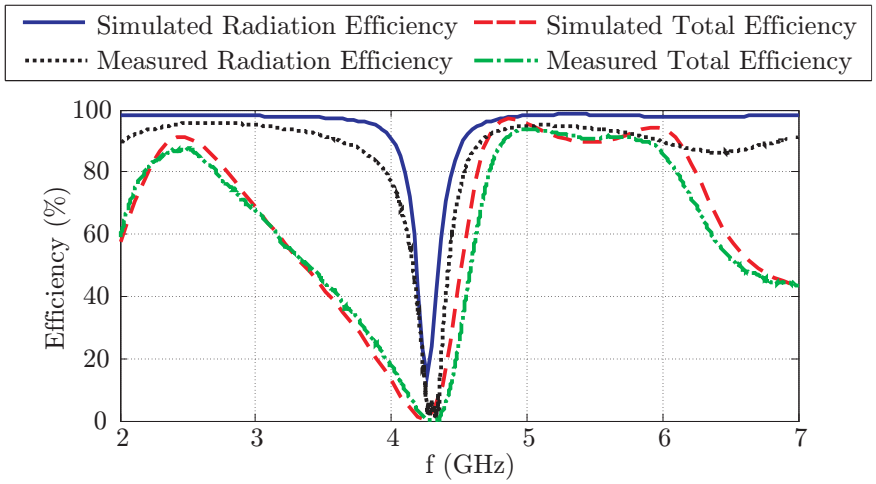

Figure 2.33: *Radiation efficiency and total efficiency of the prototype whose dimensions are shown in table 2.3. Efficiency measurements were carried out using the method presented in [69].*

total efficiency is higher than 85 % in both operating bands. For technical reasons, Method of Moments - Finite Element Method (MoM-FEM) FEKO simulations include dielectric losses but exclude copper losses, resulting in optimistic in-band radiation efficiency and somewhat larger errors out-of-band near the resonator resonance where copper losses are particularly important. Interestingly, the measured efficiencies confirm the overall FEKO predictions, which are especially useful for determining that the frequency of the minimum radiation efficiency is out-of-band.

The novel antenna analyzed in this section is also suitable for the central unit. Furthermore it is important to point out that its dimensions could be reduced loading the monopole with only one resonator, however with this asymmetric configuration the antenna performance is slightly degraded and crosspolar levels are increased.

2.3.3 Triple band SRR loaded monopole antenna

In the previous section a resonator loaded monopole has been presented in order to obtain a dual band radiator. Now, we will present a resonator loaded monopole that takes advantage of the dual band behavior of the Split Ring Resonator (SRR) to achieve triple band performance.

The SRR has already been used to load a dipole and obtain dual band behavior [64, 65]. In [65] the lower band was defined by the dipole resonance whereas the upper band was based on the first SRR resonance. However, the SRR also exhibits an upper resonance which has led recent papers to propose these 'particles' as basic building blocks for dual

band filters [71, 72]. Therefore we will present a structure that combines the dual band SRR with the first resonance of a monopole to obtain triple band performance with good radiation efficiency and similar radiation patterns in all the three bands. In this design, the new frequency band will be used to cover one band of the 802.15 standard (3.244 - 4.742 GHz).

SRR analysis

Conventional SRRs are made up of two concentric open rings with their slits on opposite sides. To evaluate the resonance frequency of the isolated rings and the SRR in free space we followed the procedure presented in [73] and calculated the monostatic radar cross section of the structure when a plane wave impinges as shown in figure 2.34.

Because of the coupling between rings, the SRR has two resonances (figure 2.35): one below and one above the individual resonances of the isolated rings. The SRR resonances depend on the length of the open loops and the gap between rings which controls the strength of the coupling. More details about the SRR design can be found in [71].

The simulated SRR current distributions (figure 2.36) agree with those in [71]: in the lower resonance the induced circulating current generates a magnetic dipolar moment aligned with the impinging magnetic field, whereas an electric dipolar moment aligned with the impinging electric field is created in the upper resonance.

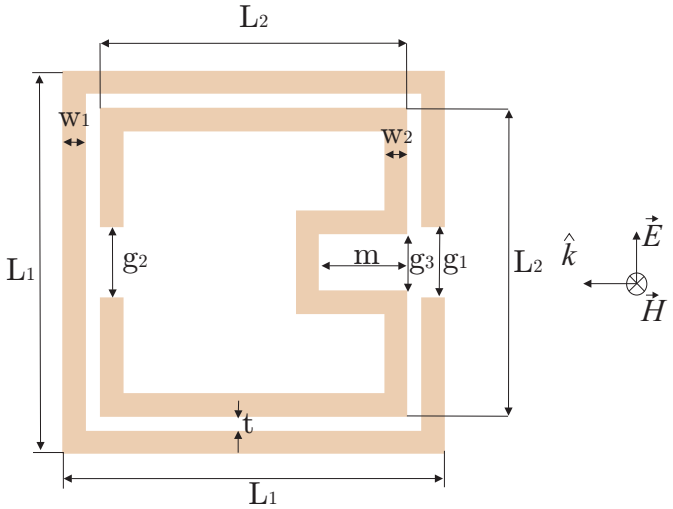

Figure 2.34: *SRR geometry and impinging plane wave for computation of the monostatic radar cross section. The SRR is supported on Rogers RO4003C 0.508 mm substrate ($\varepsilon_r = 3.38$, $\tan\delta = 0.0027$). $L_1 = 8.2$ mm, $L_2 = 6.6$ mm, $w_1 = w_2 = 0.5$ mm, $g_1 = g_2 = 1.5$ mm, $t = 0.3$ mm.*

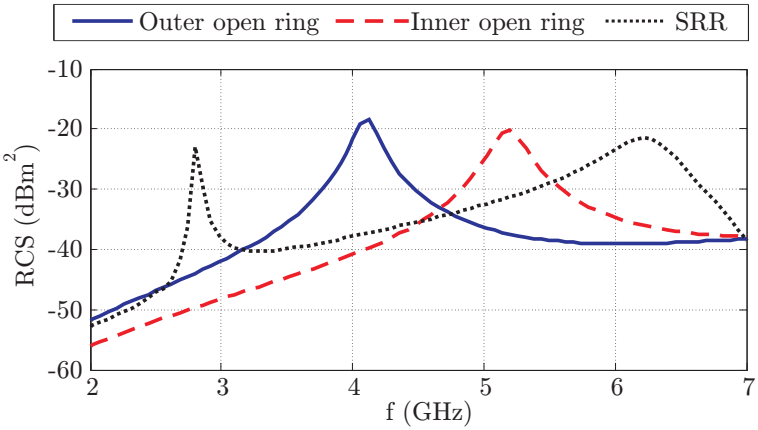

Figure 2.35: *Computed monostatic radar cross section in free space for the SRR of figure 2.34. Solid line: stand alone outer open ring. Dashed line: stand alone inner open ring. Dotted line: SRR.*

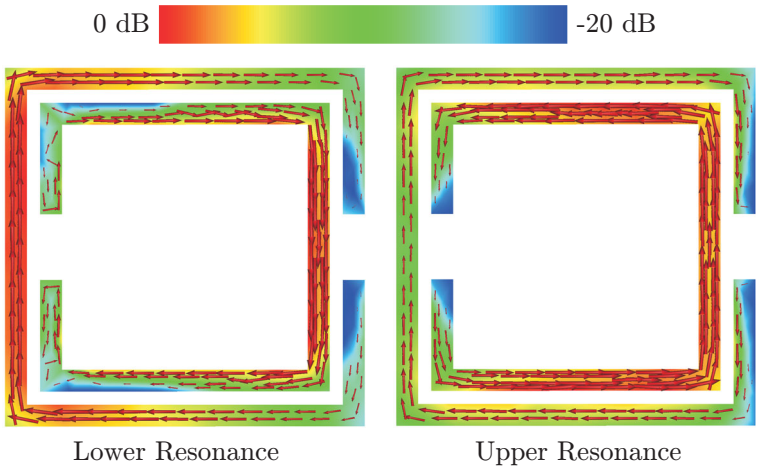

Figure 2.36: *Simulated current distributions. Each image is individually normalized and displayed on a 20 dB scale. Arrows are scaled according to the normalized current levels.*

Antenna design

The SRR loaded monopole antenna geometry consists of a monopole loaded with two identical SRRs (figure 2.37). The triple band performance could be achieved with a single SRR but a symmetric structure will result in highly symmetric radiation patterns with low crosspolar levels. The main drawback of the symmetric structure is an increase in the antenna width.

The design begins by considering the middle band (3.244 - 4.742 GHz) and adjusting the monopole parameters L_m, w_m, L_0 and w_0 to obtain impedance matching in a large

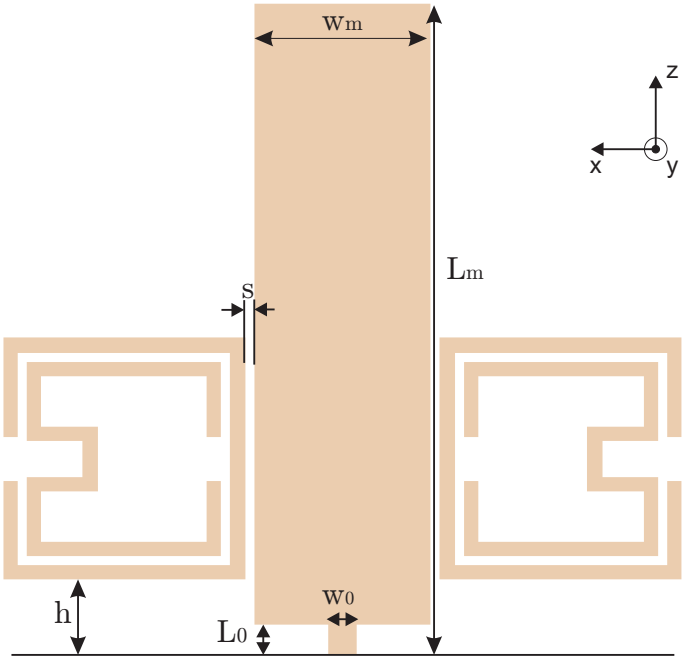

Figure 2.37: *SRR loaded monopole. The structure was fabricated on Rogers RO4003C 0.508 mm substrate (ε_r = 3.38, $\tan\delta$ = 0.0027). L_m = 22 mm, w_m = 6 mm, L_0 = 1 mm, w_0 = 1 mm, h = 2.5 mm, s = 0.3 mm. SRRs dimensions are the same as in figure 2.34.*

bandwidth centered just below the limit of this band, because according to figure 2.38, the presence of the SRRs will introduce an upward frequency shift in the monopole matching band. Using the values of figure 2.37, about 1 GHz of bandwidth centered at 3 GHz is obtained.

The SRRs are designed to resonate just above the upper limits of the 802.11 standard lower (2.4 - 2.5 GHz) and upper (4.9 - 5.875 GHz) bands. The SRR shown in figure 2.34, which resonates at approximately 2.8 GHz and 6.2 GHz (figure 2.35), is used. The orientation of the SRRs with respect to the monopole is selected in order to obtain maximum coupling. Other orientations do not provide enough coupling to obtain good matching levels over all the operating bands.

Figure 2.38 shows that when loading the monopole with the SRRs, two peaks appear at the SRRs resonances in both S_{11} and input impedance. Just before these peaks, two minimums in S_{11} appear used to allocate the lower and upper bands of the universal 802.11 standard. The mid-band response shifts higher in frequency when the SRRs are introduced.

The return losses and the position of the minimums can be slightly adjusted with the

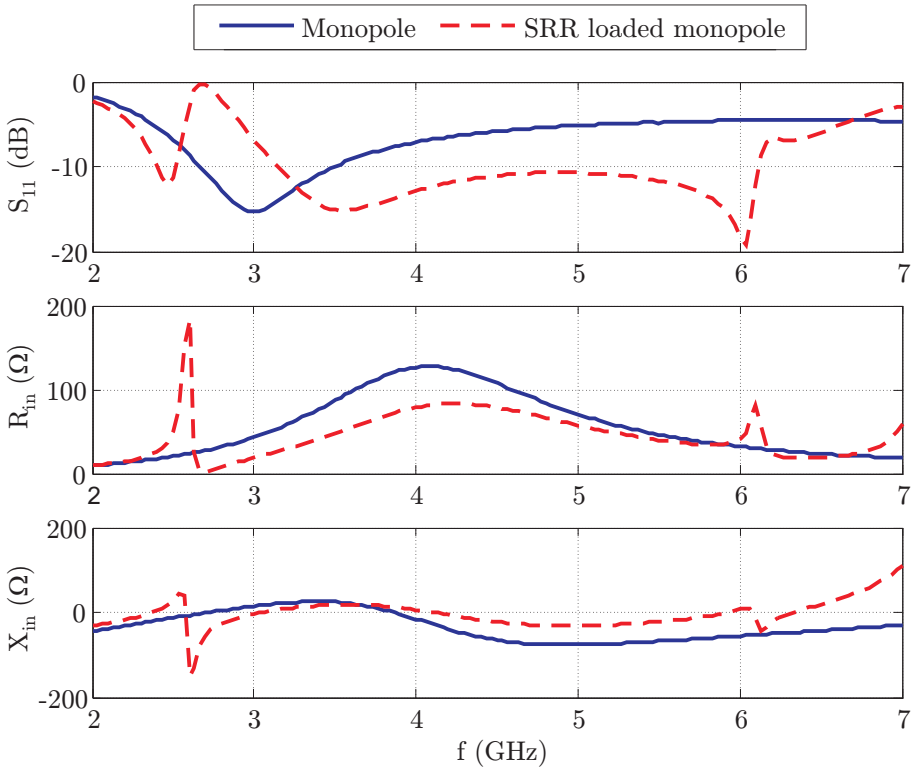

Figure 2.38: *Simulations comparing the stand alone monopole and the SRR loaded monopole.*

parameters s and h defined in 2.37. The coupling between SRRs and monopole reduces with increased separation s, resulting in smaller peaks in the impedance and less shift in the middle band. The SRRs to ground plane separation h sets the SRRs load position on the monopole, with larger values of h having a less significant loading effect on the input impedance. A fine tuning of these parameters gives the values of figure 2.37 and the results of figure 2.38 that meet the requirements.

The simulated antenna radiation efficiency is plotted in figure 2.39. The efficiency minimums introduced by the resonators losses are out of band and coincide with the S_{11} peaks, as a result the radiation efficiency in the operating bands is not expected to be significantly degraded by the high losses of the resonators at their resonance frequencies.

Prototype antenna: Fabrication and measurement

Figure 2.40(a) shows the fabricated prototype mounted on a large ground plane. The measured S_{11} parameters agree well with simulations (figure 2.40(b)). However the upper SRRs resonance is slightly shifted in frequency and its effects on the monopole input impedance are weaker than the simulation predictions. This may be due to tolerances

in the fabrication process. Anyway, according to table 2.5 a clear matching band can be observed at 2.45 GHz, and a broadband matching frequency range is obtained from 3 GHz to 6.2 GHz, covering the requirements of the ISM bands and the 802.11 and 802.15 standards.

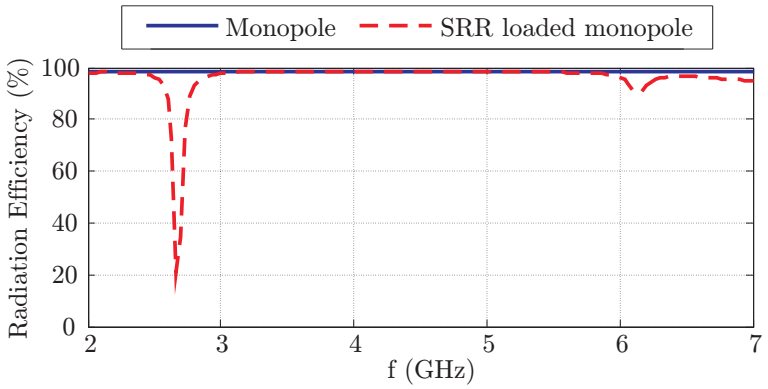

Figure 2.39: *Simulated radiation efficiency of the stand alone monopole and the SRR loaded monopole.*

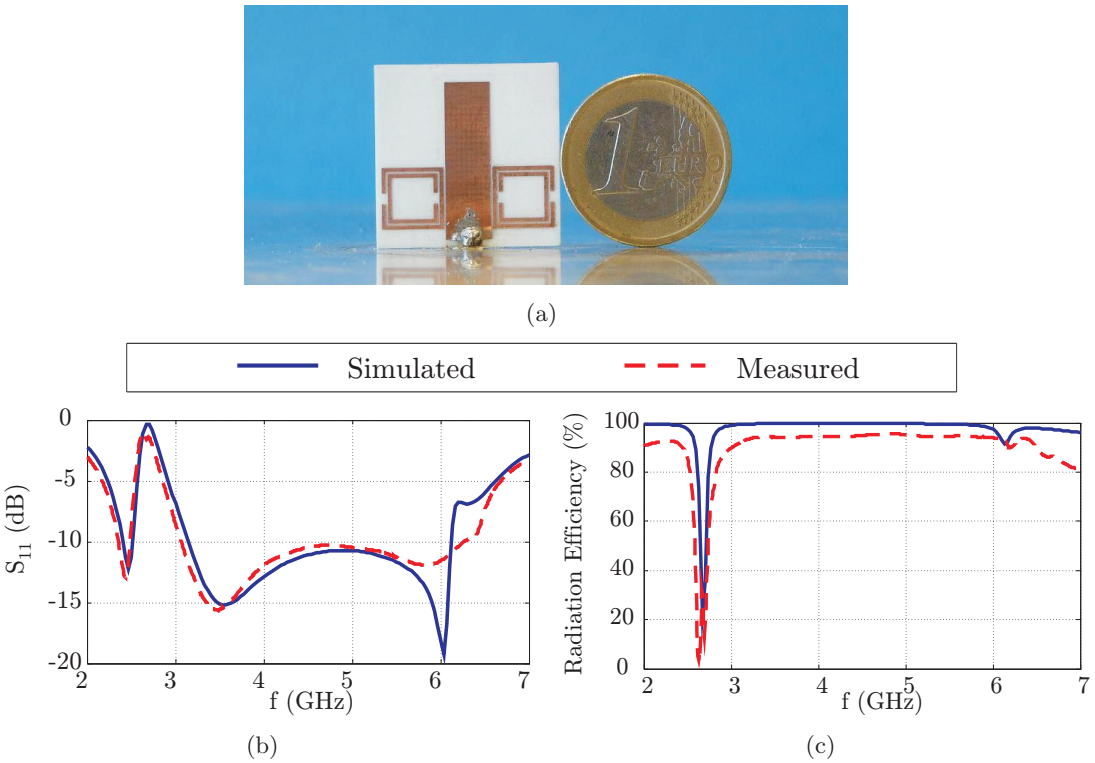

Figure 2.40: *SRR loaded monopole prototype antenna. (a) Prototype antenna mounted on a large ground plane. (b) Simulated and measured S_{11} parameters. (c) Simulated and measured radiation efficiency.*

Table 2.5: *Measured operating bands of the triple band SRR loaded monopole antenna (figure 2.40(a)). The second and the third bands have been combined obtaining a broadband matching frequency range from 3 GHz to 6.2 GHz.*

SRR loaded monopole antenna		
Operating band (GHz)	Center frequency (GHz)	Relative bandwidth(%)
2.35 - 2.5	2.43	6.2
3.06 - 6.25	4.65	68.5

The radiation efficiency (figure 2.40(c)) was measured using the method presented in [69]. By virtue of the off-resonance loading principle, the in-band radiation efficiency is practically unaffected by the SRRs losses, resulting in efficiency levels higher than 85% over all the operating bands. These measurements confirm that, although FEKO radiation efficiency simulation is optimistic, it predicts the overall behavior of the structure and the efficiency minimums position. At frequencies lower than 2 GHz and frequencies higher than 6.4 GHz efficiency measurements are distorted due to the limitations of the measurement method [69].

Figure 2.41 shows the measured copolar and crosspolar components of the normalized radiation pattern cuts in the main planes ($\phi = 0°$, $\phi = 90°$ and $\theta = 90°$) at 2.45 GHz, 3.5 GHz and 5.8 GHz. The E-plane cuts are quite similar for all the frequencies and the H-plane cuts are essentially omnidirectional. Furthermore, due to the antenna symmetry, measured crosspolar levels are low, normally less than -20 dB. The measured gain values range from 5 dB to 6 dB over all the bands, and are in agreement with the measured efficiency values (figure 2.40(c)).

These results demonstrate that the antenna presented in this section offers good triple band performance and could be used for the central unit, taking into account that the central unit could also use the 3.2 - 4.7 GHz frequency band of the 802.15 standard to transmit information.

2.3.4 Triple band resonator loaded monopole antenna based on the use of an asymmetric structure

As has been mentioned with fractal geometries, asymmetric structures are a good option to increase design flexibility in multiband antennas. In this section a novel antenna design that uses two different loading resonators to obtain a triple band asymmetric monopole will be shown. The use of an asymmetric structure will introduce a new degree of freedom in the design process and with the off-resonance loading principle the resonators losses in

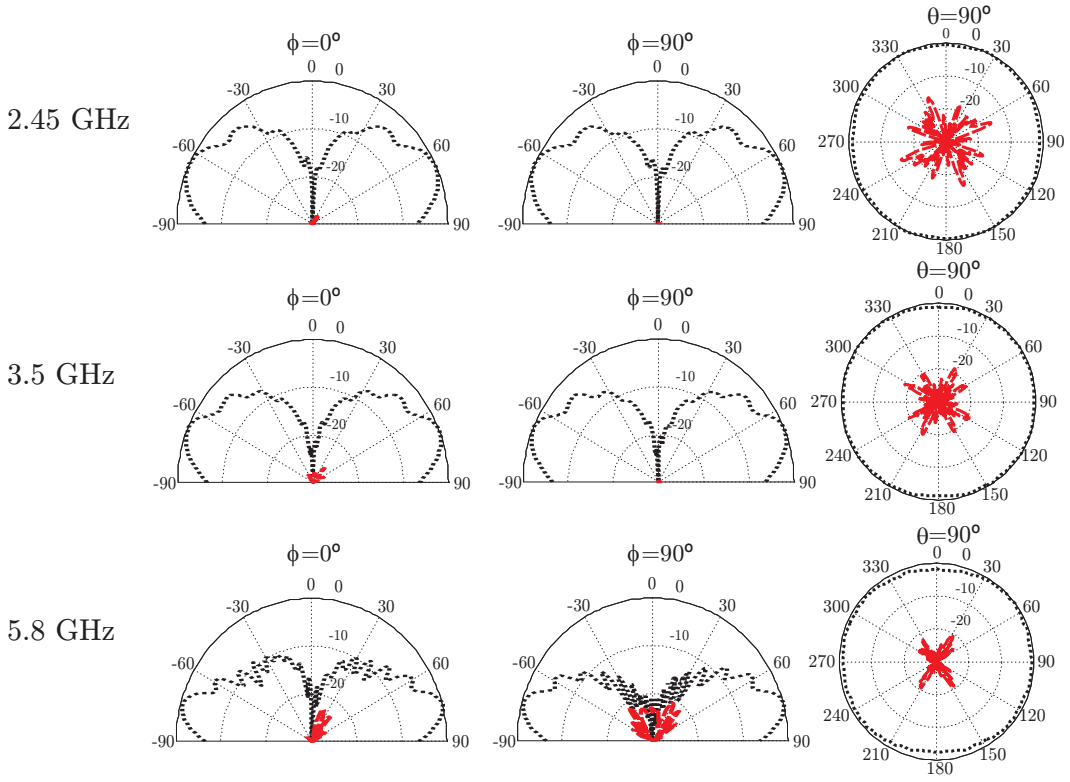

Figure 2.41: *Measured normalized radiation patterns of the SRR loaded monopole. Each cut has been normalized with reference to its maximum. Black dotted lines are used for the copolar component; red dashed lines are used for the crosspolar component.*

the matching bands will be avoided.

Antenna design

The antenna geometry consists of an asymmetric structure based on a monopole loaded with two resonant particles with different resonance frequency (figure 2.42). Figure 2.43 shows the existence of three matching bands around 2.45 GHz, 3.5 GHz and 5.4 GHz.

The first S_{11} minimum is used to cover the lower band of the 802.11 standard (b / g) and the 2.45 GHz ISM band. As can be seen in figure 2.44 currents have the typical distribution of a $\lambda/4$ monopole with significant currents in the resonators, especially in the largest one. Therefore this band corresponds to the first resonance of the straight monopole, taking into account that it is slightly frequency-shifted due to the resonator loading effects.

With the second S_{11} minimum, the 3.5 GHz band of WiMAX can be covered. This minimum basically appears due to the large resonator effects (it resonates at a frequency

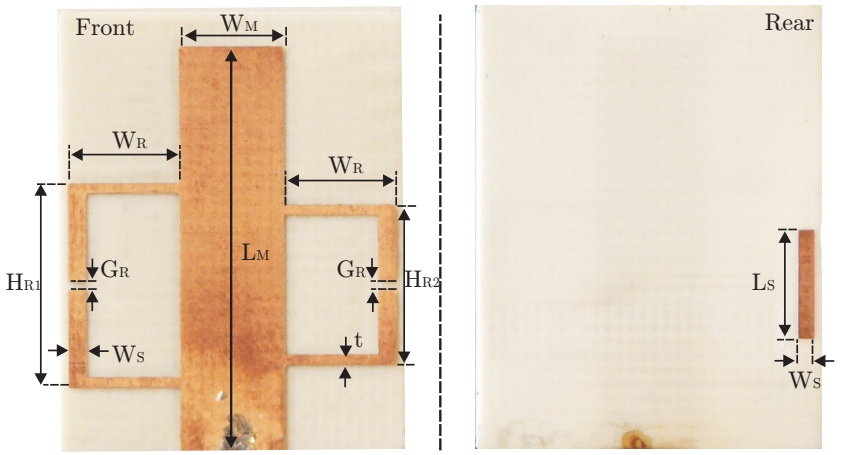

Figure 2.42: *Fabricated prototype. In the rear side a conductor strip is used to reduce the resonance frequency of the large resonator.*

around 2.9 GHz) and its position can be controlled adjusting the resonance frequency of this resonator. In the design of this resonator, a conductor strip in the rear side of the substrate is used to increase its capacitance and decrease the resonance frequency without a significant increase in the resonator dimensions. In this frequency band currents in the small resonator are also significant (figure 2.44), and hence it will be slightly frequency-shifted due to the effects of this resonator.

Finally, the upper band of the international 802.11 standard (a / h / j) and the 5.8 GHz ISM band are covered by combining the third and fourth S_{11} minimums. According to figure 2.44, the third S_{11} minimum is mainly due to the minor resonator effects (it resonates at a frequency around 4.5 GHz) and its position can be controlled adjusting the dimensions of this resonator. The fourth S_{11} minimum is due to the monopole second resonance. However, as in the loaded monopole of section 2.3.2, at this frequency currents tend to follow the perimeter of the structure. Therefore, this S_{11} minimum is affected by the additional path introduced by the resonator arms. For this reason, the position of this minimum can be controlled adjusting the resonators width W_R. Tuning the separation between both S_{11} minimums the available bandwidth of this band can be optimized, taking into account that a clear trade-off exists between the available bandwidth and the matching levels at the center of the band.

Figure 2.43 shows a parametric analysis of the variations of S_{11} parameter with respect to the most important design parameters of figure 2.42. The monopole length modifies the position of all the matching bands (figure 2.43(a)), while the monopole width does not significantly change the position of the bands, although it affects the overall matching levels (figure 2.43(b)).

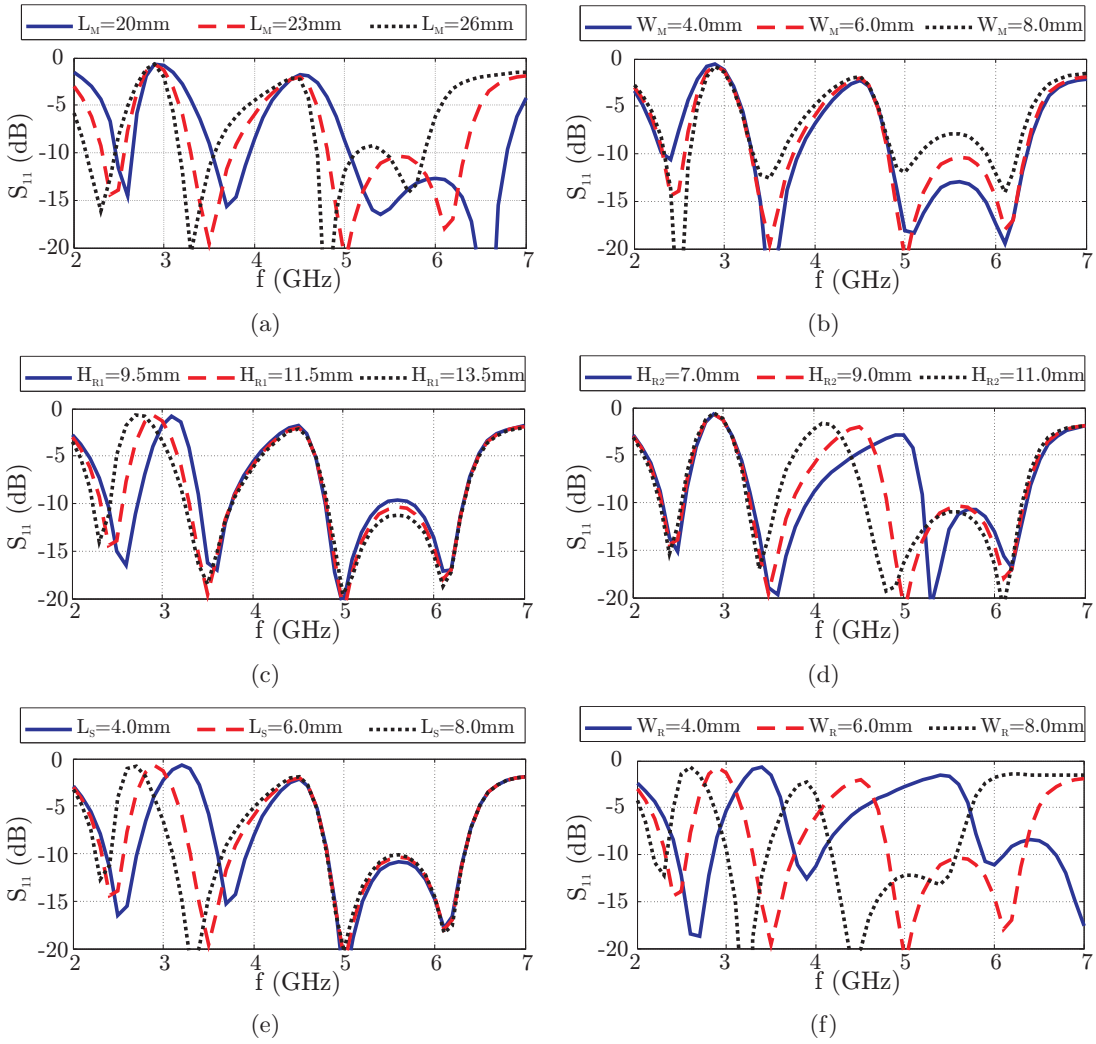

Figure 2.43: *Parametric study of the variation of the S_{11} parameter with respect to (a) the length of the monopole L_M, (b) the width of the monopole W_M, (c) (d) the height of the resonators H_{R1}, H_{R2}, (e) the length of the rear side strip L_S and (f) the width of the resonators W_R.*

The resonance frequency of the large resonator lies between the first and the second S_{11} minimums: for this reason when this resonator is modified, these two minimums will be affected. This is proved in figure 2.43(c) and figure 2.43(e), where the resonance frequency is changed by modifying the inductance and the capacitance respectively. The resonance frequency of the small resonator lies between the second and the third S_{11} minimums, therefore the modifications applied to this resonator will affect the properties of both minimums(figures 2.43(d)).

Finally, when the resonator width is changed all the S_{11} minimums are moved (figure 2.43(f)). This is logical, since this width will change the resonance frequency of both

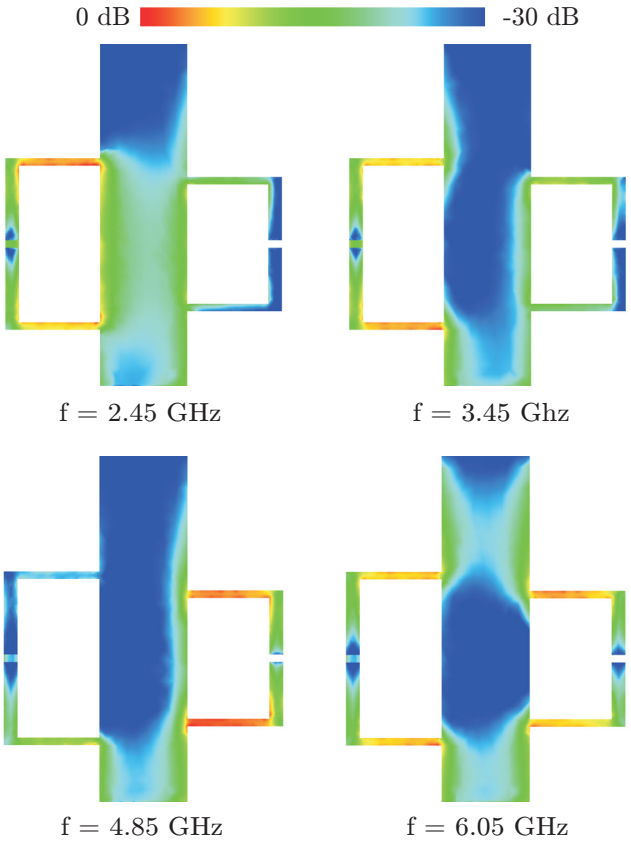

Figure 2.44: *Simulated current distributions at the S_{11} minimums. Each image is individually normalized and displayed on a 30 dB scale.*

resonators, and as it has been shown before, this will change the position of the first three S_{11} minimums. With reference to the fourth S_{11} minimum, the additional path added by the resonators arms will also change, and as a result, this minimum will be frequency shifted.

Prototype antenna: Fabrication and measurement

Taking into account the aforementioned trends, a monopole antenna for ISM / WLAN / WiMAX services was designed. The whole monopole dimensions are 20 mm x 25 mm and it was fabricated on Rogers RO4003C substrate ($\epsilon_r = 3.38$, $tan\delta = 0.0021$). Table 2.6 shows the dimensions of the prototype antenna.

In figure 2.45 three matching bands at 2.45 GHz, 3.5 GHz and 5.4 GHz are observed, with relative bandwidths of 14.7 %, 18.9 % and 23.2 % respectively, enough to cover the ISM, WLAN (802.11 a/b/g/h/j) and WiMAX requirements. More detailed information about the operating bands can be found in table 2.7.

2.2 - 2.55	2.375	14.7
3.26 - 3.94	3.6	18.9
4.83 - 6.10	5.46	23.2

The measured and simulated position of the efficiency minimums agree well (figure 2.46). These efficiency minimums are related to the resonance of the resonators and again, thanks to the use of the off-resonance loading principle, they are out of the antenna operating bands, and therefore do not degrade the in-band total efficiency. The measured total efficiency is higher than 80 % in all the three bands.

The measured radiation patterns of the proposed design are plotted in figure 2.47. E-plane radiation patterns are similar in all bands and have the typical shape expected from a quarter wavelength monopole. H plane radiation pattern cuts are essentially omnidirectional in all the bands. Crosspolar levels will be slightly degraded due to the antenna asymmetry, however in the radiation pattern cuts shown in figure 2.47, crosspolar

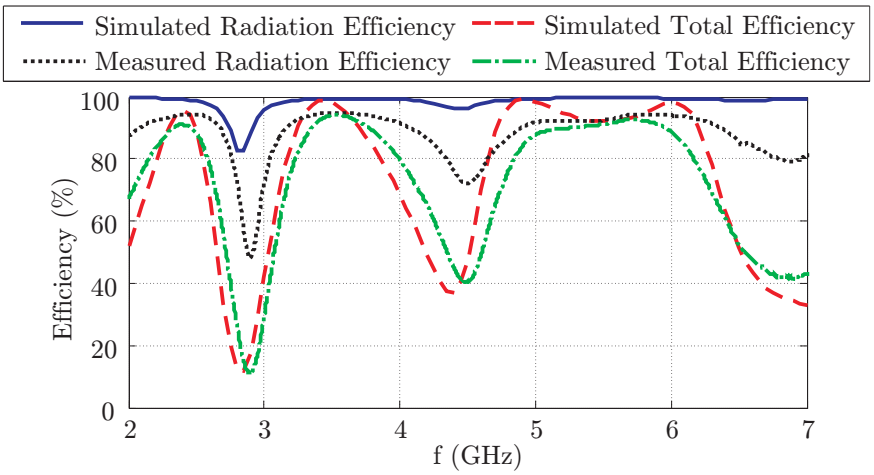

Figure 2.46: *Measured and simulated results for the radiation efficiency and the total efficiency. Total efficiency takes into account the mismatch loss.*

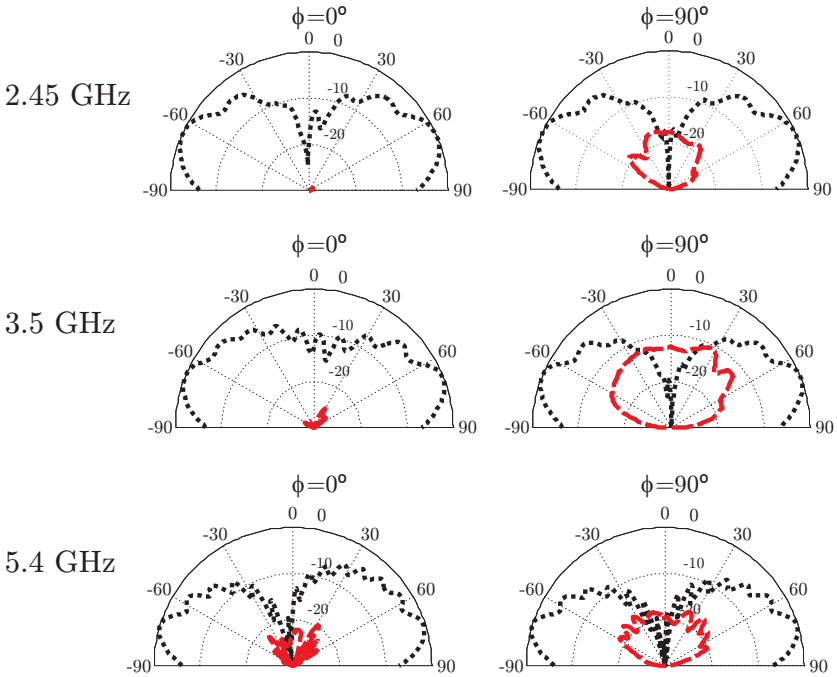

Figure 2.47: *Measured radiation patterns of the asymmetric loaded monopole in the three operating bands. Each cut has been normalized with reference to its maximum. Black dotted lines are used for the copolar component; red dashed lines are used for the crosspolar component.*

levels are below -15 dB in the directions of maximum radiation. The measured gain values range from 5 dB to 6 dB over all the bands.

Measurements and simulations show that the proposed antenna offers good matching levels, measured total efficiency levels of over 80 % and similar radiation patterns along all the three bands, therefore it is also suitable for the central unit. Furthermore, with this novel antenna the central unit capabilities could be improved using a WiMAX connection to send the collected information to the Internet without the need for any additional radiating element.

2.4 Chapter conclusions

In the central unit, multiband radiators are desirable to be able to receive information from sensors using the 2.45 GHz and 5.8 GHz ISM bands, and simultaneously send this information to the Internet using the 2.45 GHz and 5 GHz WLAN bands with a single radiating element. The solutions presented in this chapter are based on:

- Fractal shapes.
- Structures loaded with resonators.

The most commonly used fractal shape for the design of multiband antennas is the Sierpinski gasket due to its self similarity property at different scale levels. Fractal shapes have usually been utilized in the monopole element assuming that it is on a large ground plane, however they can be also applied to the ground plane. As an example a fractal-based ground plane inspired by the Sierpinski gasket has been presented. The modified ground plane adds new resonances that can be combined with the monopole element resonances to improve the antenna multiband performance. As proof of concept, two novel antenna designs have been built and measured.

The first one is a dual band antenna based on a triangular monopole mounted on a fractal ground plane. The novel ground plane has allowed us to add new operating bands to the triangular monopole without degrading radiation patterns and efficiency. Through current distribution analysis, it has been shown that currents in the ground plane scale with frequency, and thanks to the self-similarity property of fractal shapes, the current distributions in the different frequency bands are the same but at different scale levels. This is the main reason why this kind of ground plane offers good log-periodic multiband performance.

A Sierpinski monopole on a fractal-based ground plane has been also presented. The use of the fractal shape in both elements gives more flexibility to the design process. When the Sierpinski gaskets used in both elements are equal, the ground plane reinforces the monopole resonances, while if they are slightly different, resonance frequencies are not the same and the available bandwidths of the whole structure can be increased. Adjusting the height of the monopole above the ground plane, a fine tuning process can be carried out and the overall antenna performance can be improved. Comparing the first antenna design with this second, the combination of the fractal shape in both elements improves the available bandwidth in the 2.45 GHz band. These two multiband antennas cover the 2.45 GHz and 5.8 GHz ISM bands, and the 2.45 GHz and 5 GHz WLAN bands, and hence they can be perfectly used as radiating element for the sensor network central unit.

The second solution proposed in this chapter to obtain multiband behavior is resonator loaded monopoles. In order to improve the antenna performance it is advisable to use the off-resonance loading principle. This means that the resonators are designed to allocate their resonances out of the antenna operating bands. With this technique new matching bands are introduced without significantly degrading the in-band radiation efficiency.

Based on this principle a simple design procedure for a dual-band ISM / WLAN monopole antenna based on capacitively loaded magnetic resonators has been presented. A fabricated prototype that easily meets the specifications was demonstrated, showing good matching, high efficiency levels and similar radiation patterns in both bands. This prototype antenna covers the ISM and WLAN bands, and hence it is also suitable for the central unit.

The same concept can be also applied to introduce more operating bands. As an example, two novel triple band antennas have been presented. In the first, the triple band performance is achieved using dual band SRRs. The lower and upper bands positions are essentially controlled by the SRRs dual band behavior whereas the monopole dimensions define the middle band. A prototype that covers the universal 802.11 standard, the 5.8 GHz ISM bands and one band of the 802.15 standard (3.24 - 4.74 GHz) with radiation efficiencies higher than 85% was fabricated and measured.

In the second example, the triple band performance is achieved using simple resonators in an asymmetric structure. The asymmetric structure allows for the addition of new operating bands, and the position of these bands can be easily controlled by the design parameters of the loading resonators. An asymmetric prototype antenna for the ISM, 802.11 standard and 3.5 GHz WiMAX bands was fabricated and measured, proving the good performance offered by this topology. Moreover, the effects of two different dual band

resonators could be combined in an asymmetric structure to further improve the antenna multiband behavior.

These two antennas cover the ISM and WLAN bands, and therefore are suitable for the central unit. Furthermore the third band could be used to improve the system performance with a WiMAX connection for those places away from any WLAN access point.

In this chapter several novel antenna designs suitable for the central unit of the sensor network have been presented. In a real application, if we can define the ground plane geometry, the solutions based on fractal ground planes can be applied. With these solutions, the ground plane area could be covered in a transparent plastic, and the antenna could even be seen as a decorative element. However, if access to the ground plane design is not available, the solutions based on resonator loaded monopoles must be used. Both solutions could be also combined to improve performance.

Chapter 3

Small silicon integrated antennas for the remote sensors

This chapter of the thesis will focus on the design of antennas for the remote sensors. As has been said in the introduction, sensors dimensions and cost are key factors to ensure system viability, therefore small and cheap sensors are desirable. One possible solution to achieve these requirements is the use of integrated silicon antennas fabricated on standard CMOS technology silicon substrates, where the antenna, the electronic circuits and the sensor are made together in the same chip, obtaining a system-on-chip solution.

Firstly the performance offered by different miniaturization techniques when they are applied to antennas built on a low resistivity substrate will be analyzed. Next, micromachining techniques will be presented as a solution to improve antenna efficiency, and finally the performance degradation due to the presence of parasitic elements will be studied.

3.1 Introduction to silicon integrated antennas

Packaging and assembly of radio front-ends, especially at high frequencies, is currently a significant cost of the total product. Hence, monolithic integration of all the high frequency components on a single semiconductor chip has the potential of lowering the price of transceiver units to acceptable levels for mass market applications [74]. The fabrication of the antenna and the electronic circuits in the same chip reduces assembly costs and the system dimensions [75]. Despite their potential cost and integration benefits, the use of on-chip antennas has not yet become widespread. One of the main reasons is that the antenna is one of the most difficult RF-components to integrate on-chip with active circuits.

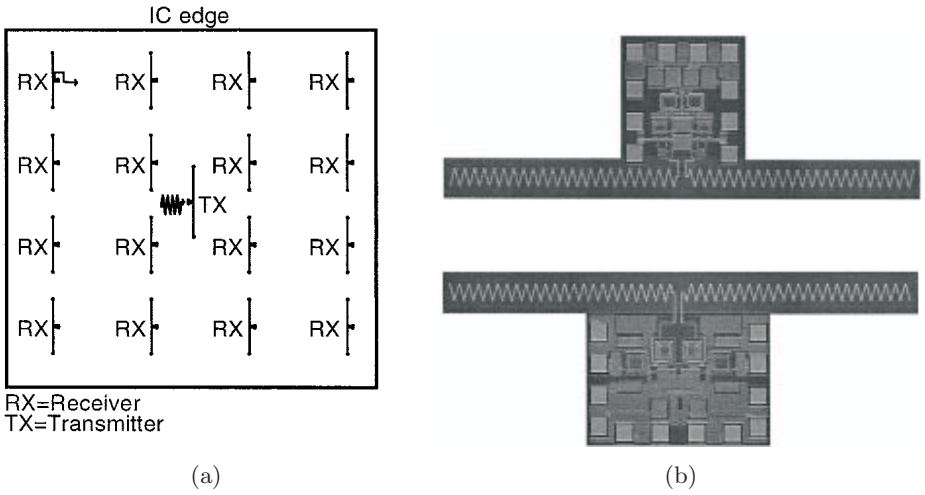

Figure 3.1: *Example of intra-chip communication system. (a) Conceptual system illustration of intra-chip wireless interconnected system for clock signal distribution. (b) 0.18 μm clock transmitter and receiver with zigzag dipole antennas [78].*

In order to reduce fabrication costs and obtain real system on-chip devices, it is also desirable to make the antenna fabrication process compatible with standard CMOS technologies using a silicon substrate not optimized for antennas production. The low bulk resistivity silicon of the wafers normally used in standard CMOS processes for the fabrication of active devices decreases the antenna radiation efficiency drastically. Furthermore this efficiency degradation is emphasized when miniaturization techniques are applied to reduce antenna dimensions [76]. All these problems mean that integrated antennas design is not an easy process.

In literature, several examples of silicon integrated antennas for intra-chip and inter-chip communications can be found. As an example of intra-chip communications, in [77, 78] integrated antennas are used for the distribution of the clock signal to minimize the delay (figure 3.1). In a similar way, integrated antennas could be also used to transmit the clock signal among different chips.

Some of the first examples of antennas for inter-chip communications and for communications with an external receiver were presented in [79], where Buechler showed some antennas built on silicon substrates (figure 3.2(a)). In [80], the folded slot of figure 3.2(b) is proposed as basic radiating element for automotive short range radar applications in the 79 GHz band.

At the millimeter wave frequency range wavelength is small and therefore complex antennas can be integrated in a reduced area. In [81] a 1.3 mm quasi-Yagi antenna with one driver, two directors and a truncated ground plane that acts as a reflector is presented

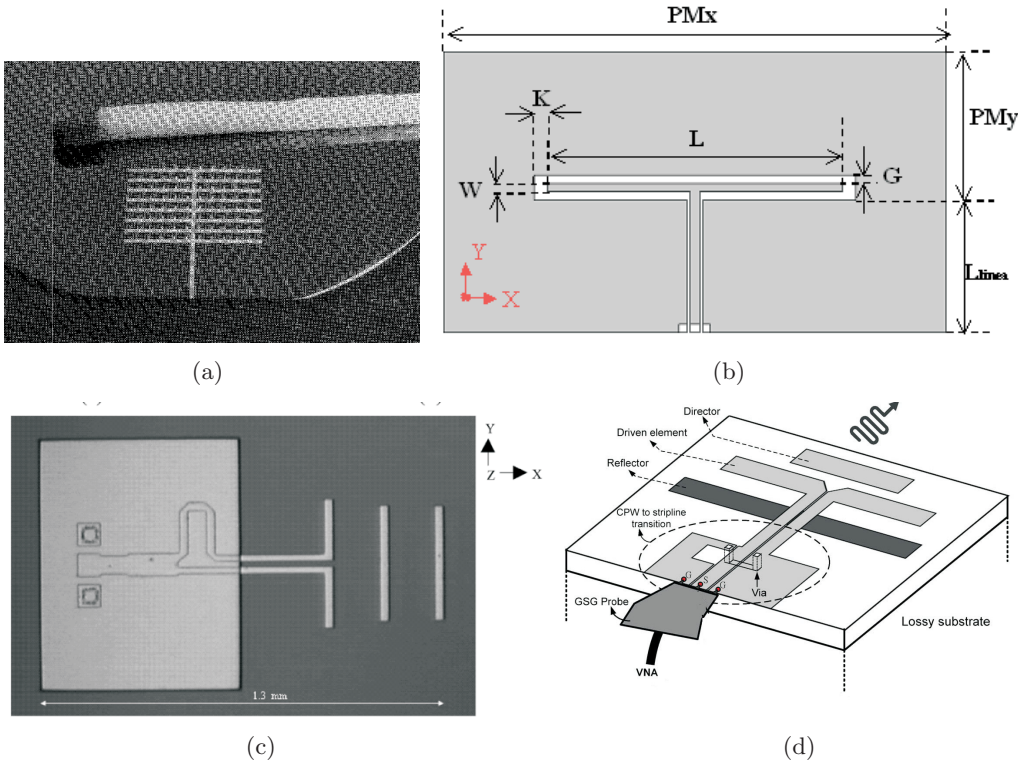

Figure 3.2: *Examples of integrated antennas operating at frequencies higher than 60 GHz. (a) Array antenna fabricated on high resistivity silicon presented by Buechler in 1986 [79]. (b) Folded slot antenna designed at 79 GHz [80]. (c) and (d) 60 GHz on-chip Yagi antennas [81, 82].*

(figure 3.2(c)). Another example can be found in [82], where a director element, a driven element and a reflector element are used on the design of a Yagi antenna with dimensions of 1.1 mm x 0.95 mm (figure 3.2(d)).

The aforementioned integrated antenna examples work in the frequency bands of 60 GHz or higher. In [75, 83, 84] Lin studies the performance of integrated antennas in the 24 GHz ISM band. These antennas are fabricated using the conductor and dielectric layers available in mainstream silicon technologies to keep the integration of on-chip antennas viable and inexpensive [75].

Figure 3.3 shows the layout of the zigzag dipole antenna presented by Lin in [83], a schematic representation of the measurement setup and the measured antenna pair gain for different environments. The antenna pair gain includes the gain of the transmitting and receiving antennas and the propagation losses. At a distance of 1 m, antenna pair gains of less than -80 dB have been measured. In spite of these low values, it can be seen that the zigzag dipole increases the antenna pair gain by 35 dB with respect to the situation

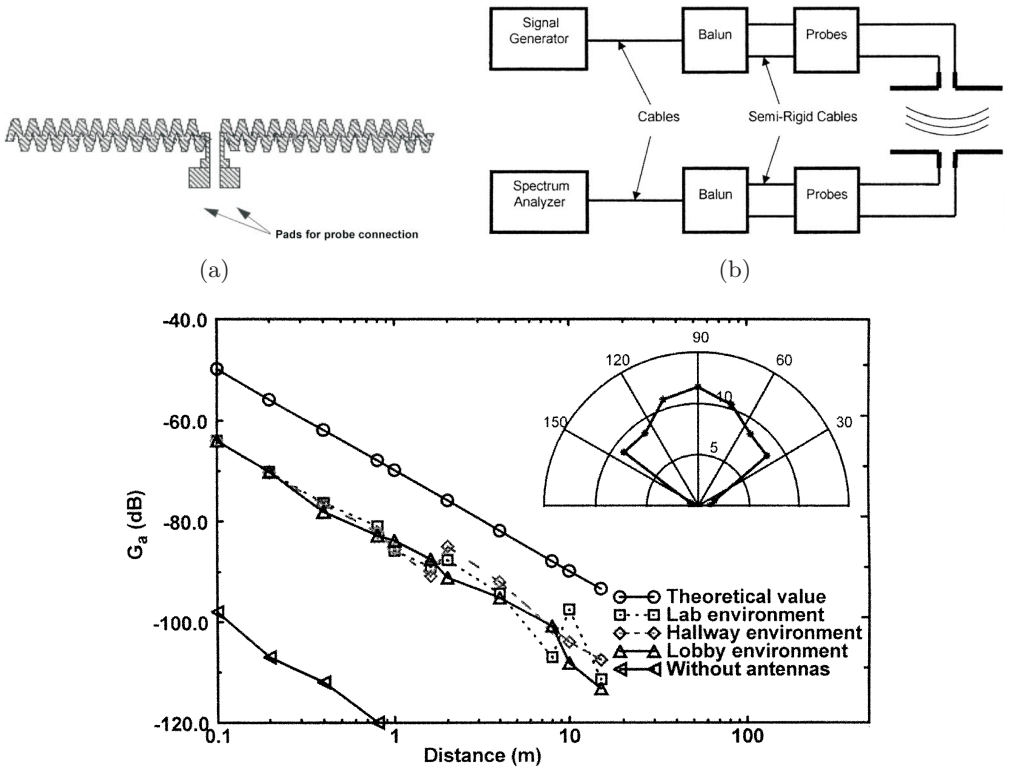

Figure 3.3: *Integrated antenna presented by Lin in [83]. (a) Layout of the 2 mm zigzag dipole. (b) Antenna measurement setup with a signal generator and a spectrum analyzer. (c) Antenna pair gain as a function of the distance in three different environments at 24 GHz. The inset shows the 2 mm zigzag dipole antenna radiation pattern.*

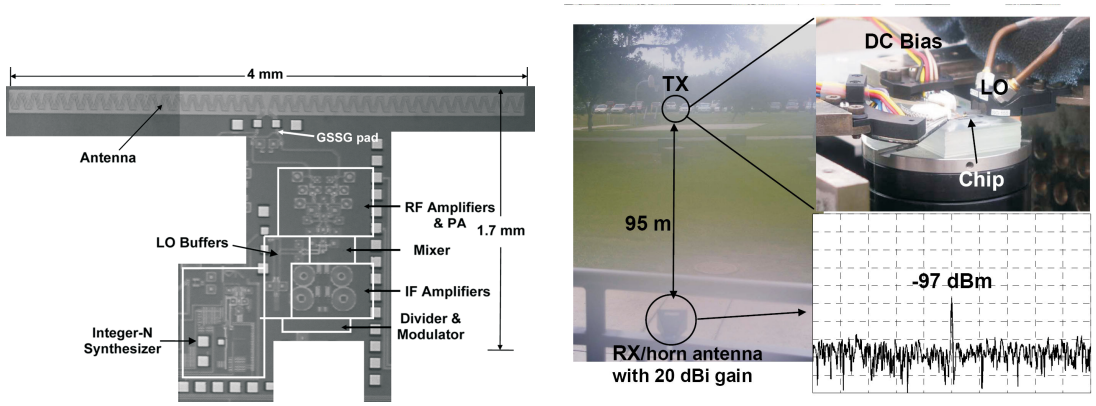
where the probes are the only radiating elements.

Other examples of silicon integrated antennas operating at frequencies higher than 10 GHz can be found in [85–89], where several techniques and topologies, such as IFA structures, micromachining or dielectric resonators, are used in order to improve the antenna performance. The previous references are focused on the antenna design, but there are also some references where the whole system is analyzed. For instance in [90, 91] a fully integrated transmitter with an on-chip dipole antenna is presented, showing that complete system integration with high system ranges is possible (figure 3.4).

In some applications, such as in implantable devices, frequencies lower than 10 GHz are desirable to reduce the additional propagation losses introduced by body tissues [92, 93]. At lower frequency bands the radiating element dimensions become a problem because antennas are larger, therefore miniaturization techniques must be applied [76] to



(a) (b)

Figure 3.4: *Fully integrated transmitter with an on-chip dipole antenna at 24 GHz [91]. (a) Photomicrograph of the fully integrated transmitter and frequency synthesizer. (b) Reception of the signal generated by a transmitter IC with an on-chip antenna using a 20 dBi gain horn antenna.*

allow antenna integration without an excessive enlargement of the chip dimensions. Some examples of integrated antennas operating at frequencies lower than 10 GHz can be found in [75, 76, 94]. For instance, in [75] Lin presented the gain plot of figure 3.5, showing that the antenna pair gain at 5.8 GHZ is significantly better than at 24 GHz.

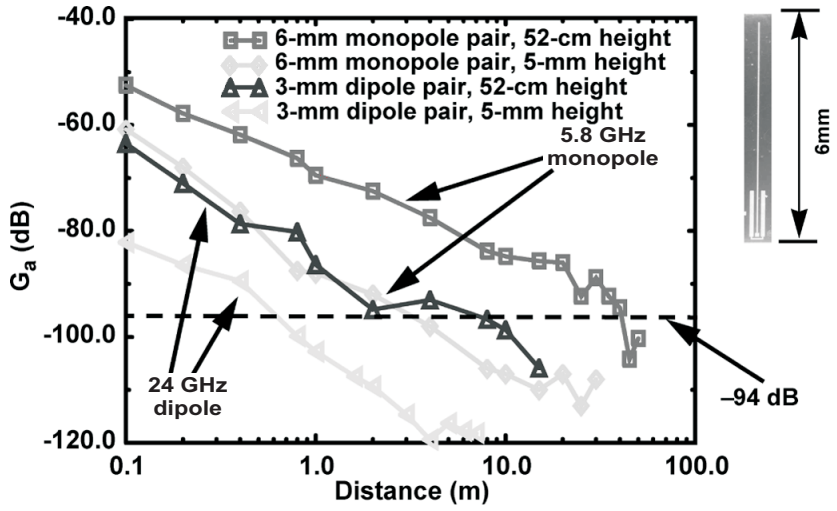


Figure 3.5: *Antenna pair gain as a function of the distance of a 5.8 GHz monopole and a 24 GHz dipole antenna. The antennas are located 52 cm and 5 mm above the ground [75].*

3.2 Prototype antennas fabrication and measurement

The objective of this chapter is the design, fabrication and measurement of standard CMOS silicon integrated antennas operating in the 5.8 GHz ISM band. A thorough study of the fabrication process is not included among the objectives of this thesis. Nevertheless some basic knowledge of the fabrication technology is necessary due to the fact that the resulting dielectric/metal layers structure and the materials properties will critically affect antenna performance and the design process.

In order to make integration of an on-chip antenna viable, the fabrication process must be inexpensive. This means that the antenna must be fabricated using the conductor and dielectric layers available in standard CMOS technologies and a silicon substrate compatible with these technologies.

The prototype antennas shown in this thesis were made in a dedicated process in the clean room of the Centro Nacional de Microelectronica - Instituto de Microelectronica de Barcelona (CNM-IMB, [95]). The process was intended to yield a metal/dielectric structure equivalent to a standard 0.18 μm RF CMOS, that is, a top metal of 2 μm thick Aluminum (Al) over 6 μm of SiO_2 (figure 3.6). The substrate was low resistivity silicon with a theoretical resistivity of 20 Ohm·cm.

Briefly, the main steps of the fabrication process were:

1. Start with a 4" wafer of P doped silicon with a resistivity of 20 Ohm·cm.
2. Growth of 2 μm of SiO_2.
3. Additional 4 μm-thick deposition of SiO_2.
4. 2 μm thick deposition of Al.
5. Al patterning with standard photolithography and etching process.

For the antennas fabricated during this thesis, two chip sizes were used. Firstly, the chip dimensions were 12.5 mm x 2 mm. Then, they were reduced to 5.25 mm x 1.9 mm to obtain smaller devices. Since the available area is very small, antenna miniaturization techniques will be necessary.

According to figure 3.6, the antenna is at a distance of 6 μm from the silicon substrate, and hence the silicon effects on the antenna performance will be important. The relative permittivity of silicon is high, $\epsilon_r = 11.9$, so it reduces the antenna dimensions. The problem

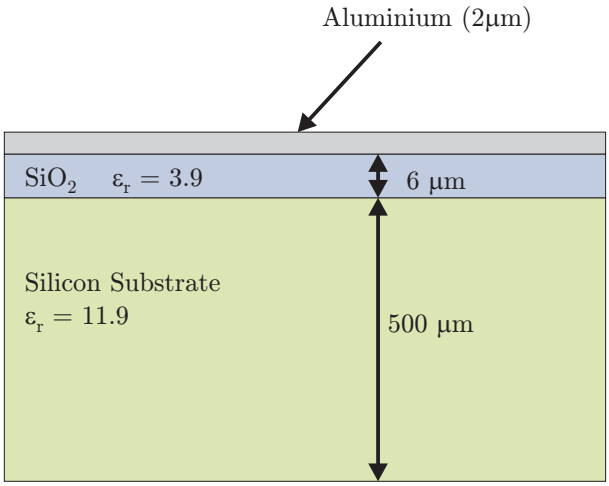

Figure 3.6: *Simplified metal/dielectric layer structure of the fabricated prototypes. It is equivalent to a standard 0.18 μm RF CMOS technology.*

is that the low resistivity of silicon significantly degrades the antenna radiation efficiency and gain.

The SiO_2 layer helps to isolate the antenna from the silicon substrate, slightly improving antenna gain. A comparison of the simulated antenna input parameters and radiation efficiency with and without the SiO_2 layer can be found in figure 3.7, showing as in the case of using the SiO_2 layer losses are slightly lower and the impedance curves are less smooth.

Numerical simulations must take into account the dielectric layers structure of the fabricated prototypes (figure 3.6). When infinite dielectrics are considered, simulations can be carried out without problems. However, some simulation problems arise with the Method of Moments (MoM) code of FEKO software when the finite size of very thin dielectric layers is taken into account. The meshing process of a thin layer is difficult because the number of triangular mesh elements is large and with a high aspect ratio. This increases the computational requirements (time and memory) and can introduce numerical errors that generate incorrect simulation results.

Finite dielectrics are necessary since the chip size is an important parameter that affects the antenna performance. To support this affirmation, the same antenna design was fabricated on three chips with different widths (2 mm, 4 mm and 6 mm). Frequency shifts higher than 500 MHz were observed due to the variation of the effective relative permittivity.

One option to avoid these problems is the use of a simulation model without the

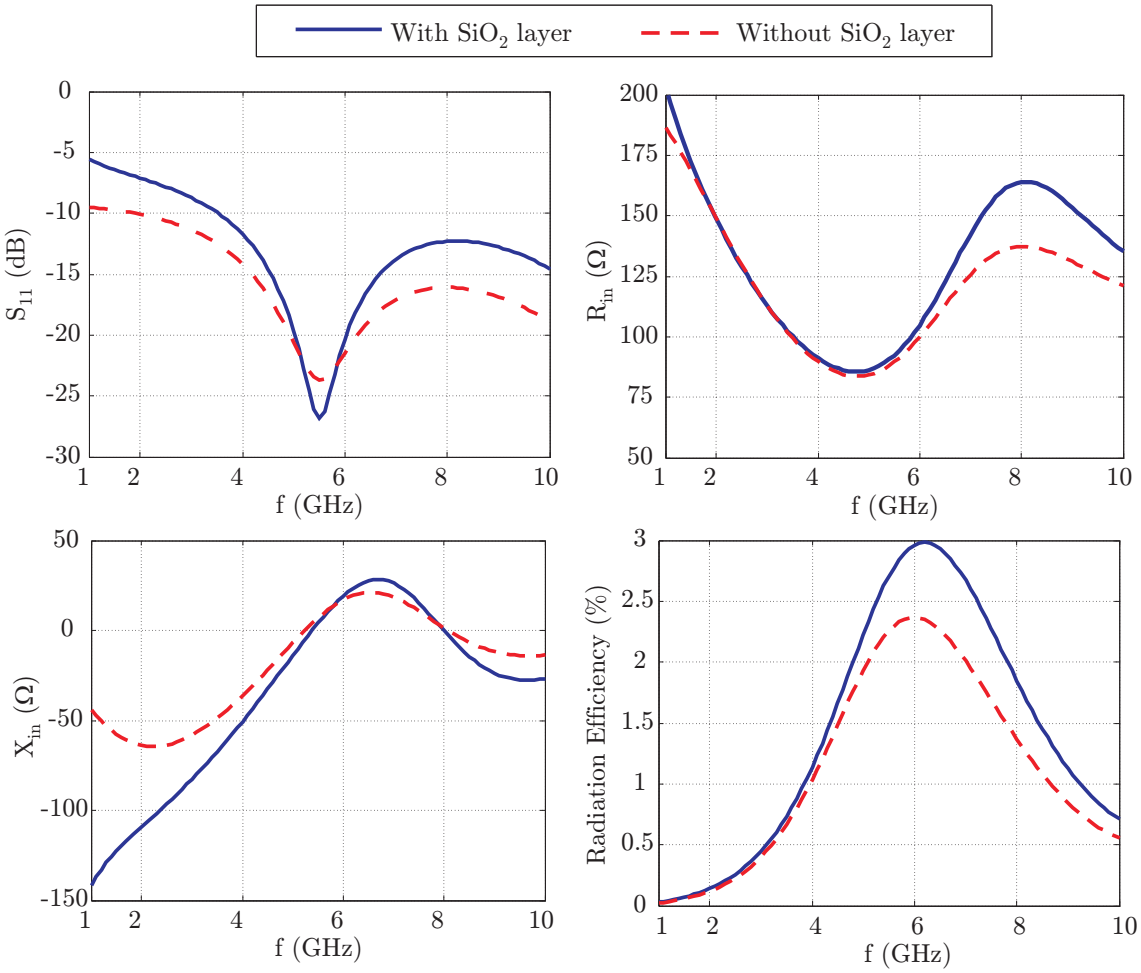

Figure 3.7: *Antenna input parameters and radiation efficiency with and without the SiO_2 layer. The silicon conductivity is $\sigma = 5$ S/m. The antenna is a meandered dipole and the chip dimensions are 5.25 mm x 1.9 mm.*

SiO_2 layer. Due to the thinness of this layer, the results would be quite similar to the real ones (figure 3.7). Nevertheless, if we want to include the SiO_2 effects in the simulations, there are other numerical methods (FDTD or FEM) that are more suitable for the study of complex dielectric structures. In our case we decided to use the hybrid Method of Moments − Finite Elements Method (MOM-FEM) FEKO code [70].

A precise simulation model was necessary in order to achieve good agreement between simulations and measurements, for this reason, the parameters of the wafers used in the antennas fabrication process were measured. Wafers thickness measurements gave the same value as the theoretical one (500 μm). The SiO_2 layer thickness ranged from 5.8 μm to 6.7 μm, and hence simulations were made using the theoretical value of 6 μm. Important differences were observed in the conductivity ranging from 11.5 Ω·cm to 13.4

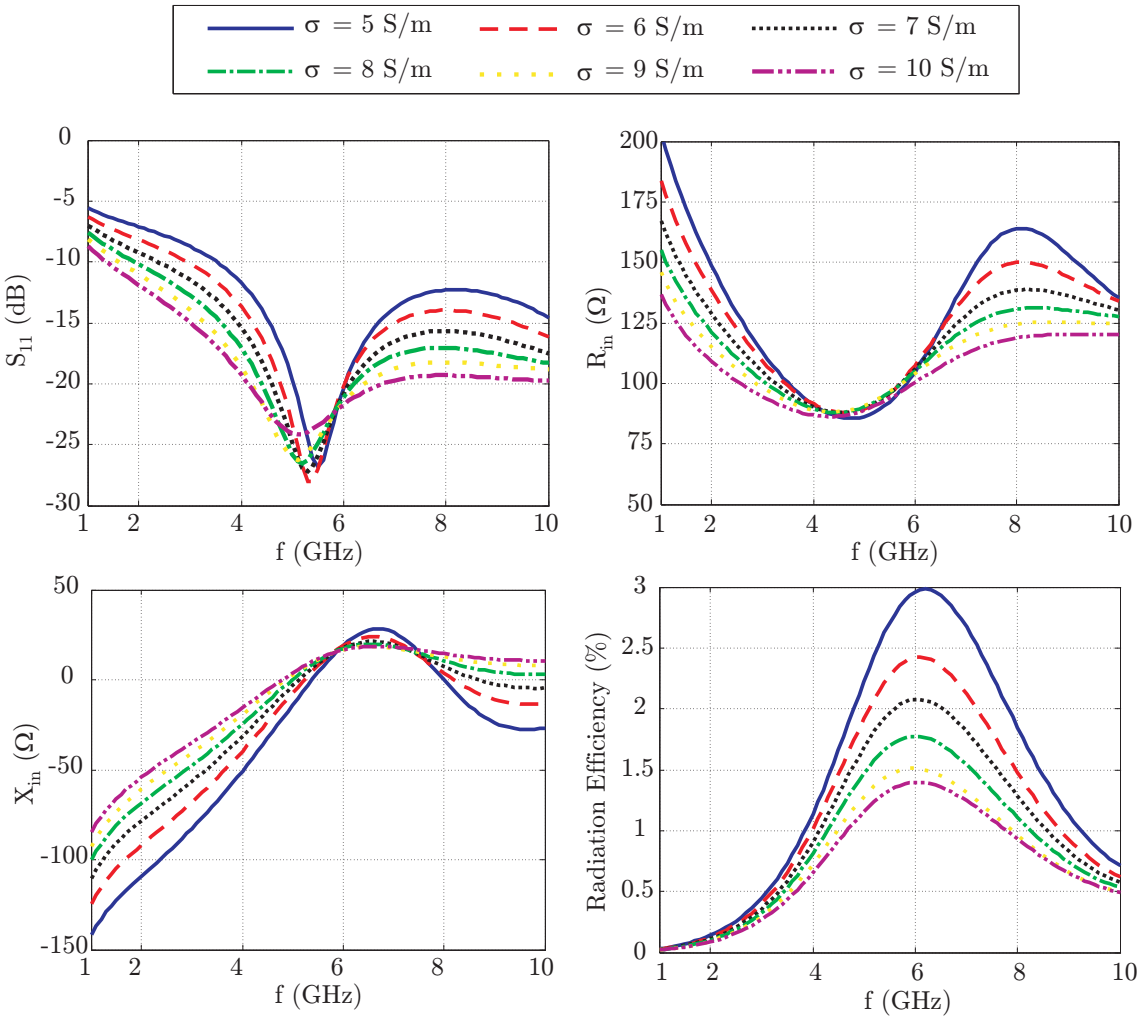

Figure 3.8: *Effects of the silicon conductivity in antenna parameters. Input reflection coefficient, input impedance and efficiency are shown. The antenna is a meandered dipole and chip dimensions are 5.25 mm x 1.9 mm.*

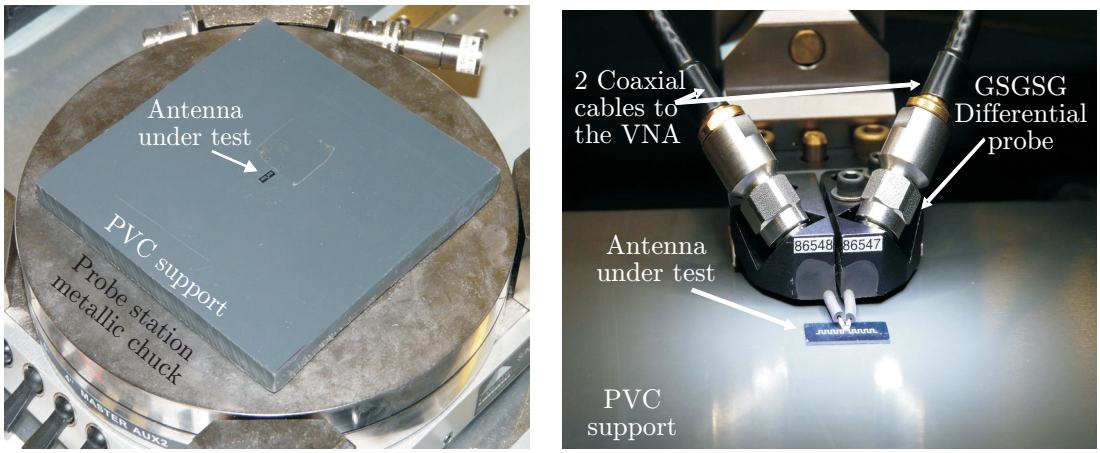
Ω·cm. Consequently, a conductivity value of 12.5 Ω·cm was used instead of the 20 Ω·cm of the wafer specifications. As can be seen in figure 3.8, the effects of conductivity are important: when conductivity is increased, radiation efficiency and gain are degraded and the impedance curves become smoother.

Dipole configurations with a differential feeding schema were used, taking 100 Ω as the differential reference impedance. A differential antenna topology was selected due to the fact that it can be easily connected to differential ended active circuits without the need for a balun. It is important to point out that good broadband matching levels were achieved due to the high silicon losses. Therefore, the main problem of integrated antennas is not the matching levels but the low gain and efficiency values.



(a) (b)

Figure 3.9: *Silicon antennas measurement setup. (a) A 1 cm PVC support was used to separate the antenna from the metallic chuck. (b) The differential dipole antennas were fed with a Picoprobe GSGSG probe.*

To validate the simulated results, measurements of the fabricated prototypes were carried out in a M150 Cascade Microtech probe station [96] using a Picoprobe GSGSG probe [97] to feed the differential dipole antennas. The antenna was separated from the probe station with a 1 cm PVC support. Otherwise the metallic chucks, directly in contact with the antenna, would invalidate the measured results. This PVC support was mechanized in order to transmit the vacuum to the antenna and avoid problems related to unwanted antenna movements during measurement. Figure 3.9 shows the measurement setup.

Dipole antennas with a differential feeding schema were measured. Typically, a balun is used to convert the single ended signal of the VNA into a differential signal. However, in the measurement of the frequency dependence of input parameters, the use of a balun can be a problem since broadband baluns are necessary. These baluns are expensive and can introduce errors. For this reason in the input parameters measurement we used a two port VNA and the mixed mode S parameters [98]. The differential input reflection coefficient can be calculated as

$$S_{dd} = \frac{(S_{11} - S_{21} - S_{12} + S_{22})}{2} \tag{3.1}$$

where S_{11}, S_{21}, S_{12} and S_{22} are the scattering parameters of the two single ended ports measurement. With this method, broadband measurements of differential antennas input parameters can be carried out avoiding the problems related to the baluns limited bandwidth

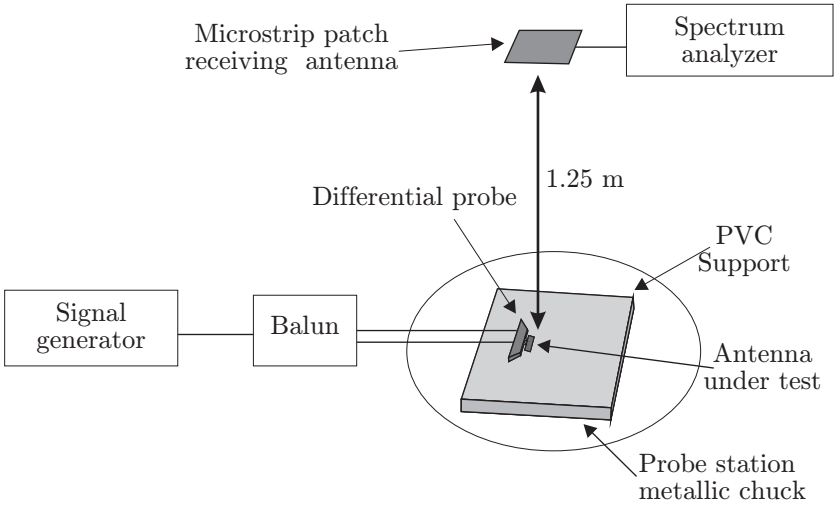


Figure 3.10: *Propagation measurement setup used for the gain measurement of the fabricated prototypes. Gain measurements were carried out in the 5.8 GHz ISM band.*

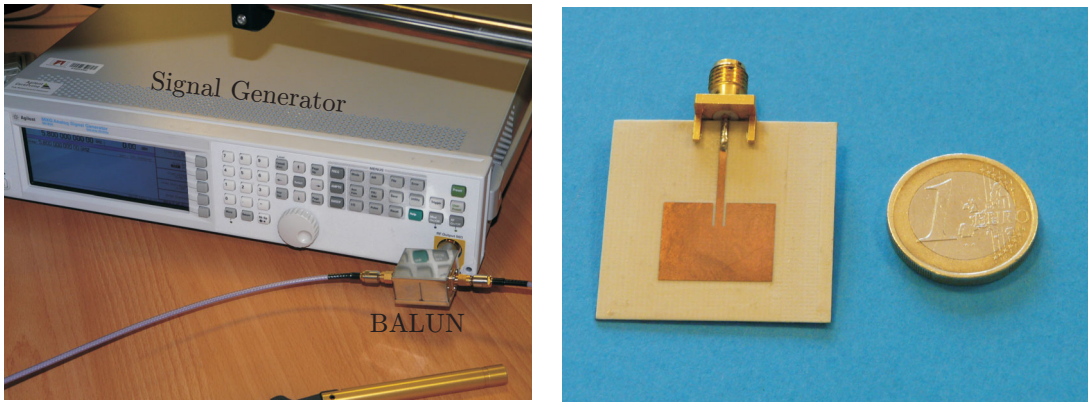
As previously said, one of the most limiting factors of the systems based on silicon integrated antennas are the low antenna gain values due to the high silicon losses. To obtain the fabricated prototypes gain, propagation measurements were carried out. In propagation measurements we could not use the mixed mode S parameters because a VNA with more than 2 ports was not available; therefore in these measurements we used a balun. Since these measurements were made at a single frequency we could use a simple microstrip narrowband balun.

Antenna gain was measured using the measurement setup shown in figure 3.10. A signal generator and a 5.8 GHz balun were used to feed the transmitting antenna (figure 3.11(a)). The receiving antenna was a 5.8 GHz microstrip patch built on Rogers RO4003C substrate ($\varepsilon_r = 3.38$, $\tan\delta = 0.0027$) (figure 3.11(b)). Measurements were performed inside the probe station, trying to maximize the clearance area near the integrated antenna and with a clear line of sight between the transmitting and the receiving antennas.

Although the probe station was adapted to minimize its effects on the antenna input parameters, it still affected the measurements. For this reason, two scenarios were considered in simulations. The first one was a simulation scenario that emulates the measurement setup: under the antenna there was a PVC block that represents the support and a PEC surface that models the effects of the probe station metallic chuck. In this scenario, good agreement between simulations and measurements was achieved (figure 3.12). Three identical antennas from different wafers were measured, proving the good repeatability of the fabrication process and measurements. In the second scenario the



(a) (b)

Figure 3.11: *Different components used for the propagation measurements. (a) Signal generator with a balun. (b) Receiving patch antenna fabricated on Rogers RO4003C substrate ($\varepsilon_r = 3.38$, $\tan\delta = 0.0027$).*

antenna was analyzed in free space in order to evaluate its performance when it is not affected by the probe station.

3.3 Miniaturization techniques applied to low resistivity silicon integrated antennas

The sensors will use the 5.8 GHz ISM frequency band to transmit the collected information to the central unit. At 5.8 GHz the wavelength is much larger than the chip dimensions, for this reason miniaturization techniques are necessary. In this section, the performance offered by various miniaturization techniques when they are applied to silicon integrated antennas will be analyzed. It is important to keep in mind that we will work with a high-loss substrate and this will affect the performance offered by these techniques. The achieved miniaturization factors will be presented, the effects on the radiation efficiency will be analyzed, and these results will be compared with the results obtained with a low-loss substrate.

3.3.1 Antenna designs

Different miniaturization techniques (figure 3.13) were used to obtain resonant dipoles around 5 - 6 GHz with a chip size of 12.5 mm x 2 mm. Two top-loading techniques were used, one based on metallic circles and the other based on capacitive loads. We also built several meandered dipoles with different number of meanders and strip widths (100 μm

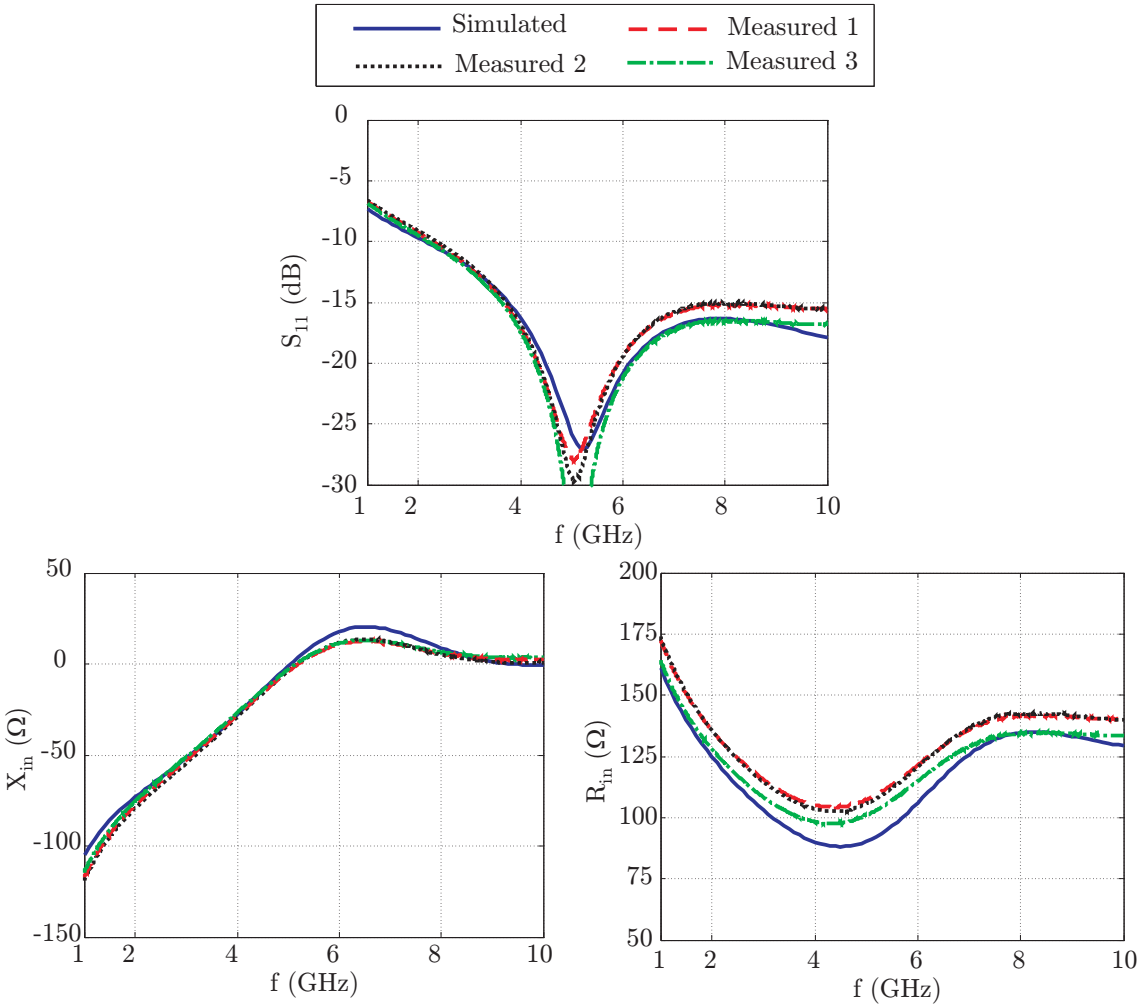


Figure 3.12: *Input parameters of a meandered dipole antenna fabricated on silicon. Solid line shows the simulated results. Dashed lines show the measured results of the same antenna fabricated on different wafers. A 100 Ω impedance was used as differential reference impedance.*

and 200 μm).

Figure 3.14 shows the simulated input parameters and the radiation efficiency of one of the meandered dipoles included in this study. The optimal matching point is near 5 GHz and the efficiency maximum is around 15 % at 5.3 GHz. This efficiency is higher than the efficiencies shown in figure 3.7 because the antenna of figure 3.7 was designed using the small chip size, and the antenna of figure 3.14 was designed using the large chip size. In the larger chips, less miniaturization is required, and as will be demonstrated later in this section, this is translated into an improvement in efficiency levels. A photograph of some of the fabricated prototypes can be seen in figure 3.15.

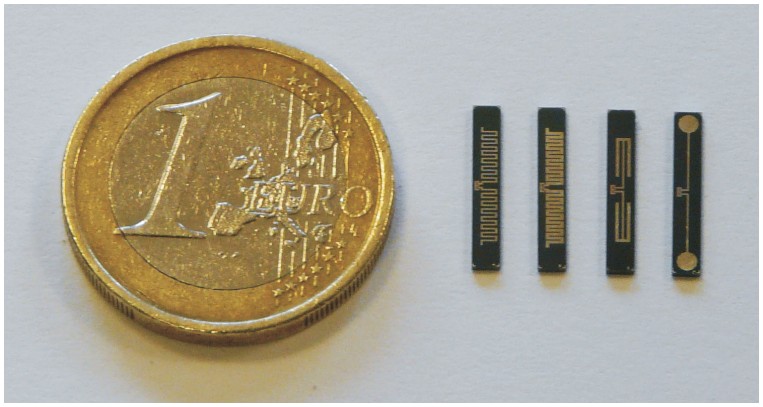

Figure 3.15: *Antennas with different miniaturization techniques. The chip dimensions are 12.5 mm x 2 mm.*

3.3.2 Miniaturization study: Measurements and simulation results

To compare the miniaturization offered by the different structures it is advisable to use the resonance frequency instead of the S_{11} minimum position since the former is not dependent on the reference impedance. Different dipole lengths (L_1) for the different topologies were used to guarantee resonance frequencies (f_{res}) of around 5 - 6 GHz, therefore they can not be compared directly. For this reason, the following figure of merit (F), valid for dipole configurations, is defined as

$$F = f_{res} \cdot L_1 \tag{3.2}$$

where it is assumed that the resonance frequency is inversely proportional to the dipole length. Low F values are desirable to achieve high miniaturization.

Using F, the miniaturization factor MF can be defined as

$$MF(\%) = 100\left(1 - \frac{F}{F_{flat_dipole}}\right) \tag{3.3}$$

where $F_{flat-dipole}$ is the measured figure of merit of a simple flat dipole built on silicon (reference antenna). The MF gives information about the length and area reductions (considering a constant chip width) offered by the different designs. High MF values are desirable.

The measured MFs obtained with the different topologies are plotted in figure 3.16(a). The reference antenna is a simple flat dipole with $F_{flat-dipole}$ = 68 GHz·mm. These miniaturization factors have been measured in the probe station scenario. Figure 3.16(b) shows the total simulated efficiency at the resonance frequency of the same topologies.

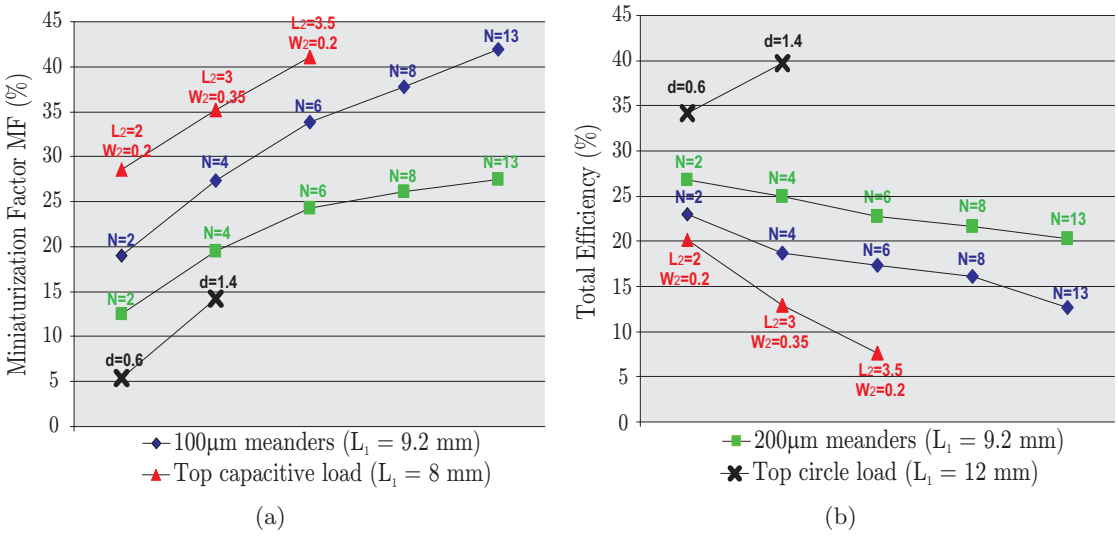

Figure 3.16: *Results of the miniaturization study in the probe station scenario. (a) Measured miniaturization factor (MF). (b) Simulated total efficiency of the different topologies. N is the number of meanders. The dimensions of the other variables (defined in figure 3.13) are in mm. The reference antenna for the MF calculation is a simple flat dipole with* $F_{flat-dipole} = 68$ *GHz·mm.*

In meandered dipoles resonance frequency decreases as the number of meanders increases. This is due to the increase in physical conductor length. However, when the number of meanders is high the efficiency of this miniaturization is reduced because close opposite currents tend to cancel each other out.

Measurements show that thin meandered dipoles (100 μm) provide more size reduction ($>$ 40 % of the total area), whereas miniaturization factors for thick meandered dipoles (200 μm) are smaller (27 %). As expected, when conductors are thin and the number of meanders (N) is increased, losses are higher and the efficiency is degraded. Therefore, there is a trade-off between antenna miniaturization and radiation efficiency which can be verified comparing figure 3.16(a) (positive slope as N increases) and figure 3.16(b) (negative slope as N increases).

Measured miniaturization factors for the dipoles with capacitive loads range from 30 % to 40 %, which are similar to the values obtained with the 100 μm meandered dipoles. Again the drawback is that radiation efficiency is reduced as the miniaturization factor is increased.

Circle loaded dipoles show the best efficiency levels, but the miniaturization obtained with these structures is less than 15 %. With this topology, there is not a clear trade-off between miniaturization and efficiency. When the loading circles diameter is increased,

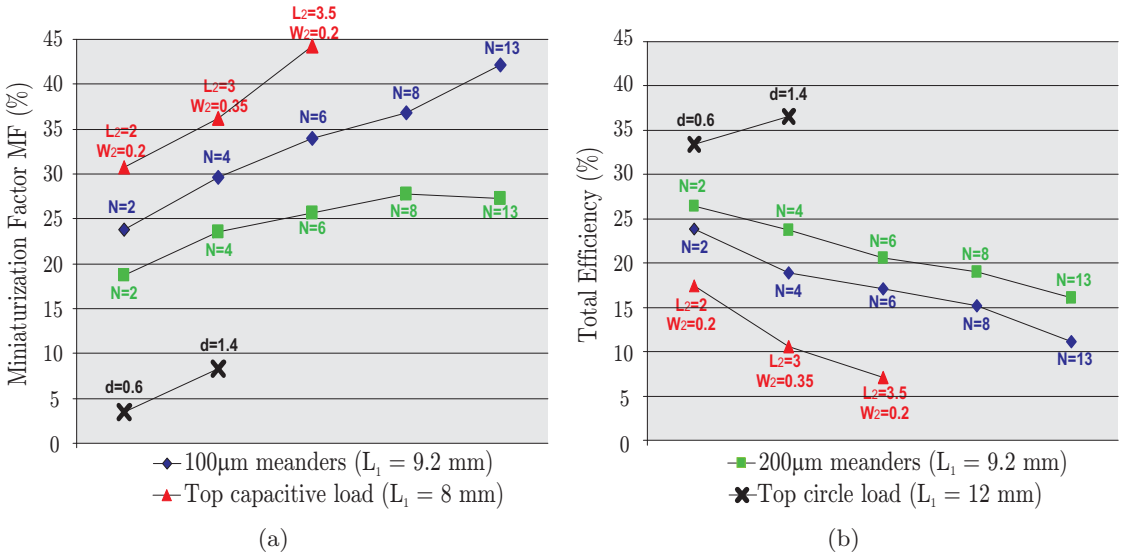

Figure 3.17: *Results of the miniaturization study in a free space scenario. (a) Simulated miniaturization factor (MF) (b) Simulated total efficiency of the different topologies. N is the number of meanders. The dimensions of the other variables (defined in figure 3.13) are in mm. The reference antenna for the MF calculation is a simple flat dipole with* $F_{flat-dipole} = 89$ *GHz·mm.*

both miniaturization and efficiency are increased, however it must be taken into account that the maximum diameter is limited by the chip width.

It is important to point out that the simulated results in a free space scenario (figure 3.17) are similar to those obtained in the probe station (checked by measurements). Hence, it is expected that similar results will be obtained in the real operating scenario of the antenna.

Radiation efficiency degradation when miniaturization techniques are applied is a well known effect. However, in silicon integrated antennas this efficiency degradation is much more significant than in low-loss substrate due to the high silicon conductivity. To prove this, the same antenna designs were simulated using a low-loss substrate with a similar dielectric constant (RO3010, $\varepsilon_r = 10.2$, $tan\delta = 0.0023$)[68].

The miniaturization factors obtained with this new substrate (figure 3.18(a)) are similar to the result obtained with the low resistivity silicon substrate (figure 3.16(a)). By comparing the radiation efficiency of the antennas built on the silicon substrate (figure 3.16(b)) and the efficiency of the antennas built on the low-loss substrate (figure 3.18(b)), it can be concluded that the efficiency degradation introduced by miniaturization techniques is emphasized when low resistivity substrates are used. Indeed, in the case of the thin meandered dipoles, in low-loss substrate the radiation efficiency is

degraded less than 15 % when the number of meanders is increased from 2 to 13, whereas in the case of standard CMOS silicon substrate the efficiency reduction is near 50 %. Table 3.1 shows the additional losses introduced by miniaturization. With the low-loss substrate a maximum degradation equal to 0.5 dB is observed, meanwhile when the silicon substrate is used, the degradation is higher than 2.5 dB.

Table 3.1: *Radiation efficiency and additional losses due to miniaturization of a 100 µm meandered dipole when the number of meanders is increased.*

		$N = 2$	$N = 4$	$N = 6$	$N = 8$	$N = 13$
Standard Silicon	Efficiency	23.0 %	18.6 %	17.4 %	16.0 %	12.7 %
	Additional losses with respect to $N = 2$	0 dB	0.8 dB	1.2 dB	1.5 dB	2.6 dB
Low-loss Substrate	Efficiency	93.3 %	90.8 %	88.7 %	86.2 %	82.7 %
	Additional losses with respect to $N = 2$	0 dB	0.1 dB	0.2 dB	0.3 dB	0.5 dB

3.4 Improving silicon integrated antennas by substrate micromachining

As it has been shown in the previous section, one of the main drawbacks of antenna integration are the low radiation efficiency levels due to the silicon losses and the efficiency degradation introduced by miniaturization techniques. In literature several solutions to improve antenna efficiency can be found, such as the use of a higher substrate resistivity, addition of low-loss insulating layers, substrate thinning or selective removal of the substrate by means of micromachining.

For instance, in [99] proton implantation of selected substrate areas is used to increase the silicon resistivity. The main problem of this technique is that rare special equipments are necessary. Another solution is to increase the distance between the radiating element and the lossy silicon. Thicker SiO_2 layers [81] or an additional layer of a low-loss material such as benzocyclobutene (BCB) can be used to insulate the antenna. These materials have low dielectric constants and very low losses, but are difficult to apply with a thickness greater than 20 - 30 μm, therefore efficiency improvements are limited. In [80, 87, 100] different examples of application of these materials as insulation layers can be found.

In [84] the silicon substrate thickness is reduced to improve the on-chip antenna efficiency. Another solution is to apply micromachining techniques to selectively etch silicon of the back side of the antenna. For example, [94] uses a micromachining process to improve the efficiency of a dipole antenna in the 5.8 GHz band. Other examples of micromachined antennas can be found in [87, 88, 101]

In previously reported designs [87, 94] a single rectangular shaped mask has been used for the selective silicon etching process. In this section, we will carry out a comparative study of several etching patterns in order to maximize the gain improvement without a significant increase in the antenna fragility. The antenna performance will be analyzed in various operating scenarios to prove that similar gain improvements can be expected in real applications.

3.4.1 Antenna designs, definition of the etching areas and fabrication process

The radiating element is a meandered dipole designed to work at frequencies near 5 GHz (figure 3.19(a)). The small chip dimensions (1.9 mm x 5.25 mm) were used for the prototypes fabrication.

The best option to improve the radiation efficiency would be to remove all the silicon

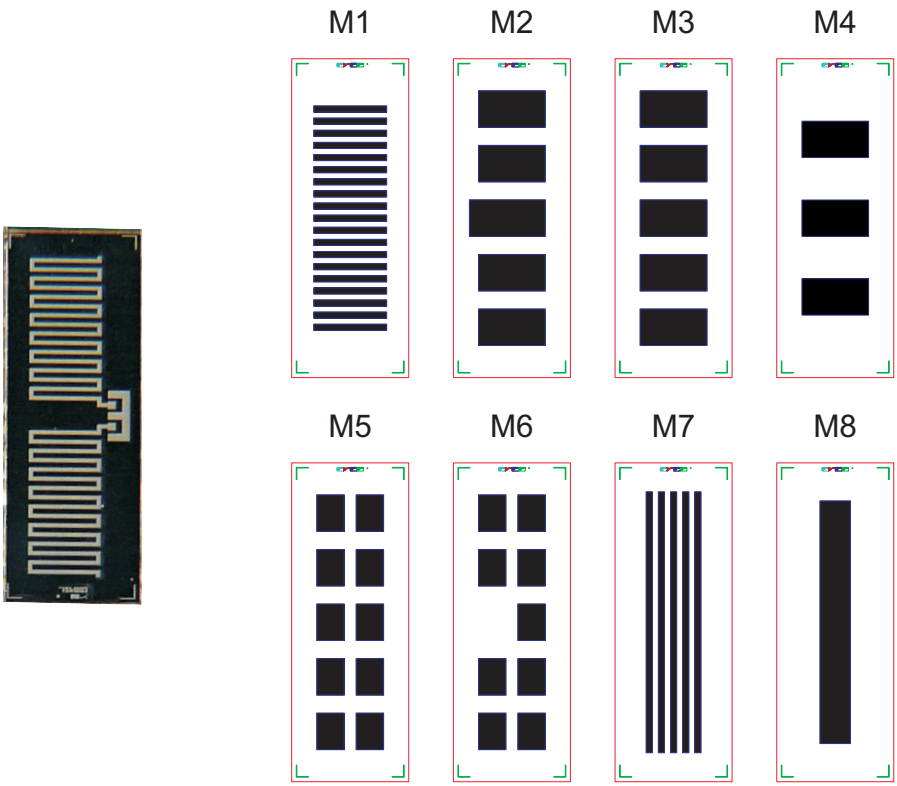

Figure 3.19: *Design of the fabricated prototype antennas. (a) Image of the fabricated meandered dipole antenna. (b) Schematic representation of the etching patterns used for the micromachining process. Black rectangles indicate the areas where silicon is etched.*

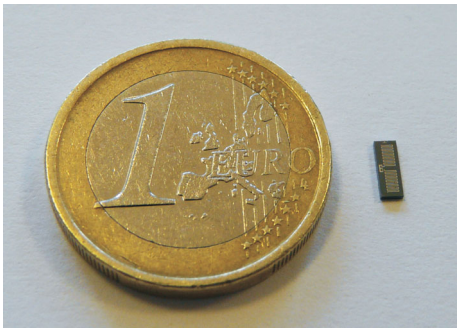
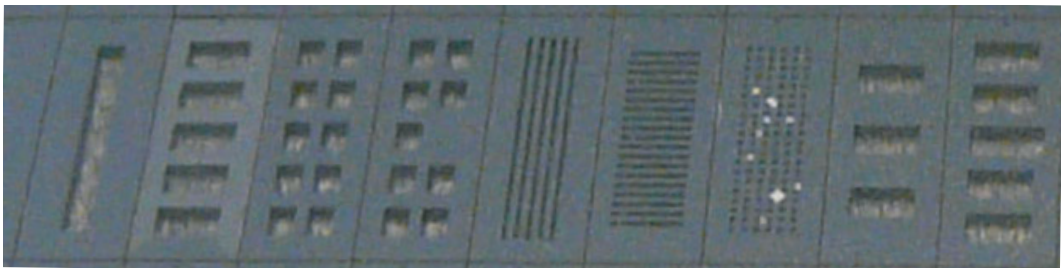
under the antenna, but the etching of large areas is problematic because the resulting membrane structure is fragile and can be easily broken. Etching an array of smaller areas can provide similar improvements without compromising the mechanical robustness. The etching patterns under study (figure 3.19(b)) try to avoid the elimination of a large, continuous silicon area, keeping silicon walls to guarantee the structure robustness.

Fabrication started with p-type silicon wafers having a resistivity of 20 Ohm·cm and a thickness of 500 μm. A 2 μm-thick layer of SiO_2 was grown with a wet oxidation process and a 4 μm-thick SiO_2 was deposited by Plasma Enhanced Chemical Vapor Deposition (PECVD). The resulting thickness of SiO_2 (6 μm) is similar to the effective thickness of the dielectric stack that some CMOS technologies have under the top metal level, so the results of the present study are valid for antennas made with standard technologies.

Next, a 2 μm-thick aluminum (Al) was deposited by sputtering. The Al layer was patterned by standard photolithography and wet etch. On the back side of the wafers, a



(a)



(b)

Figure 3.20: *Prototype antennas with micromachining. (a) Top view of one of the antennas. (b) Rear view of some of the antennas.*

1 μm-thick Al layer was deposited and patterned in the same way as above. Subsequently, the SiO_2 from the back side was removed with a dry etching process and a Deep-Reactive Ion Etching (DRIE) process was used to partially remove the silicon beneath the antenna structures. The fabrication was finished by removing the back side Al with a wet etching process. More information about these fabrication processes can be found in [102]. Figure 3.20 shows some of the fabricated prototypes.

3.4.2 Performance improvement due to the micromachining process: Measurements and simulation results

In figure 3.21 the input reflection coefficient of the antenna with different etching patterns is plotted. A slight frequency shift to higher frequencies can be seen due to the fact that the elimination of silicon reduces the effective relative permittivity. When micromachining is applied impedance curves also become slightly sharper due to the lower losses, reducing the matching bandwidth of the antenna. The effects of the different micromachining configurations on the input parameters are similar. From figure 3.21(b) it is seen that the above mentioned effects become more important when the etching depth is increased.

Micromachining effects on the input reflection coefficient are not so important to

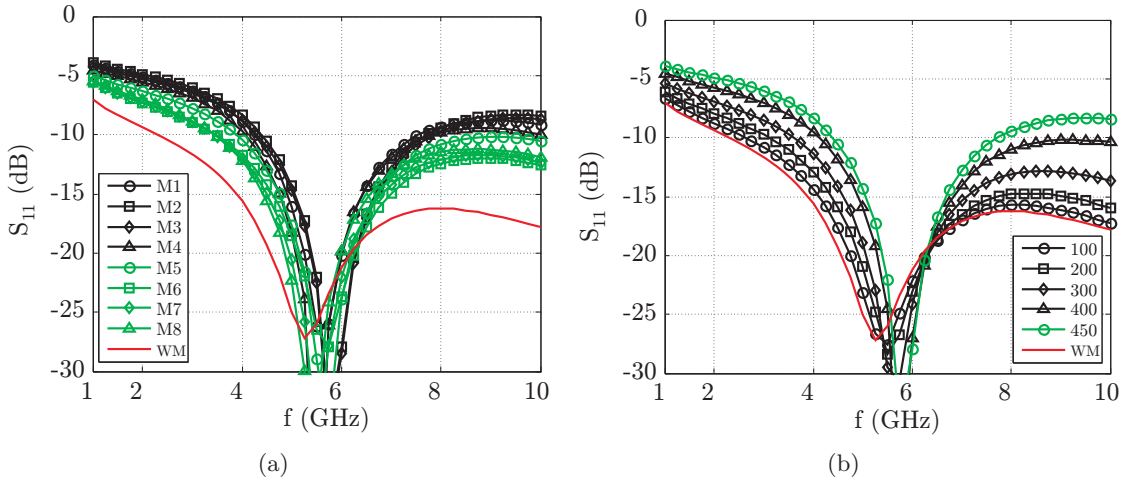


Figure 3.21: *Simulated input reflection coefficient. (a) Different etching configurations are applied. The etching depth is 450 μm. (b) Different etching depths (μm) are applied. The M2 pattern is used for the micromachining process. The wafers thickness is 500 μm. WM = Without Micromachining.*

motivate the use of these techniques; it is in the antenna radiation parameters where a significant performance improvement is obtained. In figure 3.22(a) the effects of the etching process in the radiation efficiency can be clearly seen because an efficiency improvement is observed when micromachining is applied. Depending on the etching pattern, this improvement can be higher than a factor of 2. It is important to point out that our band of interest (5.8 GHz) is near the efficiency maximum.

Figure 3.22(b) shows the efficiency at 5.8 GHz for the different etching patterns as a function of the etching depth. The wafers thickness is 500 μm in all cases. The efficiency improves when the depth is increased, and again, this improvement also depends on the geometry of the etched areas. Similar conclusions can be obtained from figure 3.22(c). A gain improvement of up to 4 dB can be achieved in the normal direction with the best etching pattern (M1). For the same etching depth (i.e. 450 μm), the gain improvement can range from 1.5 dB to 4 dB depending on the etching pattern used in the micromachining process.

To verify these results some gain measurements of the fabricated prototypes were carried out. The measured and simulated gain improvements are summarized in table 3.2. Although measured gains are slightly higher than simulator predictions there is a good agreement in the trends. With an etching depth of 450 μm measured gain improvements of near 4 dB are obtained. Higher etching depths would improve the gain even more, but the resulting structures would be more fragile. With 50 μm of silicon in the cavities, the resulting structures are strong enough to withstand the measurements in the probe station

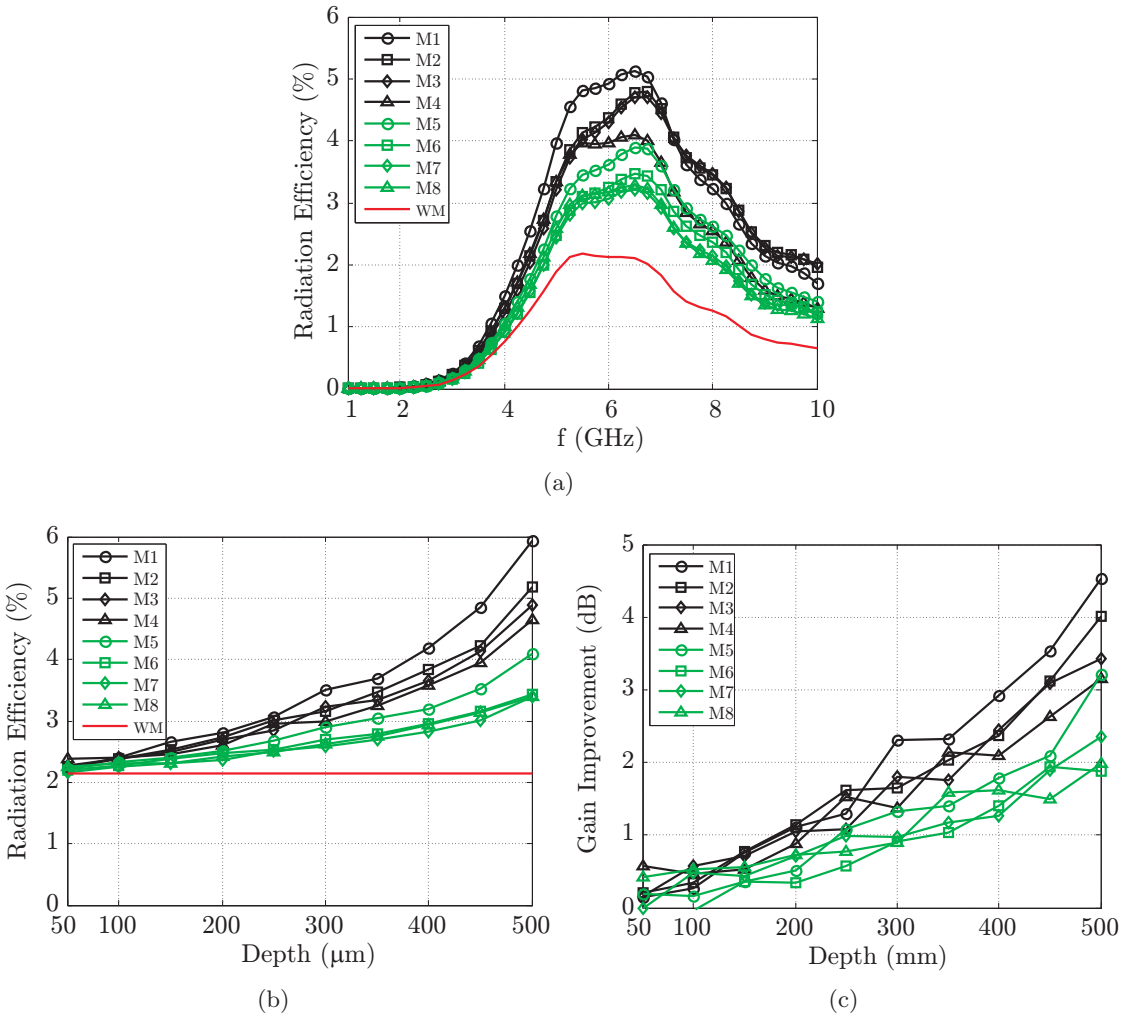

Figure 3.22: *Simulated radiation parameters when micromachining techniques are applied. (a) Radiation efficiency as a function of frequency. The etching depth is 450 μm. (b) and (c) radiation efficiency and gain improvement as a function of the etching depth. The operating frequency is 5.8 GHz and the wafers thickness is 500 μm. The reference gain for the gain improvement plot is the gain of the antenna without micromachining (−18.95 dB). WM = Without Micromachining.*

Table 3.2: *Measured and simulated gain improvement for the different etching patterns. The last column shows the etched area. The etching depth is 450 μm and the wafers thickness is 500 μm.*

Etching pattern	Simulated Gain Improvement	Measured Gain Improvement	Etched Area (mm^2)
M1	3.5	3.9	2.28
M2	3.1	3.6	3.39
M3	3.1	3.3	3.30
M4	2.6	2.8	1.98
M5	2.1	2.6	2.70
M6	1.9	2.4	2.43
M7	1.9	2.0	2.15
M8	1.5	1.8	2.00

without the need to fill the cavities with another dielectric material. We tried to completely remove the silicon from the patterns but in some of the prototypes the remaining dielectric membrane supporting the antenna broke, probably due to internal mechanical stress in the oxide layers.

Intuitively, it could be deduced that the best etching pattern is the one that eliminates more silicon under the antenna. However, this is only partially true because the geometry used for the etching process is also important. According to table 3.2, the geometry with the highest gain improvement is not the one that eliminates most silicon. The amount of silicon etched in M2 is 50 % higher than in M1 but the measured gain improvement in M1 is 0.3 dB better than in M2. In a similar way, the amount of silicon etched in M4 and M8 is nearly the same, but M4 gain improvement is 1 dB better than M8.

Based on these results, some general guidelines for the use of micromachining techniques can be given in order to maximize the gain improvement of silicon integrated dipole antennas. First of all, structures with horizontal (normal to the dipole orientation) trenches show better performance than structures with vertical ones. This is a reasonable result because horizontal trenches limit the current circulation in the substrate.

Secondly, it is better to eliminate silicon near the feeding area, where currents and fields are stronger than in the areas far away from the feeding point. This can be verified in figure 3.23, where only a small part of the silicon chip around the position Δy is etched. When the etched area is under the feeding, gain is up to 2 dB better than when it is under the antenna ends.

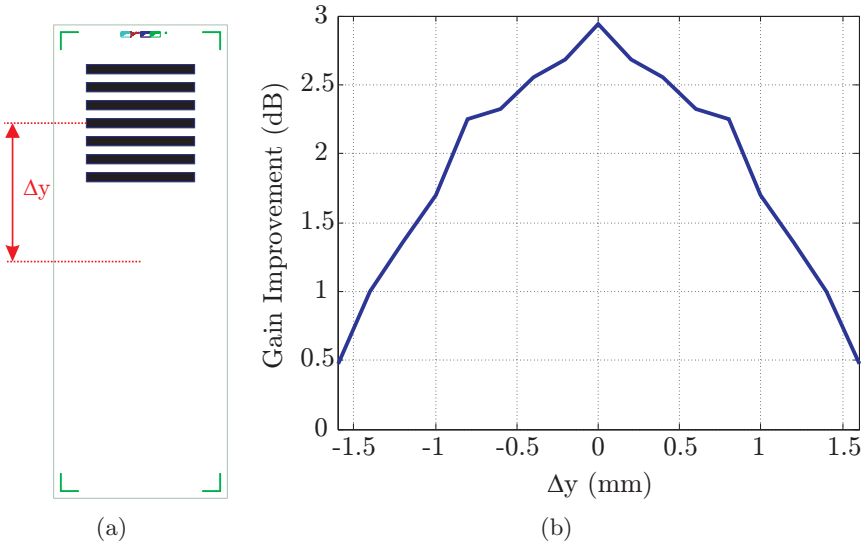

Figure 3.23: *Simulated gain improvement as a function of the etched area position. (a) Pattern used in the micromachining process. (b) Gain improvement plot. The reference gain is the gain of the antenna without micromachining (−18.95 dB).*

3.4.3 Antenna performance improvement due to micromachining in a free space scenario

In the previous section the micromachining effects have been analyzed through simulations and measurements carried out inside the probe station. One could think that the obtained results only apply in that particular case. In this section, simulations are used to assess the antenna performance in free space.

Comparing the S_{11} parameters in a free space scenario (figure 3.24(a)) with the results of the previous section (figure 3.21), the main difference is a slight frequency shift to higher frequencies. This is related to the fact that, in the probe station scenario, the antenna is on a supporting material with a relative permittivity higher than one, which tends to reduce the resonance frequency.

The gain improvement at 5.8 GHz with respect to an antenna without micromachining is shown in figure 3.24(b). The improvement is similar to the values obtained in the probe station scenario. Comparing figure 3.22 and figure 3.24, it can be seen that if the etching patterns are sorted according to their gain improvement, the same result is obtained in both scenarios. Consequently, it is expected that this improvement will also be valid in the real operating scenario of the antenna which will depend on the final application.

In this section it has been shown that with micromachining techniques a gain improvement near 4 dB is obtained. This gain improvement is relevant. If these antennas

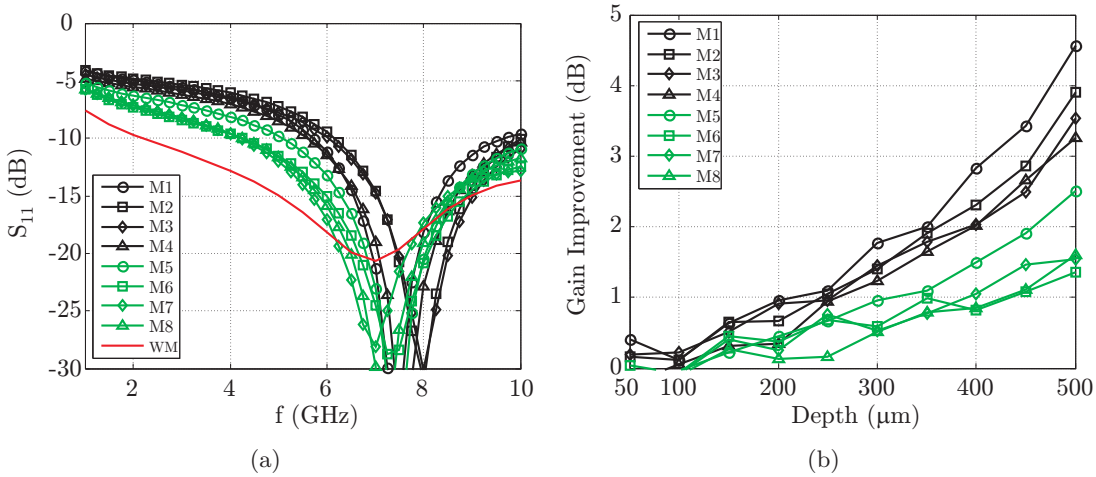

Figure 3.24: *Performance improvement due to micromachining in a free space scenario. (a) Simulated input reflection coefficient. The etching depth is 450 µm. (b) Gain improvement as a function of the etching depth. The operating frequency is 5.8 GHz and the wafers thickness is 500 µm. WM = Without Micromachining.*

are used in our wireless sensor network, the power required for the communication between nodes (keeping the same system performance) can be reduced by more than fifty percent thus increasing battery life. These techniques can be also useful to mitigate the additional losses introduced when miniaturization techniques are applied to reduce antenna dimensions.

3.5 Antenna performance degradation due to the presence of coils for an inductive link energy coupling

According to [103], previously presented remote and implantable sensors are relatively large due to the use of a sizeable battery for powering the sensor for a long time. To solve this problem it would be of interest to have a way to transmit energy to the sensor and sporadically reload its battery without having physical access to it, thus allowing for smaller batteries. In the normal system operation mode the remote sensor continuously sends information to an external receiver using the RF link (a range of over a meter [104]), but when the battery is flat, it can be reloaded with a short range inductive coupling (a range of a few centimeters [103]).

The main drawback of this configuration is that the presence of the coil for the low frequency inductive coupling will significantly degrade the RF integrated antenna performance. The coil is usually one of the bigger chip elements, and hence one of the elements that can introduce higher degradation levels to the RF link. This section will be

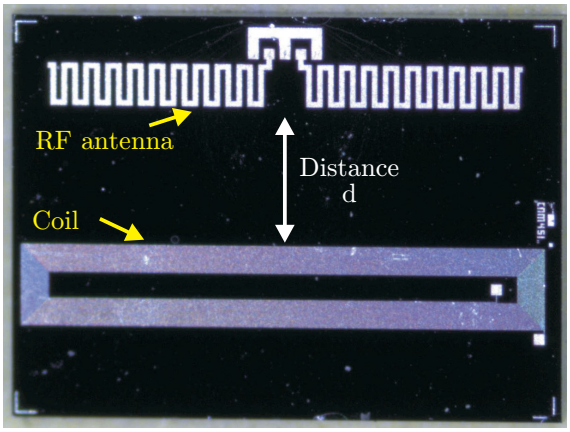

Figure 3.25: *Fabricated prototype antenna for the evaluation of the coil effects on the RF link. The chip dimensions are 3.8 mm x 5.2 mm.*

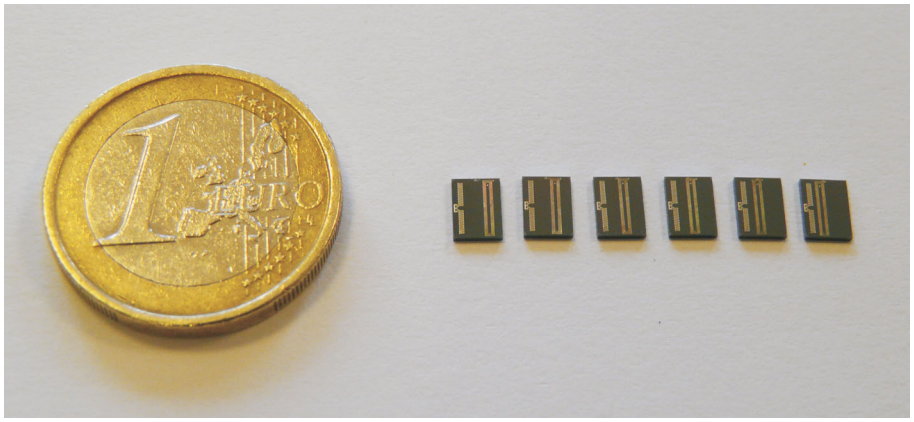

Figure 3.26: *Prototype antennas. The chip dimensions are 3.8 mm x 5.2 mm. The distances d between the RF antenna and the coil are 320 µm, 570 µm, 820 µm, 1.07 mm, 1.32 mm and 1.57 mm.*

focused on the study of the effects of this coil. One of the main parameters that defines the performance degradation in the RF link is the distance d between the coil and the RF antenna (figure 3.25). For this reason several prototypes changing this distance d were fabricated and measured (figure 3.26). As can be seen in these figures, the radiating element is a meandered dipole. The chip dimensions are 3.8 mm x 5.2 mm.

3.5.1 Performance degradation due to the coil effects: measurements and simulation results

In spite of the presence of the coil, antennas are well matched to a 100 Ω differential reference impedance (figure 3.27), showing that the coil does not significantly change the antenna input parameters. Where the degradation is more significant, is in the radiation

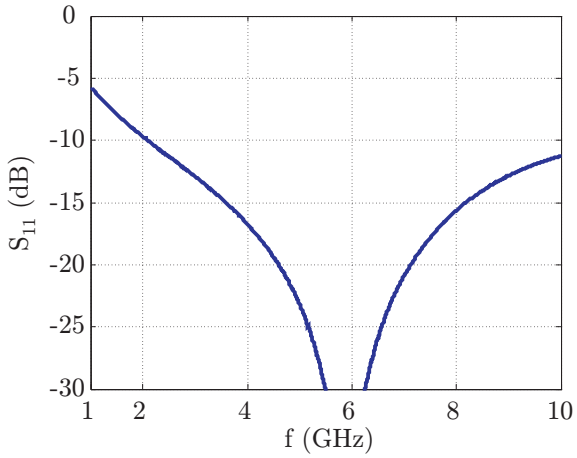

Figure 3.27: *Measured input reflection coefficient of an integrated antenna fabricated together with a coil for an inductive link (figure 3.25). The distance between the antenna and the coil is $d = 320\ \mu m$.*

parameters.

Figure 3.28(a) shows the simulated and measured gain of the fabricated prototypes. The x-axis represents the separation d between the antenna and the coil, ranging from 320 μm to 1.57 mm. Good agreement between simulations and measurements is achieved. Measurements were repeated twice, showing that the measurement setup offers good repeatability in the results. The measured gain when the coil is at the maximum distance

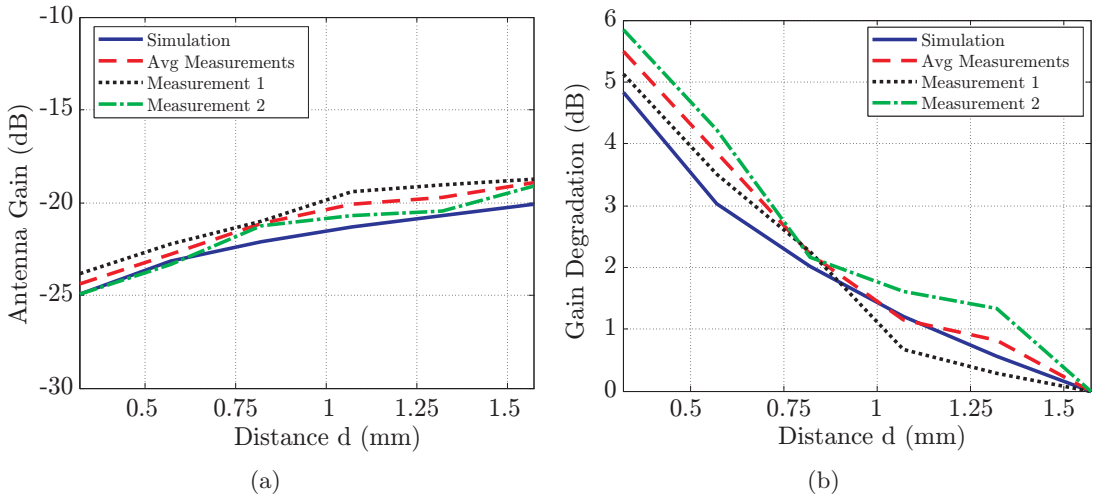

Figure 3.28: *Radiation parameters as a function of the distance d between the RF antenna and the coil. (a) Antenna gain. The simulated gain without the coil is -17.7 dB. (b) Gain degradation. The reference gain is the gain when the coil is at $d = 1.57$ mm. Operating frequency $f = 5.8$ GHz.*

Table 3.3: *Measured gain degradation and system range reduction as a function of the distance d between the RF antenna and the coil.*

Distance d (mm)	Gain degradation (dB)	System range reduction (%)
0.32	5.5	47
0.57	3.9	36
0.82	2.2	23
1.07	1.2	12
1.32	0.8	9
1.57	–	–

($d = 1.57$ mm) is near -19 dB and the gain when the coil is closest to the antenna is near -24.5 dB. The simulation of the antenna without the coil gives a gain value near -17.7 dB.

To reduce the total chip dimensions, it is desirable to have the coil close to the antenna, however when the distance between both elements is reduced the gain degradation is more significant (figure 3.28(b)). Table 3.3 summarizes the measured performance degradation when the coil approaches the antenna. Taking a distance of 1.57 mm as reference, a degradation of 2.2 dB can be seen as this distance is reduced to 820 μm. If the distance is further reduced to obtain a smaller chip, the gain degradation can be higher, obtaining 5.5 dB when the distance is equal to 320 μm.

In the last column of table 3.3 the system range reduction has been calculated assuming a free space propagation model. All the other system parameters are kept constant when the separation d is changed. Reductions of nearly 50 % of the system range can be observed. These results prove that when the inductive coil and the RF antenna are integrated in the same chip, there will be a clear trade-off between chip dimensions (limited by the separation between the coil and the RF antenna) and the system performance.

3.5.2 Performance degradation due to the coil effects in a free space scenario

In this section, the coil effects when the antenna is in a free space scenario will be analyzed by means of simulations.

In this scenario, the simulated antenna gain without the coil is equal to -21.6 dB. In the probe station this gain is higher because the support and the metallic chuck modify the radiation pattern shape increasing the gain of the dipole in the broadside direction. Figure 3.29 shows the simulated gain degradation due to the coil effects in a free space scenario as a function of the distance d between the coil and the RF antenna. Despite

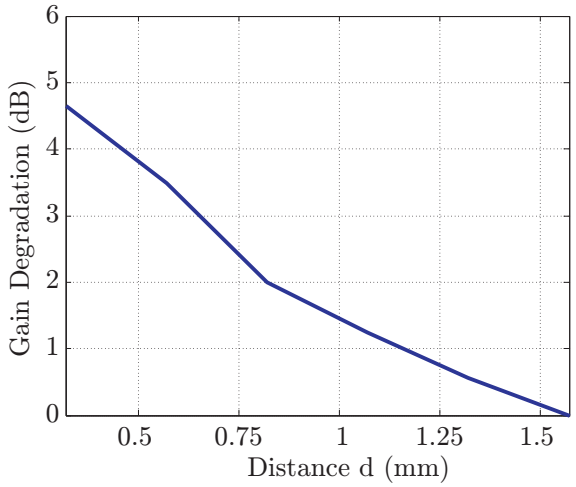

Figure 3.29: *Simulated gain degradation in a free space scenario as a function of the distance d between the RF antenna and the coil. The reference gain (-25.5 dB) is the gain when the coil is at d = 1.57 mm. Operating frequency f = 5.8 GHz.*

the fact that the absolute gain values are not the same in both scenarios, the degradation levels due to the presence of the coil are similar. Therefore it is predictable that similar degradation levels will be also obtained in the operating scenario of the real application.

3.5.3 Effects of the performance degradation in a real system link budget

Now, we will show the coil effects on the performance of a real communication system: a remote sensor network similar to the system that has inspired this thesis. The system parameters will be based on the results presented by Lin in [75]. However, we are working with low power sensors and for this reason the transmitted power will be lower than the value used in [75] in order to reduce the power consumption. The receiver antenna will be a patch antenna with a gain of 6 dB. System parameters are summarized in table 3.4.

With the information of table 3.4, and assuming a free space propagation model, the

Table 3.4: *System parameters used for the link budget.*

Link Margin	12 dB
Tx Power	-10 dBm
Rx Antenna Gain	6 dB
Rx Sensitivity	-97.8 dBm
Thermal Noise	-173.8 dBm/Hz
Data rate (100 kbits/sec)	50 dBHz
Eb/No	18 dB
Rx Noise Figure	8 dB

Table 3.5: *System range for different chip configurations.*

Antenna	Antenna measured gain (dB)	System Range (m)
Without coil	-17.7	6.6
With the coil at 1.57 mm	-19.0	5.7
With the coil at 320 μm	-24.5	3

values of table 3.5 have been obtained. The original RF link range (without the parasitic coil) is greater than 6.5 m. However when the coil is integrated with the antenna in the same chip, this range is reduced to 5.7 m, and if the distance between the antenna and the coil is reduced to 320 μm, the system range is further degraded to 3 m.

In this section we have studied the effects of a coil, but the same conclusions are also valid for any other element integrated with the antenna, such as the sensor or the other electronic circuits, because in the real application the antenna will not be alone in the chip. Furthermore it is important to point out that, as was shown in the previous section, this system performance degradation could be mitigated by the use of micromachining techniques to improve the antenna radiation efficiency.

3.6 Chapter conclusions

In this chapter silicon integrated antennas have been presented as a possible solution for the remote sensor antenna. Silicon integrated antennas allow the integration of all the elements into a single chip, obtaining a real system-on-chip solution and reducing the packaging costs and system dimensions. To minimize costs and make the integration feasible, the antenna fabrication process must be compatible with the standard CMOS technologies. This means that low resistivity silicon must be used as substrate, which significantly degrades the antenna radiation efficiency.

The communication between the sensors and the central unit uses the 5.8 GHz ISM band. At this frequency antennas are big and difficult to integrate, and hence miniaturization techniques must be applied. With some simple techniques, like meandered lines or loaded structures, size reductions near 40 % can be obtained. However, it must be taken into account that with the low resistivity silicon substrates used for the antennas fabrication, the trade-off between miniaturization and efficiency degradation becomes much more significant.

Low efficiency levels could be defined as the main problem of silicon integrated antennas. The use of micromachining techniques to eliminate part of the silicon under the

antenna is a good solution to improve these efficiencies. The micromachining effects are more significant in the radiation parameters than in the input parameters, and antenna gain improvements near 4 dB have been measured. The higher the etching depth, the better the efficiency improvement. However, when the depth is increased the structure is more fragile and the fabrication process is more difficult (we had fabrication problems with etching depths greater than 450 μm).

In the micromachining process, not only the total amount of etched silicon is important, but the way this silicon is eliminated is also significant. The most sensitive area is the area near the feeding point, where generally fields and currents are stronger, for this reason it is important to increase the amount of etched silicon in this area. Furthermore, measured and simulated results show that the configurations with trenches perpendicular to the dipole orientation offer better gain improvement. Measurements show that with the same etching depth (450 μm), gain differences greater than 2 dB can be observed depending on the etching pattern.

The effects of this gain improvement can be relevant to system performance. For instance if these antennas are used in the sensors of the sensor network, keeping the same system performance, the power delivered by the sensor to the antenna can be reduced by more than fifty percent when micromachining techniques are applied, significantly increasing battery life.

In real applications, the antenna will be integrated together with other elements built into the same chip. Normally these elements are small, but in some cases, their dimensions can be significant, and therefore, the presence of these "parasitic" elements will degrade the RF antenna performance. In this chapter, the effects of having a coil for an inductive energy coupling near the antenna have been analyzed. The presence of the coil degrades the antenna gain taking into account that when the separation between both elements is reduced the chip can be smaller, but the performance degradation is higher. Reductions of 50 % in the system range have been measured as this separation is reduced from 1.57 mm to 320 μm.

To sum up, the results of this chapter demonstrate that silicon integrated antennas in the 5.8 GHz ISM frequency band are a feasible solution and that they can be fabricated using standard CMOS technologies together with other elements such as a coil or a sensor. Therefore, silicon integrated antennas are suitable for the sensors of our sensor network. The main problem is the low efficiency levels that degrade the system performance, however measurements show that these efficiency levels can be improved with micromachining techniques.

Chapter 4

Human body effects on antennas performance

In a remote sensor network, some of the wireless sensors could be implanted inside the body. The human body is a complex dielectric structure of materials with high conductivity and permittivity values that can adversely affect antenna performance. So the study of the body tissues effects is extremely important to ensure the correct operation of wireless communication systems operating in the vicinity of or within the body.

This chapter will present a review of previous works and existing regulations. Then, the problems related to simulation and measurement of the body effects on antennas performance will be discussed and a detailed study of the propagation losses introduced by the body tissues in different ISM bands will be presented. The differences between several body models will be also analyzed. Finally, measurements with body tissue simulating liquids will be carried out to demonstrate the simulations validity.

4.1 Introduction to the human body effects

There exists a great diversity of applications where antennas interact with human tissues, but basically two scenarios can be defined: The case where both antennas are outside the body, and the case where one of the antennas is implanted inside the body. This section will present a review of previous works and existing regulations for both scenarios.

4.1.1 Antennas in the vicinity of the human body

During the last decade there has been an important increase in public awareness of

radiation hazards associated with mobile phones and in particular, with base stations. Consequently, multiple references analyzing the possible effects of cellular base stations on humans have appeared. As an example, recently the Spanish Ministry of Industry, Tourism and Commerce, and the College of Telecommunication Engineers (COIT) have jointly published a leaflet [105] providing some safety guidelines related to cellular base stations, in an attempt to answer the questions that people typically ask about the possible effects of base station radiation on the human body.

[106] investigates the minimum necessary distance between a human body and a cellular base station in order to comply with the threshold values of the Institute of Electrical and Electronic Engineers (IEEE) and the International Commission on Non-Ionizing Radiation Protection (ICNIRP). In [107] human exposure to electromagnetic fields is analyzed in a realistic urban environment, incorporating possible signal reflections of walls and buildings.

The analysis of the mobile terminal effects on the head tissues is also an important issue because the separation between the mobile phone and the users head during a call is minimal. [108] shows an extensive study of the electromagnetic absorption into the human head and neck due to mobile phones radiating at 835 MHz and 1900 MHz. The fields for various head models (adult and child head) are analyzed and compared with the regulation limits. Other references where the mobile phones effects are studied can be found in [109–113], where different antenna configurations are considered.

Another field of interest where antennas are close to the human body are wearable devices [114] and Body Area Networks (BAN). In these cases the propagation channel is quite different from a free space propagation model. For this reason, there are multiple references where the problem of BAN channel modeling is analyzed [115–117]. Another sensitive issue is the design of the antenna because small, flexible and low profile antennas are usually required to improve user mobility and comfort. Textile antennas made of electro-textile materials are a good solution for these applications [118–120].

In the previous examples the antenna is used as a radiating element for information transmission. However, in some applications, like breast tumor detection, antennas near the body are used with imaging purposes [121–124].

Guidelines and regulations for antennas in the vicinity of the human body

In certain European countries a social concern has been raised about the possible health hazards resulting from RF fields exposure. As a consequence, several international radiation safety standards, such as the European Commission Recommendation related to electromagnetic exposure (ERC, July 1999 [125]), have been published. Most of them are

based on the ICNIRP guidelines [126] and the IEEE standard of 1999 [127] (updated in [128] and [129]). In the United States, the Federal Communication Commission (FCC) has provided some guidelines to assist local government officials in devising efficient procedures to ensure that antennas comply with FCC limits for human exposure to radiofrequency [10].

In the frequency range from 100 KHz to 10 GHz, restrictions are generally based on the Specific energy Absorption Rate (SAR) values in order to prevent excessive and harmful heating of body tissues [125]. The European Commission gives the following definition: "The Specific energy Absorption Rate (SAR) averaged over the whole body or over parts of the body is defined as the rate at which energy is absorbed per mass unit of body tissue and it is expressed in watts per kilogram (W/kg). Whole body SAR is a widely accepted measure for relating adverse thermal effects to RF exposure. Besides the whole body average SAR, local SAR values are necessary to evaluate and limit excessive energy deposition in small parts of the body resulting from special exposure conditions. All SAR values are to be averaged over any six minute period" [125].

This definition can be expressed as [130]

$$SAR = \frac{d}{dt}\left(\frac{dW}{dm}\right) = \frac{d}{dt}\left(\frac{dW}{\rho dV}\right) \tag{4.1}$$

where dW is the incremental energy absorbed by (dissipated in) an incremental mass (dm) contained in a volume element (dV) of a given density (ρ) .

The SAR values are related to the electric field at a given point by [130]

$$SAR = \frac{\sigma |E|^2}{\rho} \tag{4.2}$$

where σ is the tissue conductivity and E is the RMS electric field strength. Finally, under ideal non-thermodynamic circumstances, SAR can be related to the increase in temperature by [130]

$$SAR = \frac{c \triangle T}{\triangle t} \tag{4.3}$$

where $\triangle T$ is the change in temperature, $\triangle t$ is the duration of exposure and c is the specific heat capacity.

The SAR limitations according to the ICNIRP and IEEE guidelines are summarized in table 4.1. These limitations are mainly based on the body temperature rise due to exposure, taking into account that a maximum increase lower than 1^oC is desirable. The IEEE standard of 1999 [127] presented some local SAR limits different from the ICNIRP guidelines, but in the 2005 revision of the standard, the peak spatial average SAR values

Table 4.1: *SAR: Whole body and maximum local limits [125–128].*

Exposure Situation	Whole Body Average SAR (W/Kg)	Local SAR (Head and trunk) (W/kg)
Occupational	0.4	10
General Public	0.08	2

were changed with the aim of harmonizing the basic restrictions with the ICNIRP values. These limits also agree with those defined by the European Commission in [125].

In table 4.1 two exposure situations are defined. The occupationally exposed population consists of adults who are generally exposed under known conditions and are trained to be aware of potential risks and to take appropriate precautions. By contrast, the general public comprises individuals of all ages and of varying health status, including particularly susceptible groups or individuals, taking into account that in many cases members are unaware of their exposure to electromagnetic fields. Moreover, members of the general public can not reasonably be expected to take precautions to minimize or avoid exposure, thus more stringent restrictions are adopted for the general public than for the occupationally exposed population [126].

Finally, it is important to point out that the aforementioned documents are the most important recommendations and guidelines, however other documents which give specific details can be found. For instance [130] shows several measurement methods to evaluate the SAR inside the human body, [131] presents an extensive review of experimental studies about the biological effects of RF exposure and [132] gives information about the measures employed by different countries. In this last document it is stated that the Spanish law [133] includes the contents of the European Commission recommendation of July, 1999 [125].

4.1.2 Antennas implanted inside the human body

This section will analyze the scenario where one of the antennas is implanted inside the body and a wireless link with an external antenna is desired. The implanted antenna (with a thin insulation layer of biocompatible material) will be in contact with the human tissues, critically affecting the antenna performance. For this reason the antenna must be designed taking into account the conditions that it will find inside the body.

Another sensitive issue is signal propagation through the body. Body tissues are highly lossy, especially at high frequencies, therefore, they will introduce additional losses degrading the implanted antenna gain and the wireless link performance. Most

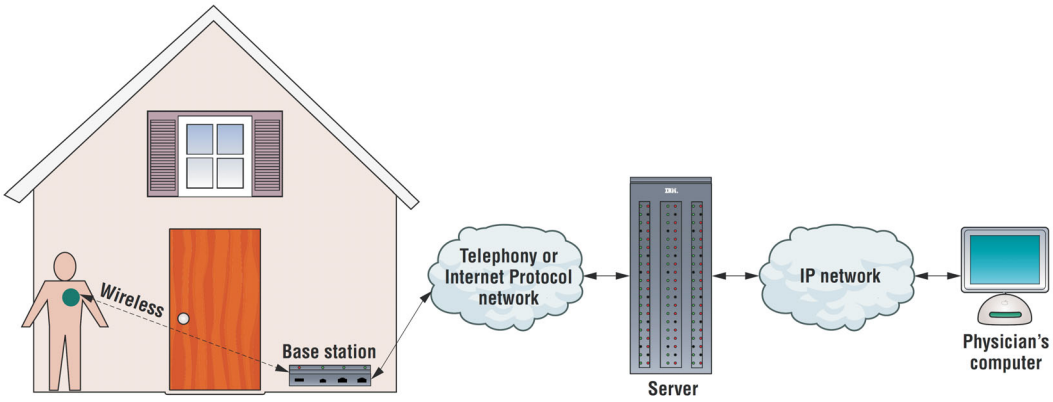

Figure 4.1: *Recent implantable cardiac defibrillators provide in-home monitoring via wireless base stations that relay data to doctors [136].*

of the efforts of this chapter will be focused on the analysis and quantification of these propagation losses. In spite of all these drawbacks, implantable antennas are an important field of interest that is growing rapidly.

During the second half of the past century an important effort was put in the design of implantable biomedical devices for the treatment of various illnesses [134]. In 1952, Dr. P. Zoll reported the first external pacemaker [135], and some years later, the first implantable pacemaker was presented. As time went by, these primitive devices evolved to the current ones, with better performance and longer lifetime. Other examples of applications with implantable devices are monitoring systems, drug delivery systems and defibrillators [134].

In these implantable devices a wireless link with an external receiver can be used to monitor the device battery level and the clinical parameters of the patient. As an example of application, an implantable sensor with a wireless communication link could be used in a glucose monitoring system [137], automatically alerting the emergency systems when a problem is detected (figure 4.1). These implantable sensors with wireless links will be one of the key points for future e-health systems, especially for the treatment of chronic diseases. One of the most important companies in this area is Medtronic [20], a company founded more than 40 years ago that offers a wide catalog of solutions for the treatment of different illnesses (figure 4.2).

The most commonly used frequency band for implantable antennas is the Medical Implant Communications Service (MICS) band allocated in 1999 by the FCC in the $402 - 405$ MHz frequency range. It is a frequency band for ultra-low power, unlicensed, mobile radio services for transmitting data in diagnostic or therapeutic applications

(a) (b)

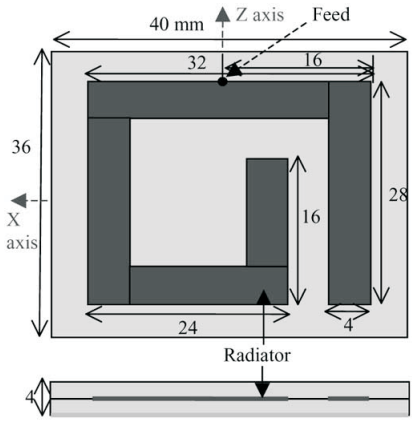
(c)

Figure 4.2: *Medtronic offers a wide catalog of solutions for the treatment of chronic diseases [20]. (a) Real time glucose monitoring system. (b) Implantable cardioverter defibrillator with wireless telemetry system. (c) Implantable cardiac monitor.*

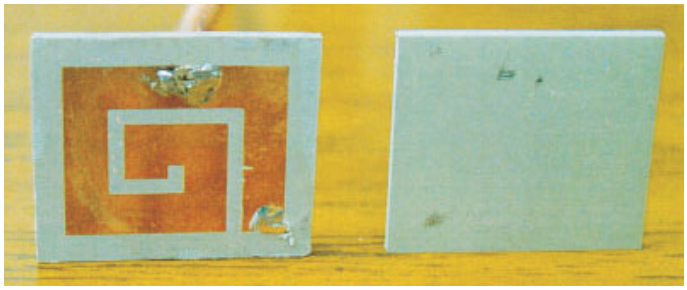
associated with implantable medical devices. Another option is the use of low frequency (13.56 MHz) inductive links [103, 138], but low ranges are obtained (4 cm) and the external coil must touch the patient body near the internal coil [103].

In [139] and [140] two antenna designs for the MICS band with a superstrate layer to improve the antenna performance were presented (figure 4.3). Due to their shape and dimensions (4 cm x 3.6 cm x 0.4 cm for the microstrip antenna and 2.4 cm x 2 cm x 0.25 cm for the PIFA), these antennas are suitable for big medical devices implanted in the human chest, like pacemakers or defibrillators. In [141] a similar design is studied, analyzing the effects of the pacemaker and battery pack on the antenna performance. Other examples of antennas in the MICS band can be found in [142–147].

The aforementioned examples, and the existing commercial solutions, typically use the MICS bands, however there exists a growing interest in higher frequencies, such as the 2.45 GHz ISM band, because smaller antennas can be obtained. For instance in [104] an implantable antenna for an intracranial pressure monitoring system (figure 4.4(a)) was presented. [148] and [149] analyze the cavity slot of figure 4.4(b) and [150] shows an implantable wireless telemetry board with an ISM band antenna for invivo transocular transmissions.



(a)



(b)

Figure 4.3: *Antennas for implantable devices. (a) Microstrip antenna. [139]. (b) PIFA antenna. [140].*

In [144, 151] a dual band PIFA antenna for the MICS and the 2.45 GHz ISM bands is shown (figure 4.4(c)). This dual band design can be used with the ultra low power implantable transceiver Zarlink ZL70101 [152] that transmits information in the MICS band and uses a wake-up signal at 2.45 GHz. Finally, of interest is the study presented in [153], where the radiation characteristics of an ingestible wireless device in different frequency bands are analyzed.

Guidelines and regulations for antennas implanted inside the human body

As in the first scenario, or even more because here the antennas are inside the body, the safety issues related to the effects of electromagnetic fields on the body tissues are a point of interest and awareness.

As was previously said, the most commonly used frequency bands, especially in commercial applications, is the MICS band. It is a free band for implantable devices that can be used without a specific license. Nevertheless, according to [19], the maximum

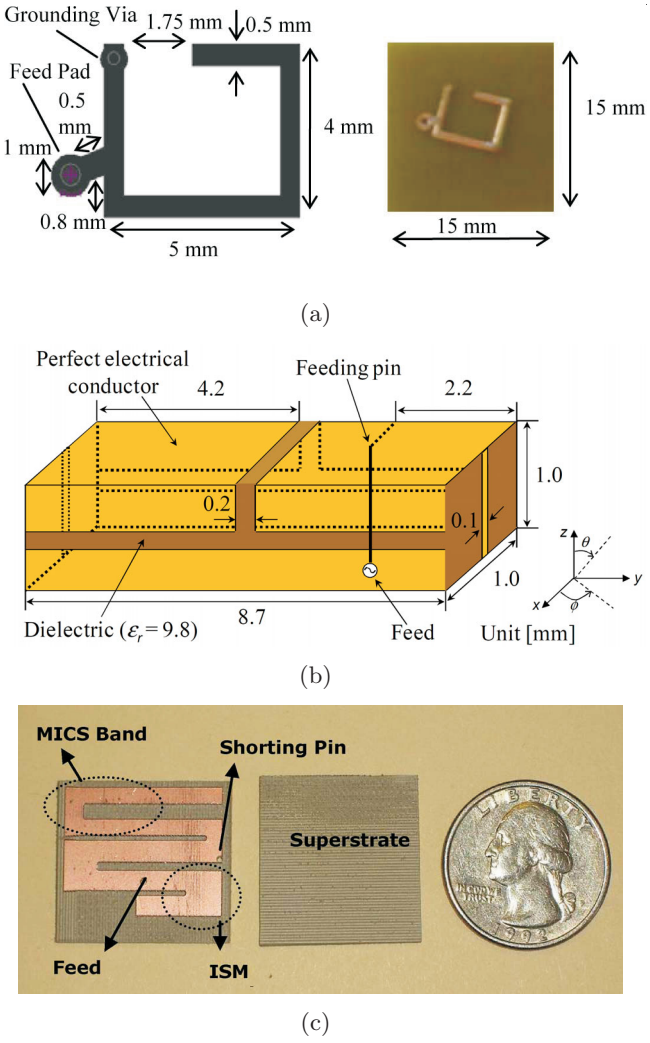


Figure 4.4: *Examples of antennas operating in the 2.45 GHz ISM band. (a) PIFA antenna for an intracranial pressure monitoring system [104]. (b) Cavity slot antenna to be implanted in the patient arm [148]. (c) Dual band antenna for the MICS and ISM bands [144].*

power in any 300 KHz bandwidth radiated by medical radio transmitters operating at 402 - 405 MHz shall not exceed 25 μw EIRP. The FCC also specifies how the EIRP measurements must be carried out. The radiated emissions and EIRP levels may be determined by measuring the radiated field from the equipment under test at a distance of 3 meters [19]. Furthermore radiated emissions and EIRP measurements must be made in accordance with a commission-approved human body simulator and test techniques. A suitable tissue substitute material is defined in the OET Bulletin 65 Supplement C [154].

Soon afterwards the definition of the MICS band, some regulatory arrangements

supporting MICS devices were done in order to enable the use of implantable devices worldwide. For instance the International Telecommunication Union Radiocommunications sector (ITU-R) developed a recommendation for the MICS band [155] taking into account that this band has to be shared with the Meteorological Aids Service (allocated in the same frequency range some time ago). However, it is not a problem because with the EIRP limit of MICS systems and the interference mitigation techniques used by the MICS equipment, no harmful interference should occur between both systems [155].

The European Radiocommunication Commission also allocated the same band for the same services in the recommendation ERC/REC70-03 [156]. [156] covers all kind of Short Range Devices (SDR), but annex 12 is focused on medical implants, under the name of Ultra Low Power Active Medical Implants (ULP-AMI). In this recommendation the maximum EIRP power of 25 μw defined by the FCC [19] is also used. The European Telecommunications Standards Institute (ETSI) developed harmonized standards for these devices [157] where some additional information about the measurements methods to test the ULP-AMI limits is given.

The aforementioned standards and recommendations are for the MICS band ($402 - 405$ MHz), but in recent years an important effort has been put into the design of antennas for implantable devices working at higher frequencies. Some examples that use the 2.45 GHz ISM band have been shown in figure 4.4. To the author's knowledge, there is not a well defined specific regulation for implantable devices at 2.45 GHz. For this reason, generally the SAR limits given for the first scenario where the antennas were in the vicinity of the human body are also used when one of the antennas is inside the body. However, in implantable sensors the transmitted power levels are usually very low in order to increase the battery life, and hence the SAR levels are below these limits. Some other authors like K. Ito in [148], also use the power limit of 25 μw for the 2.45 GHz ISM band.

4.2 Human body models

Implanted antennas performance evaluation is difficult. In simulations accurate models of the human body are necessary. In measurements, physical models called phantoms filled with special liquids are normally used. These liquids have electrical properties similar to body tissues and allow the evaluation of the antenna and the whole system performance under test conditions similar to the real body. In this section, different solutions for modeling the body effects will be analyzed.

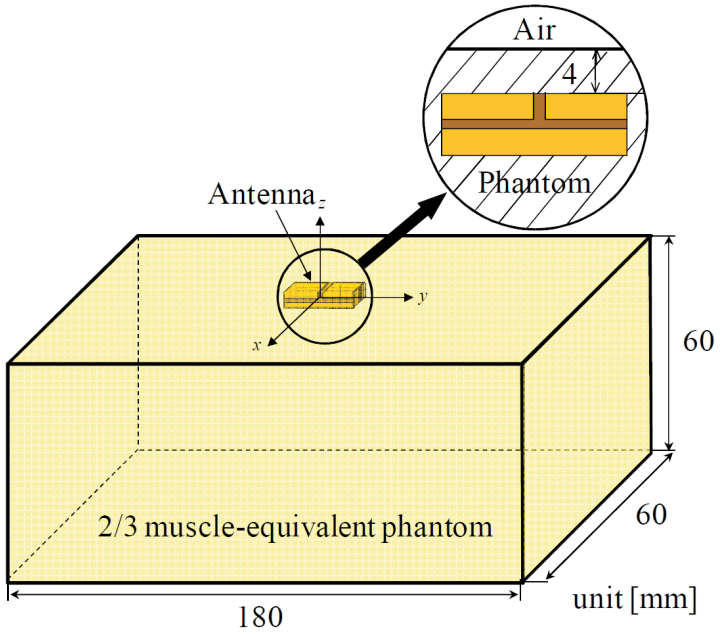

Figure 4.5: *One layer model used by K. Ito for the antenna simulation inside the human body [148].*

4.2.1 Simulations with human body models

In simulations, the simplest and fastest, but least accurate option is the use of a single layer structure of an homogenous material with properties similar to body tissues. As can be seen in figure 4.5, the antenna is simulated inside a block of this dielectric material [140, 141, 148]. However, in the one layer model there is an additional question that must be answered: What are the properties of the equivalent material used to model the overall behavior of the complex human body dielectric structure? In literature multiple solutions can be found. For instance, [149] and [158] used a material called "2/3 muscle", that is a material with the electrical properties of the muscle tissue multiplied by 2/3.

In spite of the fact that "2/3 muscle" material has been used by several authors, the Office of Engineering and Technology (OET) of the FCC published some guidelines for the SAR evaluation process (OET Bulletin 65 supplement C [154]). This document gives the properties of the equivalent material that must be used (table 4.2). The conductivity of this equivalent material is slightly higher than the conductivity of muscle and other body tissues, therefore the propagation losses simulated with this equivalent material will be slightly overestimated.

Another possible option is the use of a multilayer structure of finite or infinite dimensions. Normally, a three layer (muscle - fat - skin) model is used [139, 159, 160].

Table 4.2: *Equivalent tissue dielectric parameters for head and body models [154].*

	Head		Body	
Frequency (MHz)	ε_r	$\sigma(S/m)$	ε_r	$\sigma(S/m)$
150	52.3	0.76	61.9	0.80
300	45.3	0.87	58.2	0.92
450	43.5	0.87	56.7	0.94
915	41.5	0.98	55.0	1.06
1450	40.5	1.20	54.0	1.30
1610	40.3	1.29	53.8	1.40
1800 - 2000	40.0	1.40	53.3	1.52
2450	39.2	1.80	52.7	1.95
3000	38.5	2.40	52.0	2.73
5800	35.3	5.27	48.2	6.00

Table 4.3: *Electrical properties of body tissues in different ISM frequency bands [161].*

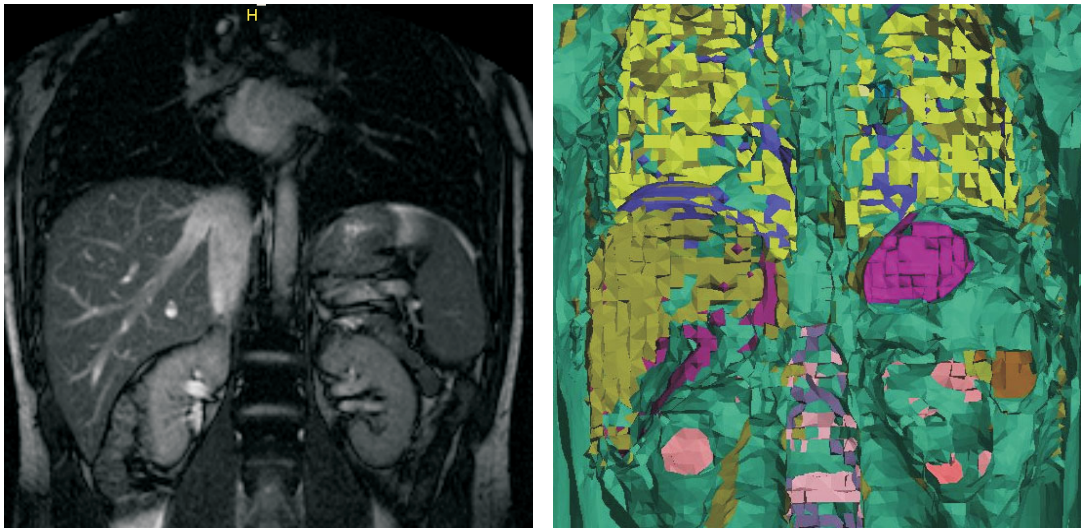
	Relative Permittivity ε_r				Conductivity σ (S/m)			
Frequency (MHz)	433	915	2450	5800	433	915	2450	5800
Skin	46.08	41.33	38.01	35.11	0.70	0.87	1.46	3.72
Fat	5.57	5.46	5.28	4.95	0.04	0.05	0.10	0.29
Muscle	56.87	54.99	52.73	48.48	0.80	0.95	1.74	4.96

The electrical properties of body tissues can be found in [161], and are summarized in table 4.3, where the skin, fat and muscle electrical parameters in some ISM bands are shown. The human head also can be modelled wit a multilayer model, like in [139] where a spherically six layer (brain - cerebrospinal fluid - dura - bone - fat - skin) head model is used.

If the antenna is outside the body, similar results are obtained with the one layer and the three layer models. However, as it will be shown later in this chapter, a three layer model is necessary when the antenna is inside the body because the antenna behavior can differ depending on the tissue layer where it is implanted.

Finally, there is the option of using 3D anatomical models [153, 162–165]. These realistic models offer the most accurate results because almost all the details of the body shape are taken into account. There are two kinds of anatomical models: the homogeneous models and the inhomogeneous models. In the first ones, the model consist of a uniform dielectric material block with the shape of a human being, meanwhile in the second ones the different body tissues are taken into account.

Inhomogeneous models can be created with the information of Magnetic-Resonance Imaging (MRI) [164] images where the shape of the internal organs can be obtained.



(a) (b)

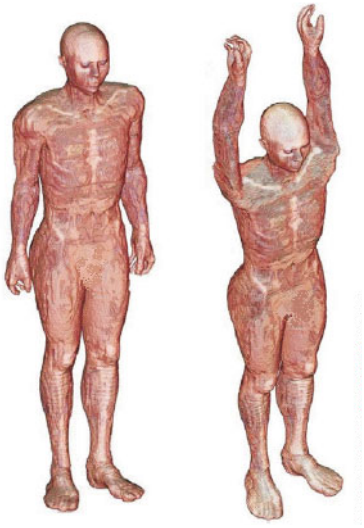
Figure 4.6: *The human body is an inhomogeneous structure. (a) MRI image of the thesis author. (b) Cut of the FEKO inhomogeneous body model. The simulation model takes into account most real body details.*

The body tissues properties at different frequencies appear in [161]. Figure 4.6(a) shows a MRI image of the thesis author and figure 4.6(b) shows a cross section of a FEKO inhomogeneous model. Comparing both figures, it can be seen that the inhomogeneous model takes into account most real body details.

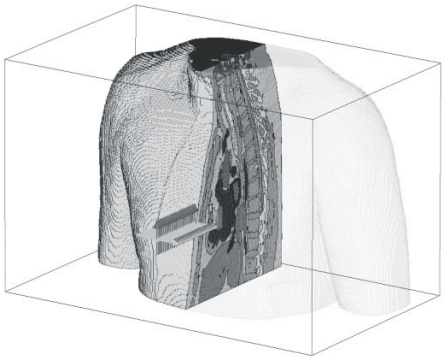
Furthermore, models with different positions and kinds of person (male, female, adult, child, ...) can be used to evaluate the effects of different body parameters in the system performance. Many examples of human body models can be found in literature (figure 4.7) and some commercial softwares, like FEKO [70], Semcad X [166] or Empire XCcel [167], also offer their own models.

In particular, the FEKO software used in this thesis provides several models of specific parts of the body, like a model of the head and the shoulders for mobile phones SAR evaluation, and three whole body models: one with a superficial mesh (SEP model), and two with a volumetric mesh to be solved with Finite Elements Methods (FEM models). The SEP model is a homogenous anatomical model. One of the FEM models is homogenous (334,733 tetrahedra) whereas the other is inhomogeneous (2.2 millions tetrahedra). Both are suitable up to 1 GHz [70].

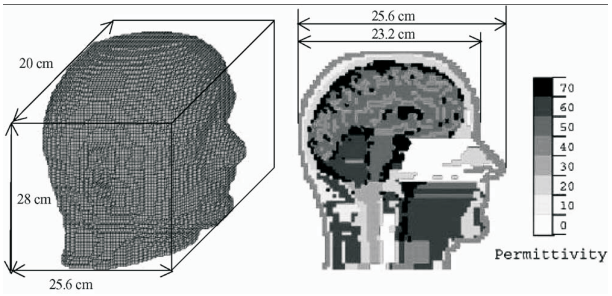
Table 4.4 shows the peak memory usage and the simulation time necessary for the simulation of a 900 MHz half wavelength dipole antenna in front of a human body. When the inhomogeneous model is used computational requirements are high, the simulation



(a)



(b)



(c)

Figure 4.7: *Examples of human body models found in literature. (a) 3D human body in different positions [164]. (b) Cut of an inhomogeneous body model [168]. (c) 3D inhomogeneous head model [139].*

Table 4.4: *Computational requirements of FEKO body models.*

Model	Peak Memory (GB)	Simulation time (s)
Homogeneous SEP model	9.45	7669
Homogeneous FEM model	2.61	1678
Inhomogeneous FEM model	15.62	33618

needs 15.6 GB of memory and the analysis of each frequency takes 33600 seconds. With the homogeneous models the requirements are smaller, for instance the FEM homogeneous model only needs 2.6 GB of memory and the simulation time is below 1700 seconds. These results show that generally the simulations made with homogeneous models are faster and need less memory than the simulations made with inhomogeneous models. Therefore there

exists a clear trade-off between the simulations accuracy (inhomogeneous models) and the simulations requirements (homogeneous models).

Furthermore, it is important to take into account that in some scenarios homogeneous models can be perfectly valid, for instance, when a dipole antenna is placed in front of a human body (figure 4.8). In this kind of simulation where the antenna is external to the body, homogenous and inhomogeneous models give the same results. Nevertheless, when the antenna is implanted inside the body normally an inhomogeneous model has to be used to obtain accurate results.

The main problem of 3D anatomical models is that computational requirements are high due to the models complexity and the need for a fine mesh to take into account all the body details. For this reason, in spite of the better accuracy of the anatomical models, the aforementioned one layer and three layers models are still very popular.

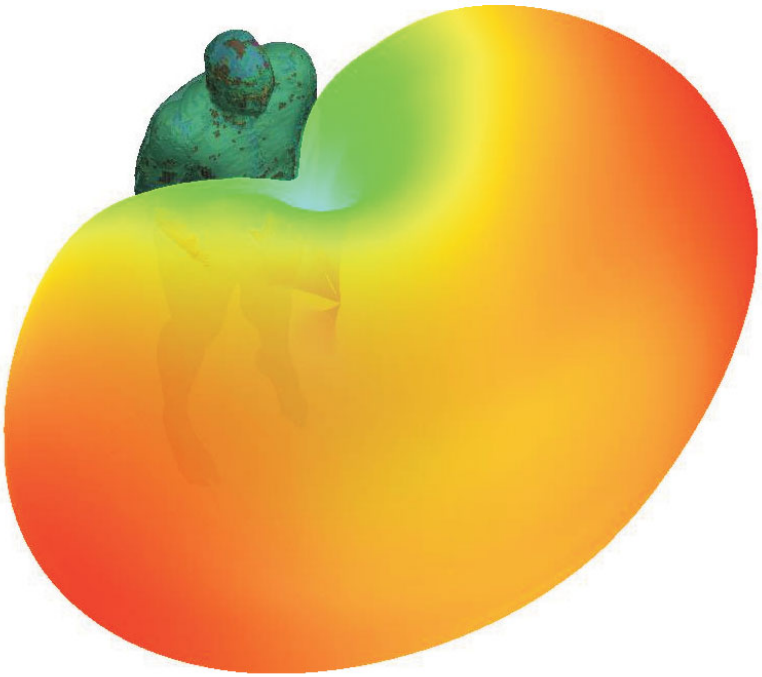


Figure 4.8: *Radiation pattern of a dipole antenna in front of a human body at a distance of 10 cm. The inhomogeneous FEM model was used, but the same results were obtained with the homogeneous one. A 30 dB dynamic range has been used for the 3D far field plot.*

4.2.2 Measurements using human body phantoms

Implanted antennas performance evaluation is not a trivial issue because it is not possible to carry out measurements in the real operating scenario, so a scenario that emulates the environment of the real human body is necessary.

The most widespread solution is the use of a container with a regular or an anatomical shape filled with an special liquid [169]. The antenna is sunk into the liquid and measurements are carried out [139, 140, 148, 149, 158]. These liquids, also known as body tissues simulating liquids, must have dielectric properties similar to the human body. There are some commercial liquids [166] with the dielectric properties of table 4.2 ready to carry out this kind measurements, and SPEAG also offers complete solutions to automatically carry out these measurements, like the Dasy 5 measurement setup shown in figure 4.9 [166].

If a container with a regular shape is used (for instance a cuboid), measurements are equivalent to the one layer model simulations, meanwhile if the container has an anatomical shape, measurements are equivalent to simulations with an homogeneous anatomical body

Figure 4.9: *Dasy 5 measurement setup. It is designed for SAR measurements, but it could be also used for the measurement of implanted antennas [166].*

model. In section 4.4 some measurements of a patch antenna using body tissue simulating liquids with a regular shape container will be presented to demonstrate the validity of the simulator predictions.

Recently Karacolak [144, 151] has been working on the use of tissue simulating gels with dielectric properties similar to the body tissues. This is an option of interest because it is a first attempt to measure using multilayer structures. There are also some authors that have carried out measurements with real tissues, but only those of animals [150, 170].

4.3 Study of the propagation losses introduced by body tissues

One of the main problems related to implanted antennas are the additional propagation losses introduced by the body tissues that critically degrades system performance. This section will focus on the analysis of these losses.

The propagation losses of body implanted antennas in the ISM bands of 433 MHz, 915 MHz, 2450 MHz and 5800 MHz will be studied. The results of the 433 MHz band can be also considered valid for the 402 - 405 MHz MICS band. It is important to point out that the aim of this study is the analysis of the body effects on propagation losses, not the design of the implanted antenna, for this reason simple straight dipoles will be used as transmitting and receiving antennas. Straight dipoles may not be the optimal solution, but they are typically used as reference antennas.

Two body models will be considered, one based on a single equivalent layer and the other based on a three layer structure, showing the advantages and limitations of each one. The study with anatomical models will not be carried out due to the high system requirements and simulation times. Firstly, the one layer and three layer models will be used to evaluate the effects of introducing the antenna inside the body. The system performance as a function of several parameters like the external antenna distance, implanted antenna depth and operating frequency will be evaluated. Then, the effects of the different tissues thickness will be studied using the three layer model, and finally the consequences of adding a coating layer to the antenna, necessary for biocompatibility issues, will be discussed.

4.3.1 Free space wireless link

One of the main parameters that defines the performance of a wireless system is the

antenna pair gain (Ga) [75]. It can be calculated using the scattering parameters as

$$Ga = \frac{|S_{21}|^2}{(1-|S_{11}|^2)(1-|S_{22}|^2)} \tag{4.4}$$

where the term in the denominator is used to subtract the mismatch losses of the transmitting and receiving antennas.

The antenna pair gain is mainly related to the propagation losses and the antennas gain. In a free space scenario, where both antennas are outside the body and far field conditions are assumed, the antenna pair gain can be computed as

$$Ga_{(fs)} = G_T \cdot G_{Air} \cdot G_R \tag{4.5}$$

where G_T is the transmitting antenna gain, G_R is the receiving antenna gain and G_{Air} is the air propagation gain or free space propagation gain defined as

$$G_{Air} = \left(\frac{\lambda}{4\pi r}\right)^2 \tag{4.6}$$

where λ is the free space wavelength and r is the distance between both antennas.

4.3.2 One layer model

Now, the effects of having one of the antennas implanted inside the body will be studied using the one layer model. Firstly, the simulation scenario will be presented and then the simulated results obtained with the FEKO MOM code [70] will be analyzed.

Simulation scenario

The system under study is based on two dipole antennas, one implanted inside the human body, and one outside the body. Half wavelength resonant dipoles are used as transmitting and receiving antennas to avoid precision errors when subtracting the mismatch losses in equation 4.4. The simulation scenario and the definition of the different parameters are shown in figure 4.10. In order to reduce the simulation computational requirements an infinite dielectric structure was used to model the body, however the results were also checked with finite dielectrics. The equivalent tissue properties can be found in table 4.2.

Simulation results

The insertion of the antenna inside the human body has two main effects: A decrease in the resonant antenna dimensions and a degradation of the gain due to the high permittivity and conductivity of body tissues.

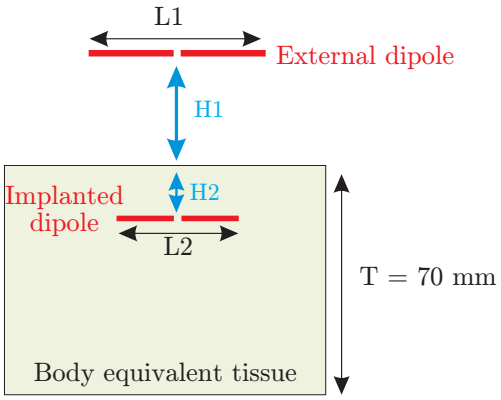

Figure 4.10: *One layer scenario. The transmitting and receiving antennas are half wavelength resonant dipoles. The equivalent tissue properties are shown in table 4.2.*

Figure 4.11(a) plots the antenna pair gain as a function of the internal antenna depth when the external antenna is 400 mm away from the body surface. The antenna pair gain decreases when the frequency is increased. For instance, if the implanted antenna depth is equal to 10 mm, the antenna pair gain decreases almost 20 dB when the frequency is changed from 2.45 GHz to 5.8 GHz. This degradation is due to the increase in the free space propagation losses (the frequency is multiplied by 2, therefore losses are increased in 6 dB) and the increase in the body conductivity (table 4.3) that introduces approximately 14 dB of additional losses.

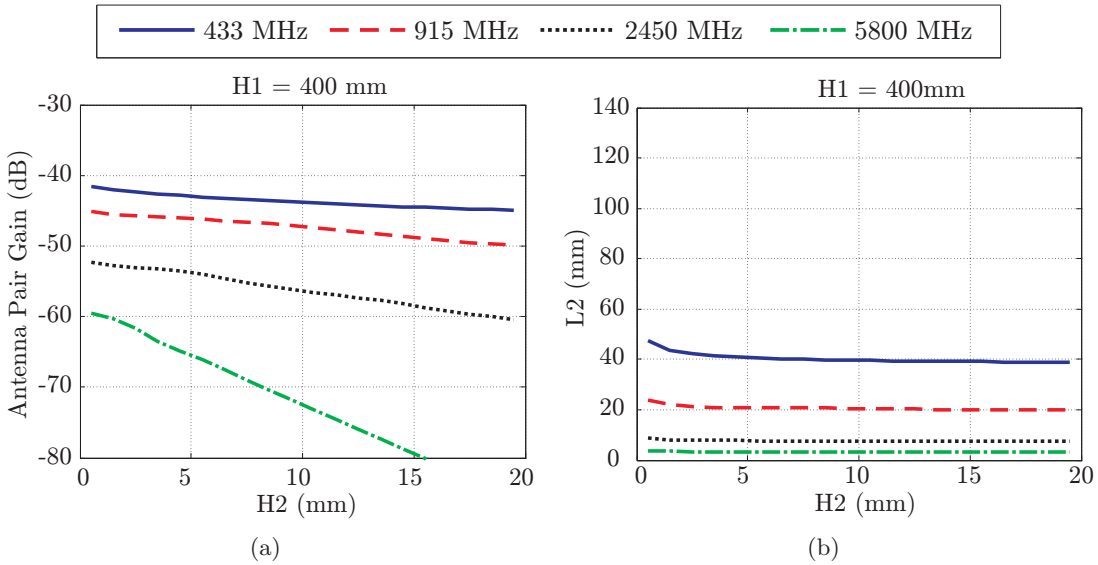

Figure 4.11: *Simulation results for the one layer model (figure 4.10). (a) Antenna pair gain. (b) Implanted dipole length to keep the antenna resonant at the desired frequency.*

Figure 4.11(b) shows the required implanted dipole length to keep the structure resonant at different depths. It was obtained empirically through an iterative simulation process. This length is inversely proportional to the frequency and it is significantly smaller than one half of the free space wavelength because of the high permittivity of body tissues. With the one layer model the dipole length does not significantly change with depth (figure 4.11(b)).

According to these results, a clear trade-off between antenna dimensions and antenna performance exists. When frequency is increased, antenna dimensions are reduced, but the antenna pair gain decreases degrading the system performance.

4.3.3 Three layer model

In this section we will study the propagation losses using a three layer model to simulate more accurately the real scenario and we will highlight the one layer model limitations.

Simulation scenario

In this scenario the body effects were modeled using a three layer model made of skin, fat and muscle (figure 4.12). Depending on the body area where the antenna is implanted the thickness of each layer can be different. For this reason thickness values used in literature may vary from author to author [137, 139, 144, 171, 172]. We used the thickness shown in figure 4.12. The body tissues properties can be found in table 4.3.

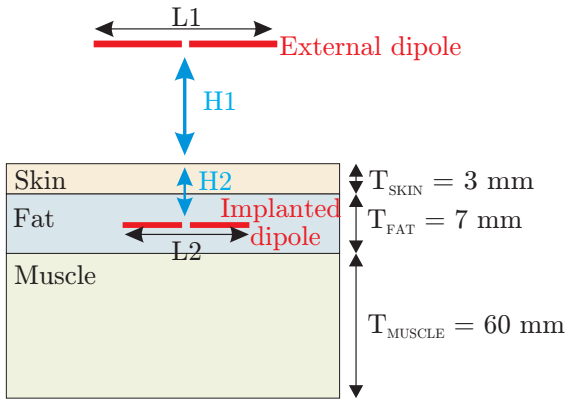

Figure 4.12: *Three layer (skin - fat - muscle) model simulation scenario. As in the previous scenario, the transmitting and receiving antennas are half wavelength resonant dipoles. The body tissues properties are shown in table 4.3.*

Simulation results

Figure 4.13 shows the simulation results with the three layer model. The antenna pair gain (figure 4.13(a)) significantly depends on the layer where the antenna is positioned. In the implanted antenna gain plot (figure 4.13(b)), the effects of the three layers can be clearly distinguished. According to table 4.3, skin and muscle tissues have higher conductivity values than fat, therefore the implanted antenna gain is lower in these layers. It must be noted that for the higher frequency bands, where the fat layer is electrically thicker, more than 10 dB of difference can be observed.

The air propagation gain (G_{air}) is shown in figures 4.13(c) and 4.13(d). Simulated air propagation gain has been obtained subtracting the internal and external antennas gain from the antenna pair gain (Ga). The theoretical results using a free space propagation model (equation 4.6) are plotted with a yellow line. When the implanted antenna depth (H_2) is changed, flat plots are obtained, proving that with typical antenna depths of some millimeters, the air propagation gain does not significantly depend on this parameter. When the distance to the external antenna (H_1) is changed, an inversely proportional quadratic dependence is observed, showing a good agreement with the theoretical model. These results prove that when far field conditions are fulfilled, body losses can be included in the implanted antenna gain and use a simple free space propagation model to evaluate the system link budget.

When the implanted dipole is in the fat layer, the effective permittivity is significantly lower than in the other layers and the dipole length (L_2) has to be increased by approximately a factor of 2 to keep the same resonance frequency (figure 4.13(e)) Again, we can see the aforementioned trade-off between antenna dimensions and performance. When the antenna is in the fat layer, its gain is higher (figure 4.13(b)), but it has to be longer (figure 4.13(e)).

In the coverage maps of figure 4.14, the antenna pair gain is plotted as a function of the implanted antenna depth (H_2) and the distance to the external receiver (H_1). These maps can be useful in the system design process. From the system specifications, the required antenna pair gain is calculated, and then the system range for a given frequency band and an implanted antenna depth can be easily predicted with the information of figure 4.14. As an example, if the antenna pair gain has to be higher than -35 dB to assure the proper system operation, we can predict that it will be impossible to have the system operating at 5.8 GHz.

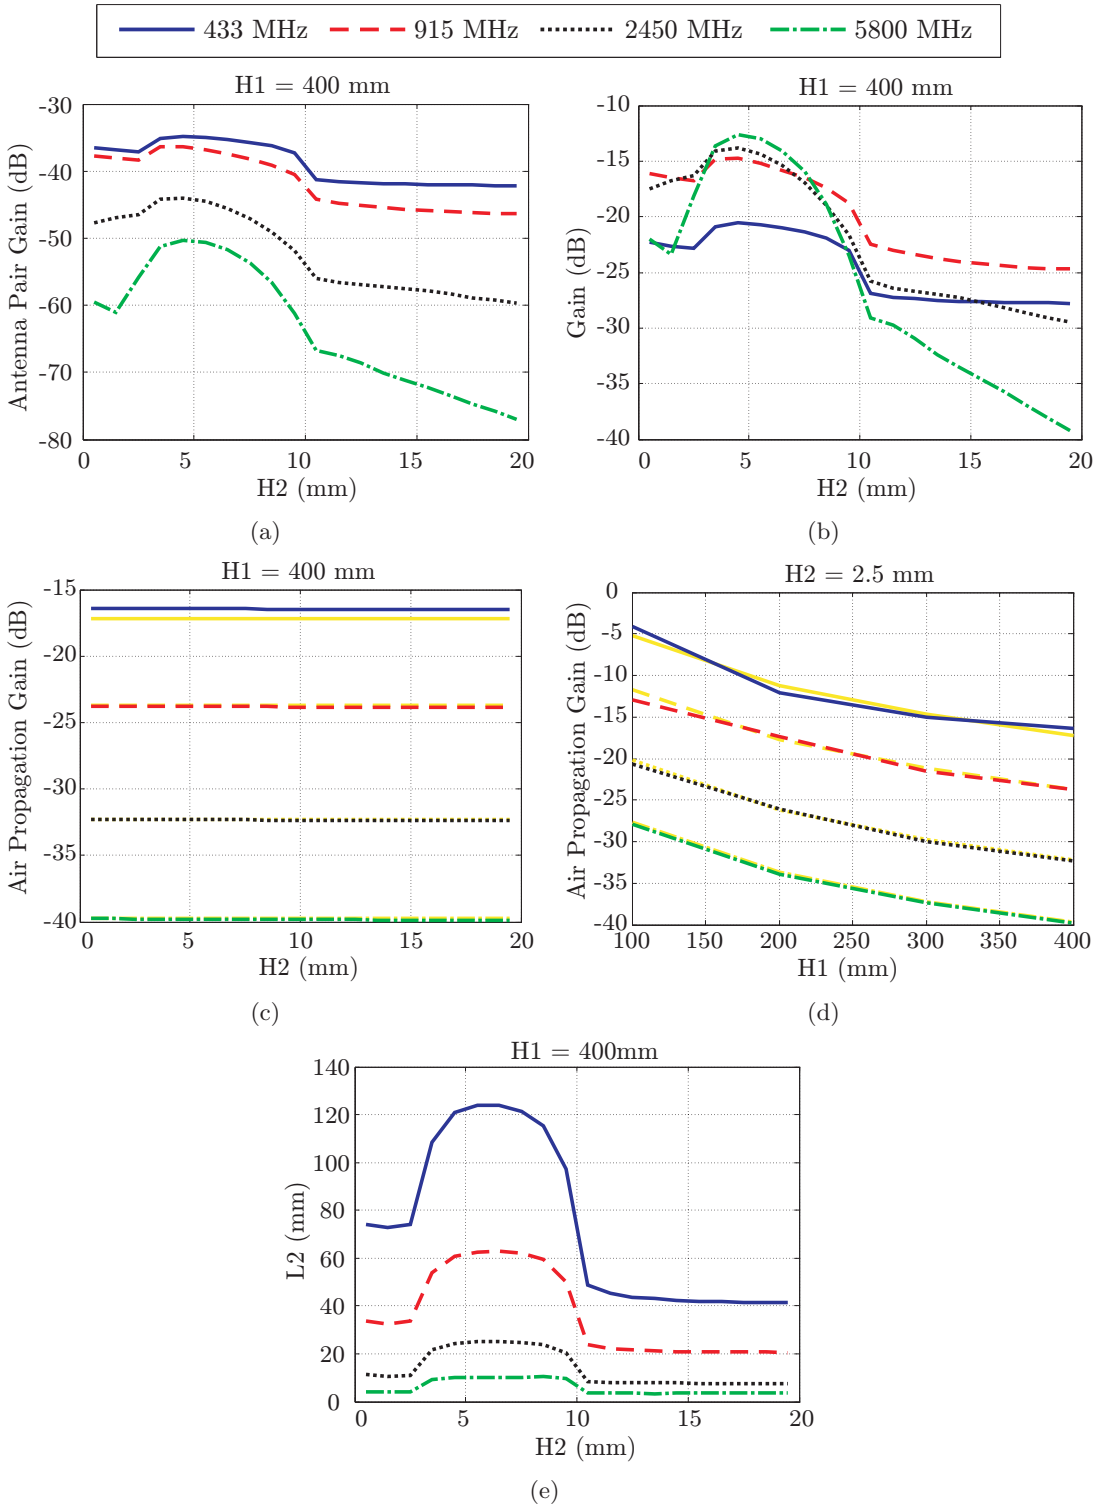

Figure 4.13: *Simulation results with the three layer model (figure 4.12). Yellow lines show the theoretical results. (a) Antenna pair gain. (b) Implanted antenna gain. (c) Air propagation gain as a function of the implanted antenna depth. (d) Air propagation gain as a function of the distance to the external antenna. (e) Implanted dipole length to keep the antenna resonant at the desired frequency.*

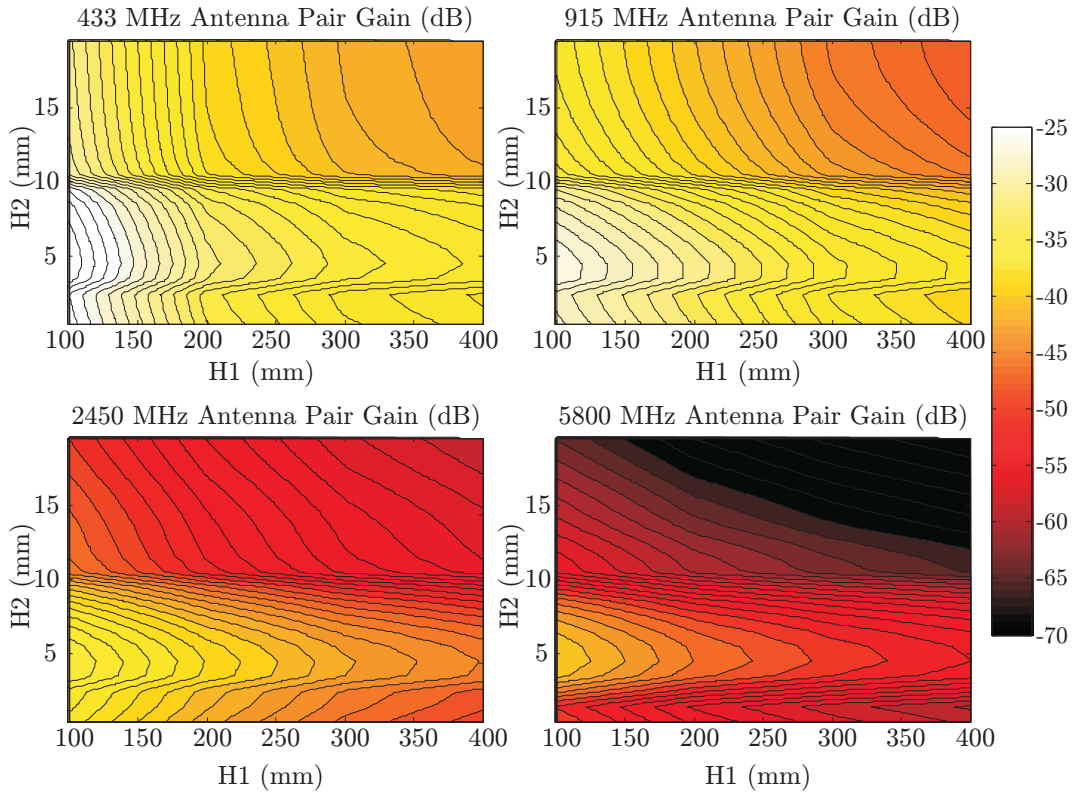

Figure 4.14: *Coverage maps showing the antenna pair gain (Ga) at different frequencies as a function of the implanted antenna depth and the distance to the external antenna. Coverage maps are useful to predict the system performance as a function of the frequency band and the antennas position.*

One layer model vs. three layer model

This section shows a comparison between the results obtained with the one layer model and the three layer model. The objective is to point out the limitations of the one layer model, which are similar to the limitations existing in the measurements carried out using phantoms filled with an homogeneous body tissue simulating liquid.

With reference to the antenna pair gain, in the one layer model (figure 4.11(a)) it is lower than in the three layer model (figure 4.13(a)). This was expected since the conductivity values used in the one layer model are slightly higher than the values used in the three layer model. Furthermore, it must be noted that the one layer model does not take into account the gain improvement when the antenna is in the fat layer. It tends to overestimate losses, so it can be accepted as a conservative approach from the point of view of the antenna pair gain.

In the three layer model differences in implanted dipole length depending on the tissue

where the antenna is implanted are significant and can be greater than a factor of 2 (figure 4.13(e)). This effect is not considered by the one layer model where the dipole length is kept almost constant (figure 4.11(b)). This is an important limitation of the one layer model and the measurements made using body tissue simulating liquids. If the antenna design is carried out taking into account the one layer model, the phantom measurements can agree with simulations, however, if the antenna is implanted in the fat layer, it will be detuned and the system might not work properly. The conclusion is that a three layer model must be used in the implantable antenna design process, especially if the antenna has to be implanted in the fat layer.

4.3.4 Effects of the layers thickness

We will show the effects of modifying the thickness of the skin and fat layers. The skin layer can change from 1 mm to 5 mm depending on the body part, and the fat layer from 3 mm to 15 mm.

The thicker the fat layer, the wider the depth range where the gain is maximum and the higher the maximum value of this gain (figure 4.15(a)). This is due to the fact that the antenna is further separated from muscle and skin, so the losses introduced by these tissues are reduced. Furthermore, as the thickness of fat layer increases, the depth range

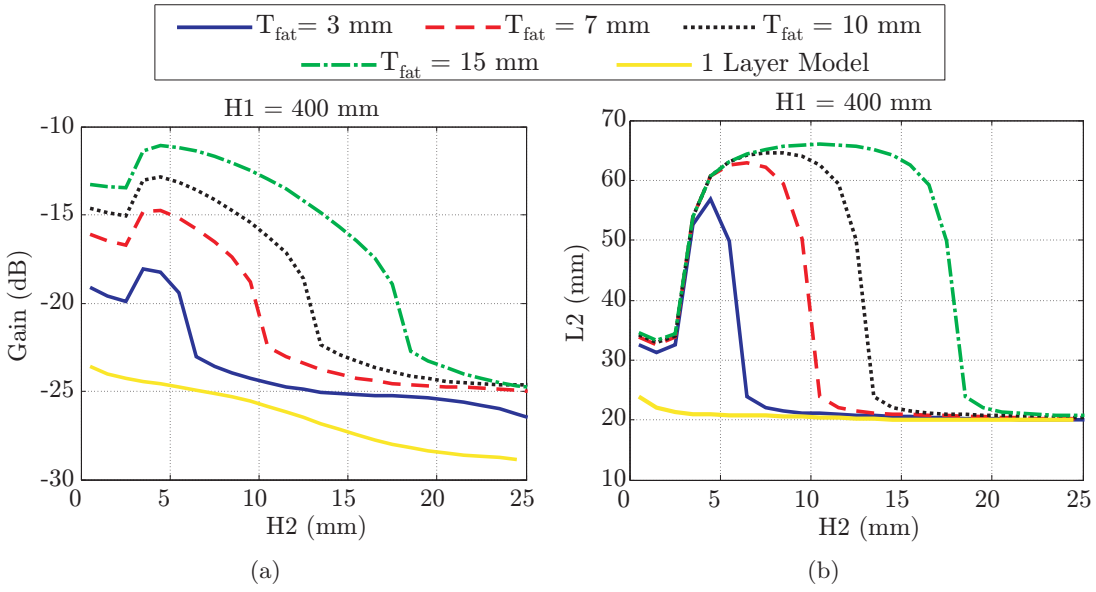

Figure 4.15: *Effects of the fat layer thickness. Yellow lines show the results obtained with the one layer model. Operating frequency $f = 915\,MHz$. (a)Implanted antenna gain. (b) Implanted dipole length to keep the antenna resonant at the desired frequency.*

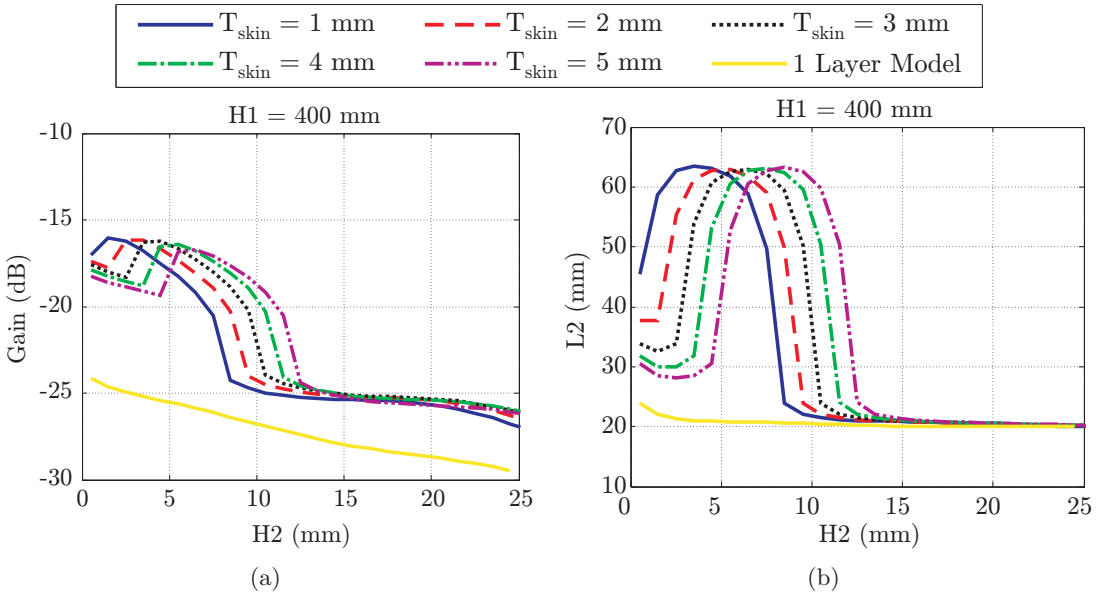

Figure 4.16: *Effects of the skin layer thickness. Yellow lines show the results obtained with the one layer model. Operating frequency $f = 915\,MHz$. (a) Implanted antenna gain. (b) Implanted dipole length to keep the antenna resonant at the desired frequency.*

where the dipole has to be longer is wider (figure 4.15(b)). Comparing the one layer model and the three layer model, the differences between both models become more significant when the fat layer is thicker.

When the skin layer thickness is increased the depth range where the antenna gain is higher changes accordingly to the fat layer position (figure 4.16(a)). The same conclusion can be drawn for the depth range where the antenna has to be longer (figure 4.16(b)).

4.3.5 Effects of a coating layer

In previous sections the antenna was directly in contact with the body. In real applications an insulation or coating layer of biocompatible material will be necessary to protect the antenna from the body tissues. Now, the effects of this coating layer will be analyzed.

In [173] Merli shows a list of materials that can be used as insulation layers. In our study, a low-loss coating layer with a relative permittivity equal to $\varepsilon_r = 4$ was used. Figure 4.17 shows the resonant dipole gain and length in the 2450 MHz ISM band when the coating layer thickness varies from 0.1 mm to 0.8 mm. Results with no coating are also plotted.

With regard to the antenna gain, the presence of a coating layer is advantageous,

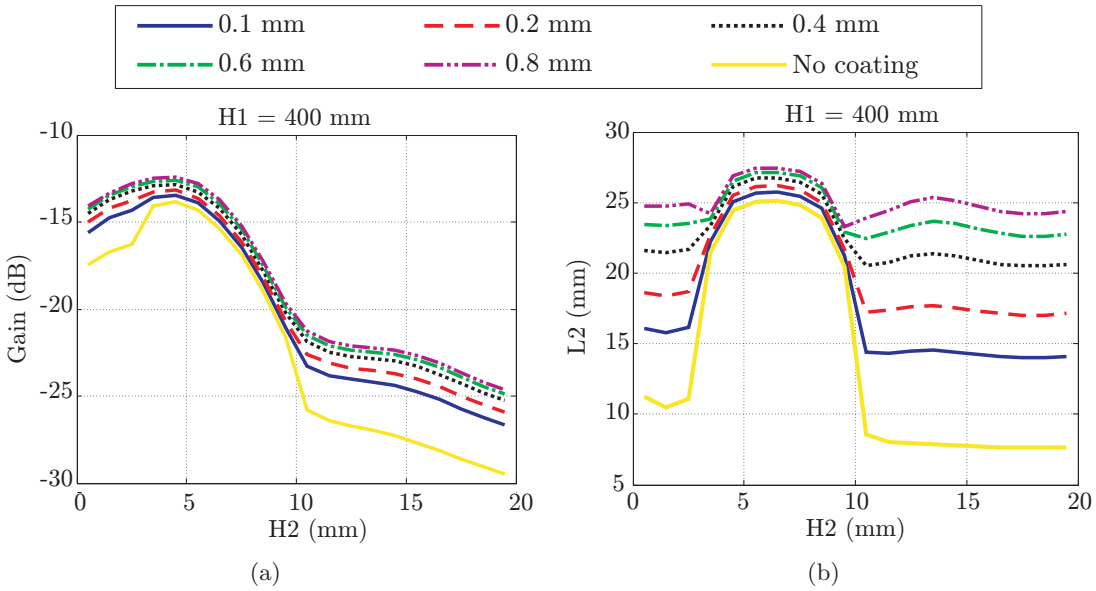

Figure 4.17: *Effects of a coating layer on the antenna performance. Operating frequency f = 2450 MHz. (a) Implanted antenna gain. (b) Implanted dipole length to keep the antenna resonant at the desired frequency.*

especially if the antenna is in the muscle or skin layers where gain improvement of around 5 dB can be obtained with coating layers thinner than 1 mm. When the antenna is in the fat layer, the gain improvement is not so significant because losses are not so great in this layer.

From the point of view of the implanted dipole length, the use of a coating layer has a positive and a negative aspect. The positive one is that the antenna becomes less sensitive to the surrounding material as the coating layer thickness increases, and therefore, the antenna detuning in the different tissues will be less significant. The negative aspect is that when the coating layer is applied the effective permittivity decreases and consequently the miniaturization obtained by the high relative permittivity of body tissues is less important. Variations in the dipole length higher than a factor of 2 can be observed depending on the coating layer thickness (figure 4.17(b)).

4.4 In-body antenna measurements with body tissue simulating liquids

All the previous results are based on FEKO [70] simulations using infinite dielectrics to model body effects, but FEKO results have not been validated with measurements. In this section some antenna measurements with an antenna immersed in various liquids will

be shown in order to demonstrate the validity of FEKO simulations when the antenna is inside a dielectric material.

Measurements were carried out around the 2.45 GHz ISM band using a homogeneous liquid inside a rectangular receptacle, and hence they are equivalent to the one layer model used in the previous section. The antenna was measured immersed in two different liquids to show the simulations validity regardless of the conductivity and permittivity values of the liquid. First of all, measurements were made with distilled water ($\epsilon_r = 80$, $tan\delta = 0.1188$ at 2.45 GHz [174–176]), and then with the SPEAG body tissue simulating liquid MSL 2450 [166] ($\epsilon_r = 52.7$, $\sigma = 1.95$ S/m at 2.45 GHz). The MSL 2450 liquid conductivity and permittivity at 2.45 GHz are similar to human body dielectric properties.

The objective of this section is to show the validity of FEKO simulations when the antenna is inside a liquid (phantom), and not the design of the radiating element. Therefore a simple patch antenna with a superstrate was used in order to minimize the problems related to the measurement setup. In a patch antenna a differential feeding system is not necessary, avoiding the need for a balun and the possible problems related to unbalanced currents. Furthermore, the patch ground plane minimizes the undesired effects of the coaxial cable.

It is true that the study presented in section 4.3 was based on a dipole configuration and in this section a patch antenna is used to prove the FEKO simulations validity. However, if FEKO correctly models the body effects on a patch antenna, it is expected that it will also correctly model the same effects on a dipole. Moreover, it is important to point out that both kinds of antenna could be used in implantable devices. Patch configurations are useful for pacemakers, meanwhile a dipole antenna could be more suitable for a glucose sensor.

The microstrip patch was made on a Taconic TFR-45 [177] substrate ($\epsilon_r = 4.5$, $tan\delta = 0.0035$), and a superstrate of the same material was used to insulate the antenna from the liquid and improve its performance (figure 4.18). The patch and the ground plane dimensions were 28 mm x 35 mm and 80 mm x 80 mm respectively. The feeding point was at the edge of the patch to improve the matching levels when the antenna is immersed in liquid.

Figure 4.19 shows the measurement setup. The antenna under test was inside a rectangular plastic container filled with liquid. A circular plastic box with holes was used to hold the antenna at a fixed height. The antenna was fed using a SMA cable with a silicone gasket to avoid liquid leakages through the hole created to insert the cable into the container. One of the main advantages of this setup is that the antenna depth can be

Figure 4.19: *Measurement setup. The antenna under test was immersed in liquid. The depth can be easily changed by adjusting the liquid level. A ruler was used to measure the antenna depth.*

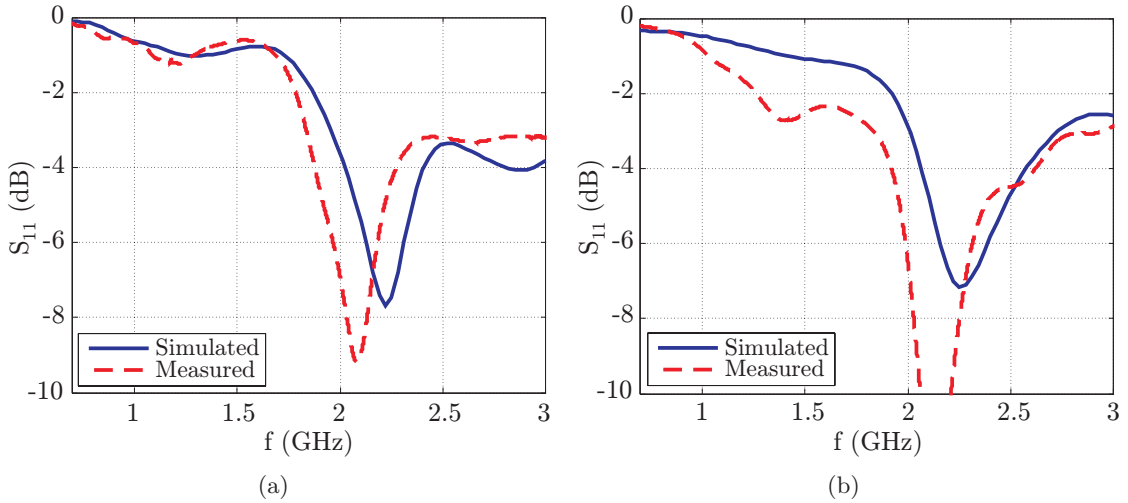

Figure 4.20: *Input reflection coefficient of a microstrip patch with superstrate (figure 4.18(b)) when the antenna depth is 8 mm. The measurement setup is shown in figure 4.19. (a) Antenna in distilled water. (b) Antenna in the SPEAG body tissue simulating liquid MSL 2450 [166].*

easily changed by adjusting the liquid level.

The input reflection coefficient of the microstrip patch was measured with the antenna immersed in distilled water (figure 4.20(a)) and in the SPEAG MSL 2450 liquid [166] (figure 4.20(b)). In both scenarios the input reflection coefficient is better than -6 dB, and good agreement between measurements and simulations is achieved demonstrating that the antenna input parameters predicted by FEKO when the antenna is immersed in a liquid are correct. Only a systematic frequency shift of less than 5 % is observed. This is mainly due to simulation inaccuracies and tolerances in the fabrication process and in the liquids permittivity and conductivity values. Furthermore, simulations do not take into account the frequency dependence of the liquids parameters.

Figure 4.20 demonstrates the validity of FEKO predictions of the input parameters. However in implantable antennas the most limiting parameter is usually the antenna gain. For this reason, measurements to prove the validity of FEKO predictions of this parameter were carried out. The antenna gain was obtained using the measurement setup shown in figure 4.21. The measured and simulated gain plots can be seen in figure 4.22.

The antenna depth was changed from 1 mm to 20 mm. Good agreement between simulations and measurements is achieved with both liquids. The general trend is that when the depth is increased, the gain is reduced because the electromagnetic waves have to propagate a higher distance through the lossy media. The gain in the MSL liquid is lower than in distilled water. This was expected because the MSL liquid conductivity is higher

Figure 4.21: *Measurement setup used to carry out propagation measurements. The receiving antenna was a microstrip patch with superstrate designed to operate in the desired frequency band (2.45 GHz ISM band) in free space. The distance between both antennas was 1.25 m. The "implanted" antenna depth was modified by changing the liquid level.*

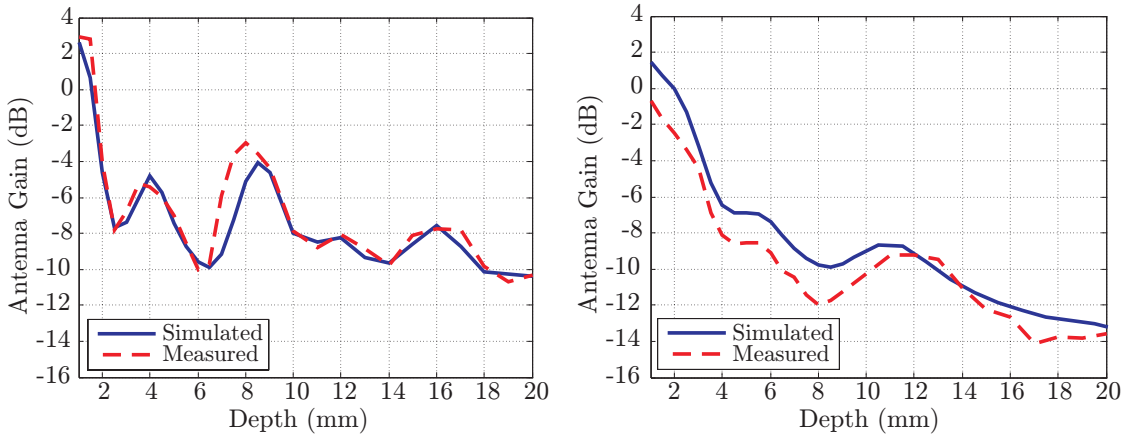

Figure 4.22: *Antenna gain in the normal direction of the microstrip patch with superstrate (figure 4.18(b)) as a function of the depth. The measurement frequency is near the 2.45 GHz ISM band. (a) Antenna in distilled water. (b) Antenna in the SPEAG body tissue simulating liquid MSL 2450 [166].*

than the water conductivity. Even with the MSL liquid, acceptable measured gain values near -10 dB are obtained. This is mainly due to the superstrate effects that significantly improve the antenna gain.

In this section we have compared the simulated and measured S_{11} parameter and gain when the antenna is immersed in two different liquids. Generally good agreement between simulations and measurements is achieved, demonstrating the validity of the FEKO simulation models used in section 4.3, and therefore, the validity of the propagation losses study.

4.5 Chapter conclusions

In some applications sensors are near or inside the body. The human body is a complex dielectric structure with high permittivity and conductivity values that significantly affects the antenna performance. In this chapter, these effects have been studied.

There are several regulations and guidelines that define the maximum allowed power levels for this kind of applications. In the few gigahertz frequency range, these maximum power levels are usually given as SAR limitations, 2 W/kg being the maximum peak SAR value permitted for the general public. There is a specific frequency band for implantable devices, the $402 - 405$ MHz MICS band with a maximum EIRP $= 25$ μw, however recent works use higher frequencies in order to reduce antenna dimensions.

The simulation of implantable antennas is complex because the body effects must be taken into account. In simulations the body effects are modeled using numerical models with properties similar to the human body called phantoms. Generally, the more detailed the simulation model, the more accurate the results but the higher the computational requirements. Furthermore, it is true that an inhomogeneous model can be necessary for implantable devices, but when the antenna is outside the body, a homogenous model is usually enough to obtain good results. In measurements, special liquids with electrical properties similar to the body tissues known as body tissue simulating liquids are used. These measurements are equivalent to the homogeneous simulation models.

A study to quantify the losses when an antenna is implanted inside the body has been presented in section 4.3. Simulations show that losses increase with frequency and antenna depth. Moreover, depending on the layer where the antenna is implanted its performance can be quite different. When the antenna is in the fat layer, its gain is better than when it is in the muscle or skin layers (with differences near 10 dB) but its length has to be longer to keep the same resonance frequency. The one layer model does not take into account these variations in antenna performance. This is the main limitation of the one layer model and of the measurements made using body tissue simulating liquids.

The effects of an insulation layer, necessary for biocompatibility issues, have been also analyzed. The presence of the coating layer is advantageous because it improves the antenna gain and the antenna becomes less sensitive to the surrounding materials properties. When the antenna is in the muscle or skin layers, gain improvements around 5 dB have been obtained with coating layers thinner than 1 mm. The negative aspect is that the antenna has to be larger because the miniaturization obtained by the high permittivity of body tissues is less important.

Finally some measurements of an antenna immersed in different liquids have been shown. FEKO simulations and measurements agree well, demonstrating the validity of FEKO predictions, and hence, the validity of the propagation losses study.

Chapter 5

Conclusions and future work

5.1 Conclusions

This thesis has been focused on the design of antennas for a distributed sensor network made up of remote sensors connected to a central unit with a wireless link. The central unit collects the sensors information and sends the data to the Internet with a WLAN connection that uses the 2.45 GHz and 5 GHz frequency bands defined by the 802.11 standards. The wireless link between the sensors and the central unit uses the 5.8 GHz ISM band, although it is also possible to use the 2.45 GHz ISM band to reduce propagation losses.

The sensor antenna and the central unit antenna are quite different. In the central unit a multiband antenna is necessary to give service to the 802.11 and the ISM bands with a single radiating element. Multiband functionality is not necessary in the sensors, but antenna dimensions are critical. The design objectives of both antennas are completely different, so for this reason they have been analyzed separately in two chapters.

Chapter 2 shows several multiband monopole configurations suitable for the central unit antenna. The designs presented in this chapter are based on two different concepts:

- Fractal geometries.
- Structures loaded with resonators.

Some fractal shapes, like the Sierpinski gasket, have been used in multiband antenna designs due to their self similarity property at different scale levels. Fractal shapes have been typically applied to the monopole element, but the results of this thesis show that

similar geometries can also be used in the ground plane to improve antenna performance. A fractal-based ground plane can reinforce the monopole resonances improving the existing bands, or even creating new operating bands. Two antenna designs have been presented, one where a triangular monopole is mounted on a fractal ground plane inspired by the Sierpinski gasket and one where a similar ground is used with a Sierpinski monopole. Both antennas fulfill the needs of the sensor network central unit, with good matching levels and similar radiation patterns in the different bands, therefore both solutions could be applied. Nevertheless, the design that uses the fractal shape in both elements is more flexible and it offers higher bandwidth in the lower band.

The second option is the use of resonator loaded structures. The multiband behavior of a monopole antenna can be improved loading the antenna with resonators. Furthermore, with the off-resonance loading principle the high losses of the resonators at their resonances can be avoided, introducing new bands without significantly degrading the in-band radiation efficiency. Based on these ideas several antenna designs have been presented.

The first is a dual band antenna based on capacitively loaded open loop resonators that covers the 2.45 GHz and 5 GHz bands of the 802.11 standard and the 5.8 GHz ISM band. The antenna operating principles have been analyzed, showing that the position of the bands can be easily controlled by adjusting the monopole and resonators dimensions. Next, two new designs that increase the number of operating bands have been shown. The first makes use of the SRR dual band behavior to achieve triple band performance. The second is an asymmetric structure that combines the resonances of two different resonators to obtain triple band performance. The third operating band available in these antennas could be used to improve the sensor network performance adding a WiMAX connection useful when the central unit is far from a WLAN access point.

All the solutions presented in chapter 2 are suitable for the central unit. If we have access to the ground plane design, the fractal-based solutions can be used, while if we do not have access to the ground plane design, then the solutions based on resonator loaded structures should be used. Moreover, both techniques could be combined to further improve the multiband performance using loaded monopoles on fractal-based ground planes.

Chapter 3 is focused on the remote sensors antenna design. A good option to obtain small and cheap sensors is the integration of the antenna and the electronic circuits into the same chip, obtaining a system-on-chip solution. To minimize costs, the antenna fabrication process must be compatible with the standard CMOS technologies. The main drawback is that the low resistivity silicon substrates typically used in CMOS technologies degrade the antenna performance.

Small sensors are desirable; therefore, miniaturization must be applied to reduce antenna dimensions. This chapter shows the performance offered by several miniaturization techniques when they are applied to antennas fabricated on silicon. The main problem is that the losses associated with miniaturization are emphasized by the use of a low resistivity substrate. For instance, the antenna gain decreases in 2.5 dB when the number of meanders is increased from 2 to 13.

Micromachining techniques are a good solution to reduce the silicon losses and improve antenna efficiency. The best option would be to eliminate all the silicon under the antenna, but the resulting membrane structure is fragile and can be easily broken. In this thesis it has been shown that the etching of an array of small cavities results in a good gain improvement without compromising the structure robustness. Measurements show that not only the total amount of etched silicon is important, but the way how this silicon is eliminated is also relevant. The best etching patterns are the ones that eliminate more silicon near the feeding point and create horizontal trenches. With an etching depth of 450 μm, gain improvements up to 4 dB have been measured.

The antenna will be fabricated in a chip together with other electronic circuits that can degrade the RF link performance. This degradation has been analyzed with a particular example: the degradation introduced by a coil necessary for an inductive energy coupling. This is one of the worse cases because coil dimensions are similar to the antenna. Measurements show that the gain degradation depends on the separation between both elements. When this separation is reduced to obtain smaller chips, the RF link degradation is greater, with measured degradations of near 7 dB when the separation between both elements is 320 μm.

Some sensors can be implanted inside the human body. The analysis of this scenario is complex due to the presence of the body tissues. In simulations, complex numerical models have to be used to take into account the body effects. In measurements phantoms filled with body tissue simulating liquids are needed to emulate the real operating scenario of the antenna.

Chapter 4 studies the body effects when the radiating element is implanted. The main effects of having the antenna inside the body are a reduction of the antenna dimensions and a degradation of the antenna gain due to the human tissues high permittivity and conductivity values. The body effects in different ISM bands have been analyzed, showing that there exists a trade-off between antenna dimensions and system performance. When frequency is increased, antennas are smaller but the gain is lower, with differences near 20 dB when the antenna depth is 10 mm. Simulations also show that the antenna behavior

can change depending on the tissue layer where it is implanted. If it is in the fat layer, antenna gain is better, but it has to be larger to keep the same resonance frequency.

The main limitations of the one layer model have been analyzed. From the point of view of propagation losses the one layer model can be accepted as a conservative approach because it tends to overestimate the losses. However this model does not take into account the antenna detuning when it is moved from one tissue layer to another. Therefore, if the antenna design is carried out with the one layer model and finally it is implanted near or inside the fat layer, detuning problems can appear. For this reason multilayer models are recommended for the design of implantable antennas.

The effects of an insulation layer, necessary for biocompatibility issues, have also been analyzed. The insulation layer improves the antenna gain and antenna dimensions are less sensitive to the layer where it is implanted. The main drawback is that the antenna is larger. The propagation losses study of this chapter is based on simulated results, however the validity of FEKO simulations has been demonstrated with measurements of a patch antenna immersed in a body tissue simulating liquid.

Finally, it is important to point out that the results of this thesis have permitted the author to publish 5 journal papers and 7 conference papers (1 best paper award).

5.2 Future work

In this thesis the design of multiband antennas and silicon integrated antennas for a sensor network have been analyzed. The thesis is finished, but research never ends. For this reason, a list of topics that could be studied in future is given here:

- Use of other fractal shapes with self-similarity properties for the design of multiband antennas.
- Use of the resonator loading techniques with other kinds of antenna, like monopoles with small ground planes or PIFA antennas.
- Combine the use of fractal shapes with resonator loaded structures to improve multiband behavior.
- Study of multiband antennas performance degradation when they are in the vicinity of human tissues.
- Use of other fabrication processes (not necessarily compatible with standard CMOS

technologies) to improve antenna performance. It is important to evaluate the trade-off between performance and costs.

- Implementation of a measurement setup to carry out measurements of silicon integrated antennas outside the probe station.
- Use of an external antenna coupled to the chip (e.g. with an inductive coupling) to improve the radiation parameters without the need for physical connections between the chip and the external antenna.
- Study of silicon integrated antennas performance degradation when they are implanted inside the human body.
- Design of implantable antennas optimized for the 2.45 GHz and 5.8 GHz ISM bands.

The rise of optogenetics provides unique opportunities to advance materials and biomedical engineering, as well as fundamental understanding in neuroscience. This protocol describes the fabrication of optoelectronic devices for studying intact neural systems. Unlike optogenetic approaches that rely on rigid fiber optics tethered to external light sources, these novel devices carry wirelessly powered microscale, inorganic light-emitting diodes (μ-ILEDs) and multimodal sensors inside the brain. We describe the technical procedures for construction of these devices, their corresponding radiofrequency power scavengers and their implementation *in vivo* for experimental application. In total, the timeline of the procedure, including device fabrication, implantation and preparation to begin *in vivo* experimentation, can be completed in ~3–8 weeks. Implementation of these devices allows for chronic (tested for up to 6 months) wireless optogenetic manipulation of neural circuitry in animals navigating complex natural or home-cage environments, interacting socially, and experiencing other freely moving behaviors.

INTRODUCTION

Optogenetics is a relatively new field of neuroscience that gives researchers the ability to control cellular signaling and neural activity in a cell type–selective manner. *In vivo* applications of optogenetics have rapidly aided in the understanding of neural circuit function in behavioral models[1–10]. Despite the success of these studies, tethered fiber-optic approaches have restricted opportunities for the study of more complex, ethologically relevant behavioral paradigms such as enclosed home-cage behavior, spontaneous pain, wheel running and freely moving social interactions. Here we present a protocol for the fabrication of flexible devices that carry wirelessly powered microscale μ-ILEDs and multimodal sensors to study neural circuitry in awake, freely moving animals. The devices described in this protocol are robust, self-contained, multifunctional and they are capable of wireless operation with conventional electronics and power supplies. These fully electronic systems eliminate the need for high-powered light sources, fiber coupling fixtures and optomechanical hardware for *in vivo* optogenetic experiments. The following protocol is based on technology and approaches developed jointly in our two laboratories[11–16].

Development of the protocol and comparison with traditional light sources

This protocol is the result of advances in material science that have led to the development of flexible electronics, biodissolvable adhesives, microscale sensors and high-efficiency μ-ILEDs[12–14,17,18]. Although other groups have successfully implemented wireless schemes and LEDs for optogenetics[19–22], the protocol described here provides a completely customizable approach for combining various materials engineering approaches to design and implement devices that can be optimized for an individual laboratory's experimental needs.

The current standard in neuroscience for light delivery into the depth of the brain is to use chronically implanted fiber optics[23]; this approach offers substantial advantages over acute delivery of fibers via metal cannulae[1,11]. These chronic implants, however, have their own limitations. Principally, light from fiber-optic implants can only escape from the tip of the implant to illuminate ventral brain structures. Although adaptations to this ventral light delivery are possible[10,24,25] (available commercially at http://www.doriclenses.com), the range of customizability can be limited and often restricts the user to only delivering light without the capability of observing physiology. Furthermore, μ-ILEDs create opportunities to restrict or expand spatial targeting by selecting from a range of sizes (625–10,000 μm^2), by altering the number and arrangement of μ-ILEDs, and by using reflective materials to direct light. This protocol provides a basis from which any combination of μ-ILEDs and sensors can direct light within the brain and measure physiological function without the restriction of enforced light trajectory.

Various strategies have been used for delivering multiple wavelengths of light into the same animal[24–26]. These approaches require establishing an extensive network of optics and tethered optical equipment external to the behaving animal. Depending on the laboratory behavioral space, such setups can restrict experimental possibilities, and they can require advanced experience

with optics to maintain optimal conditions. This protocol may require access to external facilities for some laboratories, but the end result is a device that can be operated with basic laboratory equipment that is already likely to be present in most neuroscience laboratories. Furthermore, the rescue and recycling of these devices for reuse is relatively easy, meaning that these devices can be used for several rounds of behavioral experimentation with different sets of animals. For light-evoked activation of channelrhodopsin-2 [ChR2 (H134)], optically sensitive seven-transmembrane domain receptors (i.e., OPTO-α_1, OPTO-β_2), and other blue light–sensitive optogenetic constructs, GaN μ-ILEDs are appropriate[2,11,27]. A device that uses these 450-nm-emitting μ-ILEDs is the focus of this protocol. However, it is important to note that μ-ILEDs emitting at other relevant wavelengths are also possible to fabricate for use in other contexts[11,28]. The combination of μ-ILEDs of different wavelengths provides the user with access to activation spectra of multiple optogenetic constructs with a single implanted, electronic device. Furthermore, the electronic nature of these devices ensures that they can be operated wirelessly. Wireless optogenetic manipulation of neural circuitry has been achieved by other means[20,21], but these approaches can restrict behaviors accessible to study because the animal is required to remain in a fixed environment. By using radiofrequency (RF) power scavenging, the devices and approaches contained in this protocol free the user of constraints on behavioral assays, thereby allowing for experimental testing in any space.

Applications of the protocol

Although the focus of this protocol is on the creation of devices engineered to deliver μ-ILEDs into the brain for optogenetic applications, this same protocol can be used to fabricate devices to measure electrophysiological, thermal and other properties of intact brain tissue (**Box 1**). The flexible nature of these devices provides the potential to extend their application into other intact tissues such as the peripheral nervous system and the circulatory system/cardiac tissue of larger organisms.

Experimental design

Subjects. This protocol and these devices have been optimized for use in adult (25–35 g) male C57BL/6J mice and mutant mice backcrossed to the C57BL/6J mouse strain. However, as the optogenetic toolbox expands to other mammals[29–34], these devices will probably have broader utility in other animal models. Specifically, larger organisms such as rats and nonhuman primates will tolerate the ~700-mg wireless antenna with greater ease than mice. Unlike animals with polished fiber-optic implants, animals with chronically implanted μ-ILEDs can be housed with other animals, as the metal pin connectors cannot be damaged by cage mates. Before beginning this protocol, all the procedures described herein should be approved by the Animal Care and Use Committee of the investigating institution and conform to US National Institutes of Health (or other relevant governmental guidelines) guidelines regarding animal research. For this protocol, all procedures were approved by the Animal Care and Use Committee of Washington University and conformed to US National Institutes of Health guidelines.

Controls. As noted elsewhere[2,11,23], the proper controls for *in vivo* optogenetics are mice that express genetically encoded fluorescent reporters in the absence of an opsin. These control mice will account for any disturbance from viral injection, device implantation, heating confounds from light delivery and fluorophore fluorescence within the brain. Another important confound to consider when conducting light-evoked single-unit electrophysiological experiments is the potential for generating neural activity downstream of retinal stimulation. These devices prevent the external light escape that is common with fiber-optic implants, but activity from the visual system has the potential to activate the retina and retinal ganglion cells from within the brain, depending on the brain region[35]. Recordings performed with external light stimuli can control for these effects. In addition, properly counter-balanced within-subject experimental designs are possible with these devices by withholding power to the devices during the behavioral testing period.

Limitations. Although these devices offer numerous advantages over traditional fiber-optic implants, the technology is not intended to replace protocols that work well to manipulate neural circuitry *in vivo*[1,23]. The greatest limitation associated with this procedure is the accessibility to the facilities and the technical skill required to fabricate these devices and their scavenging antennas. That being said, subsequent recovery and refabrication of the devices is straightforward and accessible to any laboratory. Once the protocol is followed, there are a few considerations when designing behavioral experiments. First, depending on the panel antenna used, the signal can be polarized. In current designs, both the panel antenna and the antenna on the scavenger are directional with linear polarization. A maximum efficiency of power transmission and reception is achieved when the polarizations of both antennas are aligned. The power transmitted by the panel antenna can typically be adjusted to accommodate mismatches that can occur in most practical situations. Such issues can be avoided entirely by the use of a transmission antenna with circular polarization or multiple-panel antennas. Care should also be taken to ensure that the animal's surroundings do not interfere with the RF signal by powering a free-standing device in the behavioral context[11]. Wireless control of these devices is compatible with a wide range of behavioral assays. In our hands, the devices have performed well in tests of anxiety-like behavior (open field test, elevated zero maze), reward-related behavior (conditioned place preference, operant behaviors and self-stimulation), social behaviors (social defeat stress and social aversion), pain behaviors (Hargreaves test) and home-cage behaviors[11]. In our experience, commonly used materials for behavioral apparatuses (wood, polyvinyl chloride, poly(methyl methacrylate) and the metal from cage lids) do not interfere with the RF signal, but they can reduce the overall power if they are positioned between the panel antenna and the headstage scavenger (see TROUBLESHOOTING).

The current protocol only provides wireless access to power the μ-ILEDs and not to receive information from the sensors. This backward data-stream restriction is largely based on the weight that an animal can endure on the headstage. For a mouse, electrophysiological sensors, temperature sensors and photosensors currently require a wired connection. For larger mammals, the devices can be integrated with existing telemetry setups (commercially available at http://www.plexon.com), provided that they do not interfere with the RF signal[36,37].

Box 1 | Combining multifunctional sensors and optoelectronics ● TIMING 1–4 d

One hallmark of these devices is their ability to both deliver light into the brain and to record information from the brain. Depending on the experiment, users may wish to outfit the devices with a variety of multiple and optional modalities. Each different modality can be combined with any other modality; devices can have between one and four different modalities incorporated. However, if the electrophysiological sensor is incorporated it should be the outermost layer to have direct exposure to the tissue.

1. The following steps provide information on adding functional layers (temperature sensors, option A, see also ; μ-IPDs, option B; and μ-electrodes for electrophysiological sensors, option C) to the devices. If these optional modalities are desired, **Box 1** should be completed before Step 16 of the PROCEDURE.

(A) Fabrication of temperature sensors

(i) Generate PR patterns on a needle-shaped piece of PET (same substrates used in Step 12) and deposit platinum (Pt, 10 nm) by sputtering. Remove PR by acetone and generate Cr/Au (15/300 nm) metal lines that connect to the Pt resistor.

(ii) Calibrate the temperature sensor. Dip the temperature sensor into DI water and measure reference resistance using a digital multimeter. With precisely controlled temperature of the DI water, measure the changes in resistance. As the resistance change (ΔR) of the Pt resistor depends linearly on the temperature change (ΔT), the formula for estimated temperature is $\Delta T \sim k \times \Delta R$, where k is constant.

(B) Fabrication of μ-IPDs

▲ CRITICAL (2nd layer shown in **Fig. 3**) Additional details of this method are shown in a previous publication[50].

(i) Deposit SiO_2 by PE-CVD on a silicon-on-insulator (SOI) wafer, with a top silicon layer thickness of ~1 μm.

(ii) Generate PR patterns to pattern the SiO_2 with HF.

(iii) Remove the PR and clean the wafer surface by RCA cleaning. First perform SC (standard cleaning)-1 with 1:1:5 solution of ammonium hydroxide (NH_4OH):hydrogen peroxide (H_2O_2):DI water at 80 °C for 15 min. Second, remove the SiO_2 layer using 1:50 solution of HF:DI water. Finally, perform SC-2 with a 1:1:6 solution of hydrochloric acid (HCl):H_2O_2:DI water at 80 °C for 15 min (RCA cleaning: http://inside.mines.edu/fs_home/cwolden/chen435/clean.htm).

(iv) Carry out solid-state doping of the silicon to form a p-type region.

(v) Repeat steps i–iv for n-type doping.

(vi) Generate PR hole patterns on the entire wafer surface and etch the silicon layer, to define the lateral dimensions of the photodetectors.

(vii) Etch the buried oxide (BOx) layer using HF.

(viii) Retrieve an ~1-μm-thick Si membrane photodiode using a PDMS slab and release it onto the needle-shaped PET substrate (described in Step12).

(ix) Form metal (Cr/Au, 15/300 nm) lines for interconnection.

(B) Fabrication of μ-electrode for electrophysiological sensor

(i) Generate PR (AZ 2030) lift-off patterns (1st layer shown in **Fig. 3**).

(ii) Deposit Pt (30 nm), a needle-shaped piece of PET (described in Step 12), by sputtering. Generate a pattern of SU-8 2 (2 μm thick) with a 20 × 20 μm^2 square opening.

▲ CRITICAL STEP An additional oxygen de-scum to the remove residual PR layer is recommended. The impedance of the Pt μ-electrode should be ~1.0 MΩ at 1 kHz.

© 2013 Nature America, Inc. All rights reserved.

Finally, independent control of individual μ-ILEDs is also possible with these devices, but this protocol has not been optimized for these conditions in a wireless control mode. If independent control is a desired feature, it is recommended that smaller connections featuring a number of channels be used over the pin connectors that we present here (many options are commercially available at http://www.omnetics.com).

Upon completion of the protocol presented here, users can expect to have devices with four μ-ILEDs that can be wirelessly powered with suitable light output from 2 m away. In our experience, more μ-ILEDs can be added to a single device with relative ease (the maximum we have tested is 25 (5 × 5) μ-ILEDs from a single power scavenger). Furthermore, the RF power-scavenging approach is appropriately suited for powering multiple μ-ILED devices (presumably in multiple animals) by using a different power-scavenging headstage antenna for each device. The upper limit on the number of simultaneously powered devices is primarily dependent on the spatial constraints of the experimental space and apparatus to achieve equal powering to all devices.

Notes on the materials and equipment used in this protocol. Accurate injection of these devices into brain tissue requires a stereotaxic adaptor for standard cannula holders. The basic principle of this adaptor is to allow the μ-needle to be mounted in line with the existing stereotaxic system. The dimensions of such an adaptor will vary by stereotaxic alignment system make and model, but most university machine shops should be able to fashion such an adaptor. The adaptor presented in this protocol was specifically designed for use with the KOPF single cannula holder (model 1966). It is also possible that other commercially available electrode holders may be capable of accurately targeting the devices (e.g., KOPF model 1768). More detailed information on the machining and dimensions of the adaptor for the KOPF model 1966 can be found in **Supplementary Figure 1**.

To deliver pulse trains of light, the devices can be controlled using a traditional function generator to drive amplitude modulation of the wireless powering equipment. Amplitude modulation is an internal function available on most RF generators. This function allows an internally or externally supplied modulating

signal to control the amplitude of the output RF signal. The internal modulating signal is usually a sinusoidal waveform with a much lower frequency compared with that of the RF output. For the positive region of the sinusoidal signal, the RF generator can output an RF signal whose amplitude is modulated by the low-frequency sinusoidal signal, and it can change from 0 to the maximum set power and then back to 0. For the negative region of the modulating signal, the output RF signal maintains at 0. An external transistor-transistor logic (TTL)-modulating signal is preferable in terms of modulating the amplitude of the output RF signal. Here, the high state of the TTL causes the RF generator to output a constant set power, whereas in the low state of the TTL the RF generator outputs 0 power. Thus, the TTL-modulating method is more suitable for generating constant light intensity during the high state of the TTL. The pulse width and frequency of photostimulation should be determined and based on physiologically relevant conditions[7,10,38–40].

Postmortem rescue of the devices for reuse is a delicate but straightforward process. The dental cement presented here (Lang Dental) allows for such rescue. Other cements and bonding agents can inhibit the process and destroy internal components. It may be necessary to use a stronger bonding agent in some scenarios (see TROUBLESHOOTING). In such cases, the reusability might be compromised.

MATERIALS

REAGENTS

Preparation of releasable polymer template

- UV-curable epoxy (SU-8 2 and 100 photoresist (PR); Microchem)
  ! CAUTION Partially cured or uncured epoxy needle can induce excess chemical contamination in the brain.
- SU-8 developer (Microchem)
- Isopropyl alcohol **! CAUTION** Isopropyl alcohol is flammable.
- Acetone **! CAUTION** Acetone is flammable.
- Silk adhesive (details are shown in other papers[13,17,18]; see Reagent Setup)
- Benzocyclobutene (BCB, DS-4022 35; Dow Corning)
- BCB developer (advanced developer, DS2100, Dow Corning)
- Water-soluble tape (3M)
- PRs (AZ 1518, AZ 2070; Capital Scientific)
- AZ 300 MIF developer (Capital Scientific)
- Hydrofluoric acid (HF) **! CAUTION** HF is extremely corrosive. Wear gloves and use eye protection when using HF.
- Chrome (Cr) etchant, gold (Au) etchant, palladium (Pd) etchant (Transene)
- Polydimethylsiloxane (PDMS; Sylgard 184, Dow Corning)
- Polyethylene terephthalate (PET; polyester film, 2.5 and 6 μm thick, Mylar film, Chemplex)

Preparation of μ-ILEDs

- Gallium nitride (GaN) LED epitaxial materials grown on sapphire substrates (Cermet)

Injection of virus and μ-ILEDs into targeted brain structure

- Isoflurane, USP (Isothesia, Butler Schein, cat. no. 029405) **! CAUTION** Before beginning this protocol, the Animal Care and Use Committee of the investigating institution should approve all procedures and conform to US National Institutes of Health (or other relevant governmental guidelines) guidelines regarding animal research **! CAUTION** Ensure that proper ventilation and gas scavenging methods are in place to prevent potential inhalation of excess isolflurane.
- Betadine solution (Purdue Products, cat. no. 67618015017)
- Ethanol (Sigma-Aldrich, cat. no. 362808) **! CAUTION** Ethanol is flammable.
- Hydrogen peroxide, 3% (wt/vol) USP (Select Medical Products, cat. no. 117)
- Lidocaine ointment USP, 5% (wt/vol) (Fougera)
- Ophthalmic ointment (Altalube Ophthalmic Product)
- Adhesive luting cement (C&B-Metabond, Parkell, cat. no. S380) **! CAUTION** Methyl methacrylate monomer, stabilized is a flammable liquid. It may also cause skin irritation; avoid contact with skin, eyes and clothing. Use it with adequate ventilation.
- Light cured bonding adhesive (VLC one-etep prime and bond adhesive, cat. no. 305-006-030) **! CAUTION** Methyl methacrylate monomer, stabilized is a flammable liquid. It may also cause skin irritation; avoid contact with skin, eyes and clothing. Use it with adequate ventilation.
- Dental cement (Jet denture repair, Lang Dental, cat. no. 1223, see Reagent Setup) **! CAUTION** Methyl methacrylate monomer, stabilized is a flammable liquid. It may also cause skin irritation; avoid contact with skin, eyes and clothing. Use it with adequate ventilation.
- Sodium chloride injection, 0.9% (wt/vol), USP, 9 mg ml^{-1} NaCl (Hospira, cat. no. RL-0497(9/04))
- Enrofloxacin (Baytril, Bayer, cat. no. R30901)
- Antibiotic ointment (Neosporin; Johnson & Johnson, cat. no. 174-73087Q)
- Viruses of interest (adeno-associated virus and lentiviruses are available from the Washington University of St. Louis Hope Center Viral Core, https://hopecenter.wustl.edu/?page_id=99 and/or the University of North Carolina Viral Vector Core, http://genetherapy.unc.edu/services.htm). Herpes simplex viruses are available from the Massachusetts Institute of Technology (MIT) Viral Core, http://mcgovern.mit.edu/technology/viral-core-facility)
  ! CAUTION Follow the appropriate safety precautions pertaining to the particular virus in use. It may be necessary to obtain a higher Biosafety Level certification before use.
- Artificial cerebral spinal fluid (ACSF; Tocris, cat. no. 3525 or custom, see Reagent Setup)[1,41]
- Animal(s) to be injected with the μ-ILED device. The procedure describes how to use a μ-ILED device with a mouse, as previously described[11]
  ! CAUTION Before beginning this protocol, the Animal Care and Use Committee of the investigating institution should approve all procedures and conform to US National Institutes of Health guidelines (or other relevant governmental guidelines) regarding animal research.

Behavioral procedures using RF power scavenging

- Thermal grease (Wakefield Solutions, cat. no. 120-2)

EQUIPMENT

Preparation for μ-ILEDs and multifunctional sensors

- Sputter (AJA international, ATC 200) metal deposition for Au (gold), Ni (nickel), Pt (platinum), etc.
- Rapid thermal annealing (RTA) **! CAUTION** High temperature, semi-transparent L-shaped current spreading layer on p-side on GaN LED should be used in thin metal layers (15/15 nm Ni/Au) followed by annealing at 500 °C.
- Mask aligner (Karl Suss, MJB)
- Inductively coupled plasma etcher (ICP; PlasmaTherm SLR-700, etching for GaN)
- Reactive ion etcher (RIE, PlasmaTherm 790, etching for SiNx)
- Plasma enhancement-chemical vapor deposition (PE-CVD; STS-mixed frequency nitride deposition system)
- Wafer bonder (Electronic Visions, EV501)
- Laser lift off (LLO; Krypton Fluoride (KrF), 0.9 J cm^{-2}, 248 nm wavelength (IPG Photonics (http://www.ipgphotonics.com/microprocessing.htm)) or Yttrium aluminum garnet (YAG):Nd laser (0.3 J cm^{-2}, 266 nm single pulse with 5 ns exposure, Sandia National Lab) **! CAUTION** Avoid eye contact with the laser; always wear eye protection.
- Digital multimeter (Fluke 115 or other commercially available multimeter)
- Printed circuit board (PCB) for headstage connection (General Circuits)
- Male pins for headstage PCB, 2.54-mm spacing male pins (Sunlight Inc., cat. no. P2540-H254-S180)

Measurement of μ-ILED

- Ocean Optics (Ocean Optics, HR4000; for measuring wavelength spectrum, light output power)
- Probe station (Agilent 4155; current-voltage (I-V) characteristics)
- Pulse generator (Global specialties, 4001)

© 2013 Nature America, Inc. All rights reserved.

- Oscilloscope (Agilent, DSOX2004A, 70 MHz)
- IR camera (QFI InfraScope II)

Injection of virus and μ-ILEDs into targeted brain structure

- Stereotaxic alignment system (KOPF model 1900) ! CAUTION Before beginning this protocol, the Animal Care and Use Committee of the investigating institution should approve all procedures and conform to US National Institutes of Health guidelines (or other relevant governmental guidelines) regarding animal research.
- Stereotaxic alignment indicator (KOPF model 1905)
- Centering microscope, 40× (KOPF 1915)
- Stereotaxic drill (KOPF model 1911) and no. 66 drill bit (KOPF, cat. no. 8669)
- Stereotaxic single cannula holder (KOPF model 1966)
- Stereotaxic adaptor for cannula holder (see **Supplementary Fig. 1**, made in your institutional machine shop or other)
- Anchoring screws (CMA Microdialysis, cat. no. 7431021)
- Needles (Becton-Dickinson, cat. no. 305111)
- Microinjection syringes (Hamilton, cat. no. 88011)
- Infusion pump and controller (UltraMicroPump III, World Precision Intstruments, cat. nos. UMP3 and UNC4)
- Forceps (Miltex, cat. no. 6-100)
- Surgical scissors (Miltex, cat. no. 18-1430)
- Hemostats (Miltex, cat. no. MH7-26)
- Microspatula (Chemglass, cat. no. CG-1982-12)
- Electric clippers (Wahl, cat. no. 8064-900)

Behavioral procedures using RF power scavenging

- RF generator (Agilent, N5181 MXF)
- Function generator with standard TTL (AMPI Master-9 or other)
- RF amplifier (Empower RF systems, 1100/BBM2E4AJP)
- RF antenna (ARC wireless solutions, ARC-PA0913B01, ARC 902–928 MHz, 12.5 dBi, flat panel)
- DC power supply (Mastech, cat. no. HY5005E-2)
- Relevant behavioral assay apparatus (university machine shop, MED Associates, Harvard Apparatus or other)
- Wireless headstage antenna (see PROCEDURE)
- PCB for wireless headstage antenna (General Circuits)
- Ceramic antenna (W3012; Pulse Electronics)
- Schottky diode (Digi-Key, cat. no. MMDL301T1G)
- Power meter (Bird Electronic, Thruline 43)
- Two SMA-male to N-male precision cables (Pasternack, cat. no. PE304-120)
- Fan-cooled heat sink (Fischer Elektronik, cat. no. LA 17/200 24V)

Behavioral procedures using a wired connection

- Animal(s) with injected μ-ILED device ! CAUTION Before beginning this protocol, the Animal Care and Use Committee of the investigating institution should approve all procedures and conform to US National Institutes of Health guidelines (or other relevant governmental guidelines) regarding animal research.
- Relevant behavioral assay apparatus (university machine shop, MED Associates, Harvard Apparatus or other)
- Function generator for standard TTL (AMPI Master-9 or other)
- BNC cables (Cables to Go, various lengths and cat. nos.)
- Electrical rotary joint (Moog, cat. no. SRA-73683 (ref. 42))
- BNC-to-banana plug adaptor (Fluke cat. no. BP881 or other)
- Wire, 30 gauge (Artistic Wire) and female connector (single modality devices: TE Connectivity, cat. no. AMP 3-640441-2; multimodal devices or independent μ-ILED control: TE Connectivity, cat. no. AMP 87631-4)

REAGENT SETUP

Silk adhesive Boil cocoons of the *Bombyx mori* silkworm for 30 min in a solution of 0.02 M Na_2CO_3 to remove the sericin protein. Rinse the extracted fibroin with dH_2O and dry it in ambient air for 12 h. After drying, dissolve the fibroin in a 9.3 M LiBr solution at 60 °C for 4 h, yielding a 20 wt% aqueous solution, and subsequently dialyze the solution against dH_2O by using a dialysis cassette at room temperature (20–25 °C) for 48 h until the solution reaches a concentration of 8 wt%. Silk adhesive can be stored at room temperature for up to 6 months.

Dental cement The dental cement can be prepared as described elsewhere[23] by combining the Jet denture repair powder with the Jet liquid (methyl methacrylate). A starting point is 350 l of methyl methacrylate monomer added to 225 mg of powder. In some cases, the viscosity must be adjusted (by increasing or decreasing the amount of methyl methacrylate in the mixture) to properly secure the flexible device in place and/or mount the PCB in the headcap. Dental cement can be stored at room temperature for up to a year. ▲ CRITICAL Adjusting the viscosity alters the working time of the cement.

Virus Each type of virus has different handling instructions, but all must be stored on ice until immediately before injection. In some cases, dilution of stock titers requires obtaining more of the reagent in which the viral preparation was initially concentrated.

ACSF If not purchased, the solution can be prepared according to recipes described elsewhere[1,41]. It can be stored as a stock solution at 4 °C for up to 1 month and at room temperature as a working solution for 1 d.

EQUIPMENT SETUP

Preparation of amplifier with proper heat sink The RF amplifier requires an additional cooling system during operation. Thermal grease applied on top of the heat sink facilitates thermal contact with the amplifier, which is affixed to the sink using screws. The DC power supply operates both the amplifier and the fan attached to the heat sink by supplying power with voltages of 24 V and 10 V, respectively.

PROCEDURE

Preparation of μ-ILEDs ● TIMING 7 d

1| Clean the wafer surface of GaN LED stacks (450-nm emission wavelength; p-type GaN/multi-quantum well (MQW)/spacer/n-type GaN/undoped GaN) grown on sapphire substrate with 5 wt% diluted HCl for 5 min.

▲ CRITICAL STEP Proper cleaning enables reduced turn-on voltages and improved efficiencies, both of which minimize the production of heat by the operating μ-ILEDs.

2| Deposit metals (Ni/Au, 15/15 nm) immediately after cleaning.

▲ CRITICAL STEP The deposition should be carried out at degree vacuum levels of ~10^{-6} torr or less.

3| Form L-shape patterned metals (Ni/Au) onto the p-type GaN semiconductor layer by photolithography and wet etching with Cr and Ni etchants; follow by removal of the PR with acetone (**Fig. 1a**).

4| Anneal the wafer for 10 min at 500 °C in 20% oxygen and 80% argon atmosphere to generate *p*-ohmic contact.

▲ CRITICAL STEP The annealed metal layers should be semitransparent after this step.

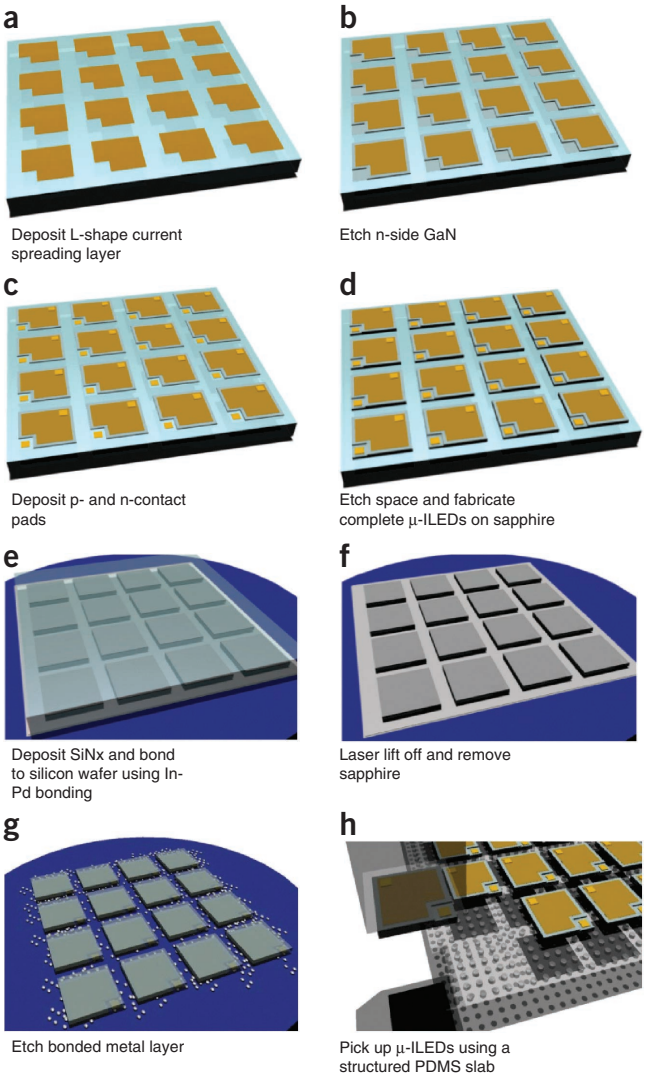

Figure 1 | Fabrication procedure for injectable μ-ILEDs. (**a**) An L-shaped current spreading layer (patterning of Ni/Au (15/15 nm) layers followed by 500 °C annealing) is formed on GaN blue lighting LED stacks grown on sapphire. (**b**) To expose n-type GaN semiconductors, etch rectangular shapes of p-type one, multi-quantum well (MQW) and spacer layers by reactive ion etching. (**c**) Generation of n- and p-contact pads (Cr/Au (15/300 nm) 25 × 25 μm^2 squares) on n-and p-type GaN sides. (**d**) Etch a 20-μm-width trench to define lateral dimensions of 100 × 100 m^2 or smaller. (**e**) Bonding μ-ILEDs on sapphire with a silicon wafer using an In-Pd metallic alloy bond. (**f**) Expose the laser on sapphire and mechanically remove the sapphire from μ-ILEDs. (**g**) Wet-etch the bonded metallic layer located on the wafer. (**h**) Transfer of all μ-ILEDs onto structured PDMS slabs and selectively pick up single μ-ILEDs by using a polydimethyl siloxane (PDMS) stamp. Panels **d**, **f**, **g** and **h** are reproduced from ref. 12 with permission from Wiley.

5| Generate 40 × 40 μm^2 square hole patterns in a negative-tone PR (AZ 2070 PR) and etch (chlorine gas–based RIE etching) the p-GaN layer, MQW, spacer to open n-side GaN (**Fig. 1b**).

6| Generate 25 × 25 μm^2 square hole patterns in PR for n- and p-type metal contact pads and deposit Cr/Au (10/300 nm) by using an electron beam evaporator. Then, remove PR (**Fig. 1c**).

7| Deposit a low-stress layer (200 nm) of SiNx on the substrate, by using PE-CVD. Next, pattern a negative-tone PR (AZ 2070) to serve as a mask for etching the SiNx and the GaN to define the lateral dimensions of the array of μ-ILEDs. Devices with dimensions of 100 × 100 μm^2 or less are formed with 20-μm spacings (**Fig. 1d**).

8| Deposit a layer of SiNx onto the μ-ILEDs to protect the devices and metal pads from further processes. Bond the LED wafer to a silicon substrate with an indium (In)-palladium (Pd) metallic alloy. This bonding uses Cr/Pd (15/150 nm) on the LED substrate and Cr/Pd/In (15/150/900 nm) on the silicon. The bonding occurs on contact with a pressure of 400 bar and a temperature of 220 °C for 2 h (**Fig. 1e**).

9| Use laser illumination through the sapphire to release the μ-ILEDs (**Fig. 1f**). Details of this LLO technique appear elsewhere[12,43].

10| Etch the unalloyed metal by immersion in 5 wt% HCl for 30 min (**Fig. 1g**).

11| Retrieve all μ-ILEDs onto the substrate of PDMS with patterns of surface relief, in the geometry of cylindrical pillars with 3 μm diameter and 1.4 μm height and 5 μm spacing. Remove residual metals, including In-Pd alloy and Cr, by Pd and Cr etchants (**Fig. 1h**).

12| Prepare a PDMS stamp with a single relief feature consisting of a post with 100 × 100 μm^2 lateral dimensions and 100 μm height. By using a mask aligner for photolithography, retrieve a single μ-ILED with the stamp and transfer it to a needle-shaped structure of PET adhered to a thin layer of PDMS on a transparent temporary substrate (**Fig. 2**).

13| Remove the passivation layer, SiNx (deposited in Step 8), with RIE and spin-coat a photosensitive BCB (6-μm-thick) onto the μ-ILED.

© 2013 Nature America, Inc. All rights reserved.

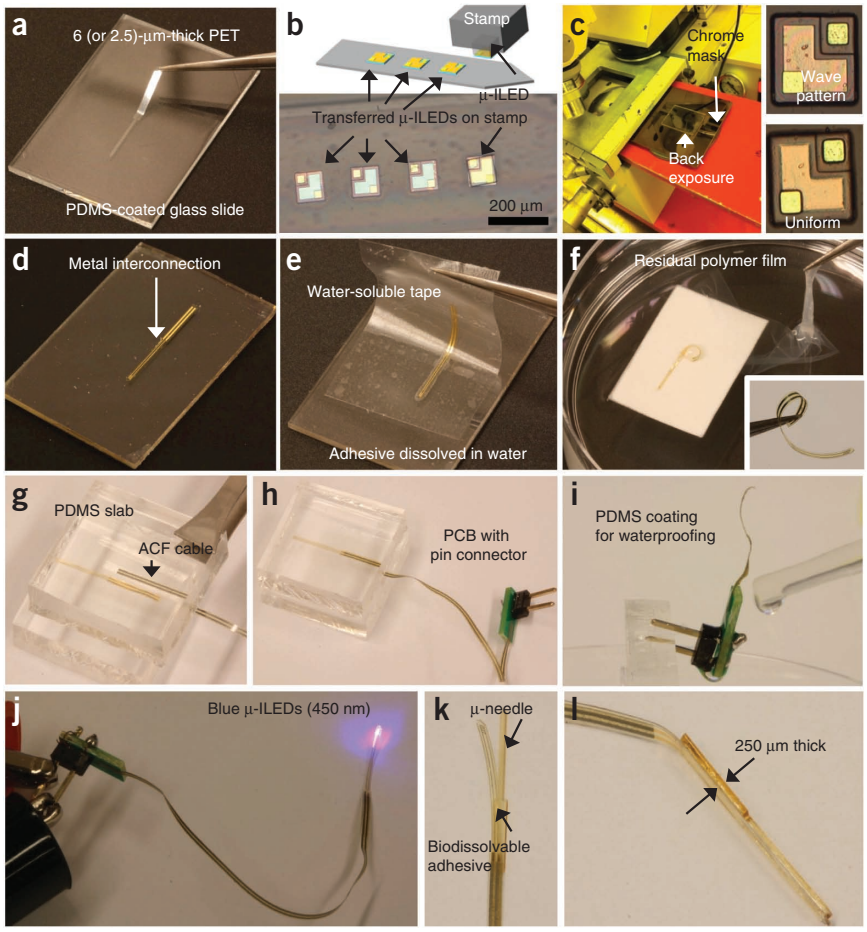

Figure 2 | Procedure for fabrication of injectable, multifunctional electronics. (**a**) Thin (~2.5-μm thick) needle-shaped PET is attached to a temporary PDMS-coated glass substrate. (**b**) Schematic and photograph demonstrating the transfer printing of four μ-ILEDs onto the tip of the PET using a PDMS stamp. (**c**) Passivation approach with photocurable BCB polymer. The back of the BCB-coated substrate is exposed to UV light. The wave pattern in the upper inset shows nonuniform coating of BCB. The lower inset shows successful uniform coating. (**d**) The metal interconnection (Cr/Au) is generated by sputtering, photolithography and metal etching to electrically connect the four μ-ILEDs. (**e**) The connected device is picked up with water-soluble tape. (**f**) The substrate is separated from the tape after the adhesive is dissolved in the water. The inset shows the μ-ILEDs on free-standing thin, flexible, needle-shaped PET. (**g**) The device is electrically connected to the ACF cable. The PDMS slabs on the top and bottom are compressed using high temperature (~150 °C) to bond the ACF cable. (**h**) The other side of the ACF cable is connected to the PCB with pin connector for wireless or wired powering schemes. (**i**) The ACF cable and PCB are coated with PDMS for waterproofing. (**j**) Blue (450 nm) μ-ILEDs are powered. The μ-ILEDs and electrical connection should be checked before injection. (**k**) The device is assembled with injection μ-needle using biodissolvable silk adhesive. (**l**) Image of a completed device ready for injection into brain tissue.

14| Pass UV light through the back of the substrate and develop the BCB with BCB developer (**Fig. 2c**) to obtain holes for n- and p-side contacts (**Fig. 2c**, lower inset). After further curing with BCB, anneal the samples at 250 °C on a hot plate for 3 h.

▲ **CRITICAL STEP** Make sure that BCB covers the μ-ILED surface when curing. Nonuniform coatings of BCB generate interference fringes that are readily visible (**Fig. 2c**, upper inset).

▲ **CRITICAL STEP** The annealing should be carried out in Ar atmosphere to avoid high-temperature damage to the BCB and polymeric layers.

? TROUBLESHOOTING

15| Deposit Cr/Au (15/300 nm) by sputtering, and form metal interconnects using positive-tone PR (AZ 15198), followed by metal etching (**Fig. 2d**).

Deterministic device assembly by transfer printing and formation of electrical interconnects ● TIMING 1 d

16| Remove μ-ILEDs fabricated on each temporary substrate, as shown in **Figure 2a**, with water-soluble tape (**Fig. 2e**). Remove the water-soluble tapes in deionized (DI) water (**Fig. 2f**) and place the devices on slabs of PDMS (**Fig. 2g**). If appropriate, follow instructions in **Box 1** to assemble a multifunctional device (**Fig. 3**).

▲ **CRITICAL STEP** Steps 16–20 describe the device assembly for μ-ILEDs alone. If you are assembling a multifunctional device, follow the instructions in **Box 1** before proceeding.

17| Connect each of the devices with anisotropic conductive film (ACF) cable to a PCB board (**Fig. 2h**).

▲ **CRITICAL STEP** Apply pressure and high temperature (~150 °C) during ACF cable bonding.

? TROUBLESHOOTING

18| Assemble all devices onto an injection μ-needle formed in SU-8 epoxy. The entire region of the injection device should be electrically insulated for *in vivo* use. Cover the flexible device with SU-8 polymer and the other parts with PDMS

© 2013 Nature America, Inc. All rights reserved.

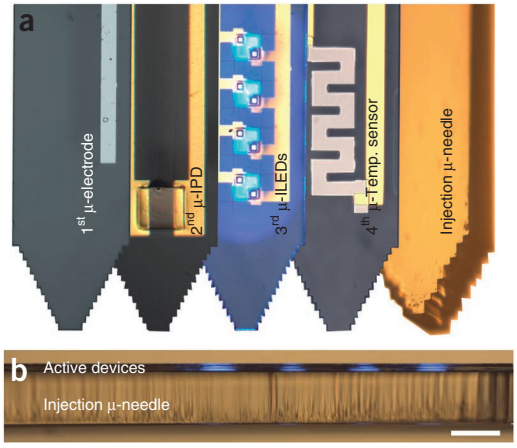

Figure 3 | Multifunctional sensors and optoelectronics. (**a**) Representative scheme for multifunctional, injectable electronics formed on an injectable needle. The devices include an electrophysiological sensor (μ-electrode; 1st layer), a silicon photodiode (μ-IPD; 2nd layer), four microscale μ-ILEDs (3rd layer), and a temperature sensor (μ-temperature (μ-temp.) sensor; 4th layer) based on a platinum resistor are formed on an injectable μ-needle fabricated from epoxy polymer. (**b**) Side view of such a device reveals the ultrathin nature of the active components of the device. Scale bar, 200 μm.

for waterproofing (**Fig. 2i**). Temporarily fix the device to the PDMS slab. Drop PDMS solution (Sylgard 180, Dow Corning, weight ratio = 10:1 (silicone elastomer precursor: curing agent), see http://www.dowcorning.com/applications/search/default.aspx?r=131en) onto the ACF cable and PCB, except for the pin connection area. After baking the PDMS in the oven at 70 °C for 2 h, the entire area except the pin adaptor is electrically passivated by PDMS.

19| To check functionality, power the device by connecting it to a power supply capable of delivering more than 1 mW (**Fig. 2j**). Use silk adhesive to bond the devices to the injection μ-needle (**Fig. 2k**,**l**).

Fabrication of wireless power harvester and preparation of wireless operation ● **TIMING 1 d**

20| Build either the robust, PCB-based (option A) or thin, flexible (option B) wireless power harvester.

▲ **CRITICAL STEP** Both options perform equally, but each has its advantages. The PCB-based option is more easily constructed and more durable, but it weighs more than the flexible version. We recommend using the PCB-based harvester for experiments that involve social interaction, whereas the flexible version is ideal for experiments involving only a single animal.

(A) Construction of the PCB-based wireless power harvester

(i) Build the wireless power harvester from two stacked PCB circuits (**Fig. 4**; general circuits). Each PCB includes top and bottom layers that are mostly covered by solid copper ground planes.

(ii) Mount the electrical components on the PCB boards through soldering. The first PCB circuit (labeled as 5 in **Fig. 4b**) contains a ceramic antenna operated at 915 MHz with a clearance space of 10.8 × 8.25 mm to the surrounding ground plane.

(iii) Connect a capacitor (8.2 pF in capacitance) between the feed line of the antenna and the ground plane to match the impedance of the antenna with the following circuit. A secondary PCB circuit (labeled as 6 in **Fig. 4b**) contains a voltage multiplier circuit constructed with six pairs of capacitors (47 nF in capacitance) and Schottky diodes (MMDL301T1G) in cascaded connection[11].

(iv) Mount the connector that is used for the μ-LEDs to the secondary PCB circuit. Join the PCB circuits and the connector with flexible copper wires (**Fig. 4c**), and then bond them together with resin epoxy (**Fig. 4d**). **Figure 4i** shows a schematic illustration of the power harvester. The circuit parts, which are labeled with numbers 5–7, correspond to the same numbers shown in **Figure 4b**,**e**.

(B) Construction of the thin, flexible wireless power harvester

(i) Fabricate the flexible PCB circuit on a 75-μm-thick Kapton film (**Fig. 4f**). Coat the film with a 6-μm-thick layer of copper by using electron beam evaporation.

(ii) Pattern the copper to form pads for the electrical components and interconnection. Spin-cast and pattern a 1-μm-thick polyimide film to expose the electrical contact pads, while passivating the interconnection (**Fig. 4f**).

(iii) Attach a ground plane made of copper tape (**Fig. 4g**) to the bottom of the Kapton film and connect it with the copper pattern on the top of the Kapton film through channels filled with solder. A schematic illustration of the flexible PCB circuit appears in **Figure 4j**.

21| Set up the wireless power transmission system. The system consists of an RF signal generator (N5181A, Agilent Technologies), an RF amplifier (1100/BBM2E4AJP, Empower RF Systems), a DC power supply (U8031A, Agilent Technologies), an antenna (ARC-PA0913B01, ARC Wireless) and a power meter (Thruline 43, Bird Electronic) (**Fig. 4a**). Connect the amplifier to the RF signal generator and an antenna by using coaxial cables (SMA-male to N-male precision cable with 160-series co-ax, Pasternack). The RF signal generator provides a 915-MHz RF signal with a power of −15 to −20 dBm. The signal is amplitude-modulated through the internal function of the generator to create a pulsed signal with a frequency of 10 Hz and

© 2013 Nature America, Inc. All rights reserved.

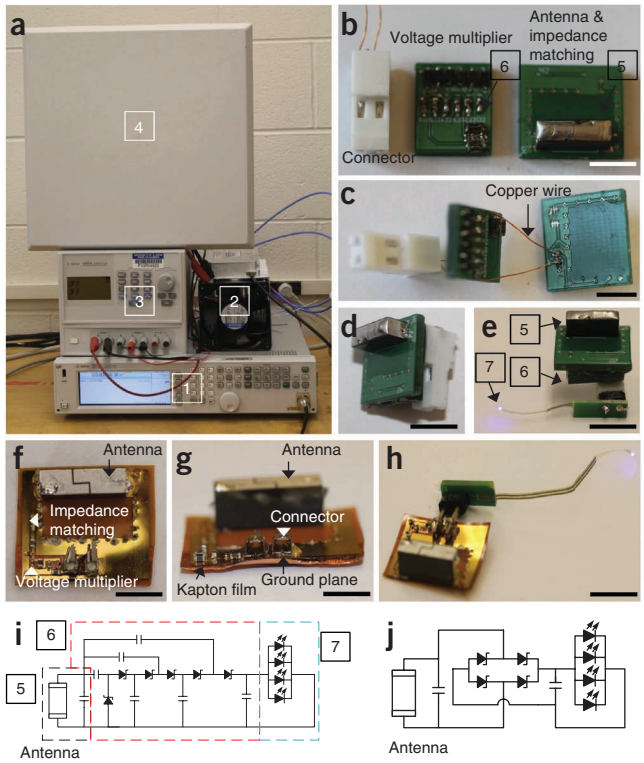

Figure 4 | Wireless operation and equipment. (**a**) An experimental setup for wireless power transmission. The setup contains an RF signal generator (1), an RF power amplifier (2), a DC power supply (3) and a panel antenna (4). Components for the wireless power harvester for μ-ILED powering with stacked PCB circuits (5: the circuit contains a ceramic antenna, and a capacitor is connected between the feed line of the antenna and the ground plane to match the impedance of the antenna with the next circuit. (**b**,**c**) A second circuit contains a voltage multiplier constructed with six pairs of capacitors and Schottky diodes in a cascaded connection(6)), before (**b**) and after (**c**) connecting with a copper wire. (**d**,**e**) A completed wireless power harvester alone (**d**) and with (**e**) connection to the μ-ILED device (7) for wireless operation. (**f**,**g**) Top (**f**) and side views (**g**) of a flexible wireless power harvester on Kapton film with similar components as the wireless harvester on PCB circuits. (**h**) A completed flexible wireless power harvester with connection to the μ-ILED device for wireless operation. Scale bars, 5 mm. (**i**) A schematic of the PCB-based power harvester. The numbered circuit components correspond to the same numbers shown in panels **b** and **e**. (**j**) A schematic of the wireless power harvester.

a carrier frequency of 915 MHz. Alternatively, an external TTL function generator can be connected to the RF signal generator to modulate the pulse width and frequency. This signal is directed to the RF amplifier, which amplifies the signal to 30–33 dBm.

22| Connect the power supply to the RF amplifier and the exhaust fan of the heat sink of the amplifier (see Equipment Setup) to provide DC voltages of 24 V and 10 V to the RF, respectively. Measure the intensity of the output power of the amplifier, and then connect the amplifier to the antenna to RF power to power the μ-LEDs at a 1~2 m distance (**Fig. 4e**,**h**).

Injection of the virus and μ-ILEDs into targeted brain structure ● TIMING 1 d, plus expression time

23| Mount the μ-ILED device in the custom-built cannula holder adaptor or another electrode or device holder (see Equipment Setup) (**Fig. 5a** and **Supplementary Fig. 1**). To do so, grasp the exposed region of the μ-needle (**Fig. 5b**).
▲ CRITICAL STEP The device must be placed along the midline of the adaptor to achieve proper spatial targeting.

24| Anesthetize the mouse in an isoflurane induction chamber using 4% (wt/vol) isoflurane and an oxygen flow rate of 1.5 liters per min.
! CAUTION Before beginning this protocol, all procedures should be approved by appropriate Animal Care and Use Committees, and they should conform to institutional and governmental regulations.
▲ CRITICAL STEP Ensure that the animal is sufficiently anesthetized before transferring it to the stereotaxic frame. The animal should have no response to a toe pinch, and its breathing rate should reduce to ~1 Hz.
? TROUBLESHOOTING

25| Transfer the animal to the stereotaxic frame, ensuring proper airflow of isoflurane to the nose cone (~2.5% (wt/vol) isoflurane; 1.5 liters per minute O_2).
▲ CRITICAL STEP Isoflurane levels should be monitored throughout the surgery to maintain sufficient anesthesia (no toe-pinch response) and breathing (1 Hz). For longer-duration surgery, isoflurane levels may be decreased to as low as 1% (wt/vol). Sterile, aseptic conditions should be used at all times to avoid infection.
▲ CRITICAL STEP Proper placement in the stereotaxic frame is required for accurate injection of virus and devices.
? TROUBLESHOOTING

26| Apply ophthalmic ointment to protect the animal's eyes during surgery.

27| Shave a 2 × 1 cm area on the animal's scalp (**Fig. 5c**).

28| Inject 0.1 ml of enrofloxacin into the hind limb (i.m.) and 0.3 ml of saline solution (0.9% (wt/vol), s.c.) to prevent infection and dehydration, respectively.

© 2013 Nature America, Inc. All rights reserved.

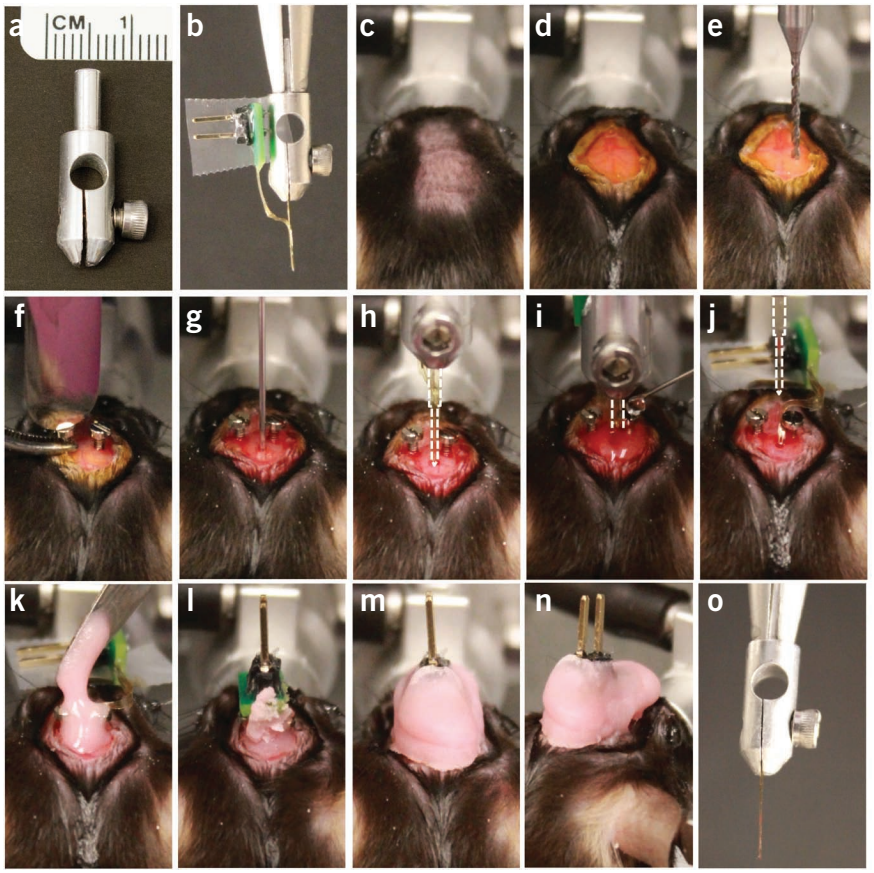

Figure 5 | Surgical procedure for injection of virus and μ-ILED devices into mouse brain. (**a**) Custom-built adapter for accurate stereotaxic placement of device (see Equipment Setup). (**b**) Mounted μ-ILED device, ready for injection into the animal. The exposed μ-needle is grasped with the adapter and a small piece of tape is used to secure the PCB during surgery. (**c**) A properly mounted mouse, with head shaved and eyes lubricated, is ready for surgery. (**d**) Betadine and ethanol are used to prevent infection and the scalp is open to expose the skull. (**e**) After leveling the skull, the drill is used to create pilot holes for the bone screws. (**f**) Forceps and a spatula or jewelry screwdriver are used to drive the screws into the skull. (**g**) The syringe needle is lowered to the desired coordinates to deliver the virus containing the optogenetic construct. (**h**) A μ-ILED device prepared to be driven into the brain using the same craniotomy as the viral injection. Dashed lines outline the shape of the device for clarity. (**i**) The μ-ILED device is lowered into the tissue and ACSF is applied to the skull surface to dissolve any external silk adhesive. (**j**) After a 15-min waiting period, the μ-needle is carefully retracted from the skull. (**k**) Dental cement is applied directly to the craniotomy site to secure the μ-ILED device in its targeted position. (**l**) The PCB connector is secured above the bone screws using a second layer of dental cement. (**m**,**n**) The PCB connector is completely encapsulated in dental cement, taking care to ensure that no bonds are made directly to the soft tissue. (**o**) The adapter is shown after surgery, containing only the μ-needle. All procedures were approved by the Animal Care and Use Committee of Washington University and conformed to US National Institutes of Health guidelines.

© 2013 Nature America, Inc. All rights reserved.

29| By using a cotton swab, apply 70% (vol/vol) ethanol and Betadine to the shaved area.

30| Carefully grasp the tissue with the forceps and use the scissors to make an incision the length of the shaved area of the animal's scalp (**Fig. 5d**).
▲ **CRITICAL STEP** Ensure that all surgical instruments are sterilized before each animal surgery.

31| After the skin separates, use the forceps and scissors to clean and remove any remaining periosteum on the skull surface.

32| Identify the skull sutures, lambda and bregma. Carefully level the skull according to the manufacturer's recommended steps for your stereotaxic frame. For the KOPF model 1900, use the stereotaxic alignment indicator. It is crucial that both lambda and bregma be level, and you must achieve a level plane laterally across the skull.
? TROUBLESHOOTING

33| Once the skull is level, move the drill to the coordinates you have selected for anchor screw placement. Carefully drill a hole with a diameter just wide enough for the screws to catch and not so deep as to penetrate the skull (**Fig. 5e**).
▲ **CRITICAL STEP** Proper anchoring is crucial to ensure that the headcap remains affixed to the skull for the duration of the behavioral experiments. Generally, anchor screws should be placed on either side of the midline within 2 mm of the site of implantation.
? TROUBLESHOOTING

34| Use the forceps and microspatula to properly anchor the screws into the skull (**Fig. 5f**).

35| Move the drill above the injection site. Drill a hole that penetrates the skull, but not the dura.
▲ **CRITICAL STEP** Drilling through the dura can cause widespread damage, bleeding and inflammation under the skull.

36| Align the infusion pump and lower the injection needle to the dorsal-ventral stereotaxic coordinates of the targeted structure of interest (**Fig. 5g**).
▲ **CRITICAL STEP** A beveled needle can penetrate the dura safely. If a blunt needle is used, the dura should be pierced using a sharp, sterile needle.
? TROUBLESHOOTING

37| By using the microcontroller, infuse the virus at a maximum rate of 100 nl min^{-1}. The volume of the virus will vary depending on the brain structure and serotype of virus used[1,2,4,44–47].
▲ **CRITICAL STEP** All viruses should be kept on ice before use, but special care should be taken with lentiviruses and herpes simplex viruses to prolonged exposure to temperatures above 4 °C.
? TROUBLESHOOTING

38| Once the infusion is complete, allow the injection needle to remain in place for 1 min for every 100 nl of virus infused. Slowly remove the needle from the injection site.

39| Position the cannula holder above the drill hole (**Fig. 5h**). Take care to orient the μ-ILED and other functionalities in the direction suitable for the experiment in order to properly illuminate the opsin-expressing brain region of interest.
▲ **CRITICAL STEP** For injection into rodents, rinse the device with ethanol to sterilize it before injection. For other mammals and primates, it might be necessary to use room-temperature ethylene oxide gas sterilization (http://www.anpro.com/sterilizers/anprolene/indexanprolene.html).
? TROUBLESHOOTING

40| Slowly lower the device into the brain to the desired dorsal-ventral coordinates.

41| By using a syringe needle, slowly apply ACSF to the skull to dissolve the silk-based adhesive. The brain tissue will dissolve the adhesive inside the skull. Wait for at least 10 min to allow for complete dissolution of the adhesive (**Fig. 5i**).
▲ **CRITICAL STEP** The adhesive must be completely dissolved before μ-needle removal. If not, the final placement of the flexible substrates will be affected.

42| Slowly remove the μ-needle. Monitor the position of the flexible substrates to ensure that zero movement occurs. If the adhesive is completely dissolved, the μ-needle will remove with ease and without movement (**Fig. 5j**).

43| Prepare the dental cement as described in Reagent Setup.

44| Use the microspatula to carefully apply a layer of dental cement directly to the point of injection to fully secure the placement of the device (**Fig. 5k**).
▲ **CRITICAL STEP** Allow this layer of cement to completely cure before building the structure of the remaining headcap.

45| Once the initial layer of cement is fully cured, position the PCB-based connector in the desired orientation. Apply a small amount of dental cement to secure it to the base layer (**Fig. 5l**).
▲ **CRITICAL STEP** The orientation of the connector will determine the orientation of the RF headstage antenna.

46| Finish the headstage by completely encapsulating the device-related hardware in dental cement. Be sure to leave the pins of the connector exposed to allow for connections to RF or wired functional generator (**Fig. 5m**,**n**).

47| Use a sterile spatula to detach any scalp skin from the cement. If the skin and the cement are connected, the headstage will be less stable over time.

48| Liberally apply (~1 g) the antibiotic ointment and lidocaine ointment to the entire incision area.

49| Remove the animal from the stereotaxic frame and place it in a clean home cage positioned on top of a heating pad for recovery. The animal should recover rapidly (<15 min), and it can be returned to its home cage once it displays normal,

© 2013 Nature America, Inc. All rights reserved.

Box 2 | Recycling the optoelectronic devices for reuse ● TIMING 2 d

1. After euthanizing the animal, use forceps to forcibly remove the headcap from the surface of the skull. Thoroughly remove any visible biological tissue or other build-up from the sides and bottom of the headcap. Take care not to damage the flexible aspect of the device. Once it has been removed and cleaned, the headcap is ready for dissolution (**Fig. 6a**).
2. Place the headcap into a glass beaker and add methyl methacrylate until the headcap is entirely submerged (**Fig. 6a**). Cover the beaker with tin foil and place in a properly ventilated fume hood overnight.

! CAUTION Methyl methacrylate monomer is a flammable liquid. It may also cause skin irritation; avoid contact with skin, eyes and clothing. Use it with adequate ventilation.

3. After overnight incubation, the dental cement should be completely dissolved. The device and bone screws should be clearly visible in the beaker (**Fig. 6c**). While you are wearing gloves and using forceps, remove these items from the beaker. The screws can be cleaned, sterilized and used for another surgery. The device will normally become inactive after dissolution of the headcap due to concurrent dissolution of the adhesive connecting the ACF cable to both the device and the PCB (**Fig. 6d**,**e**). Before proceeding to Step 4, use a multimeter to check that all μ-ILEDs still function properly (**Fig. 6f**). If any of the μ-ILEDs have electrical failure, discard the device and begin the fabrication process anew.

? TROUBLESHOOTING

4. Discard the original PCB and reassemble the device as described in Step 17 (**Fig. 2g**,**h**).
5. Apply PDMS to the entire device construction to provide passivation and waterproofing for operation *in vivo* as in Step 19 (**Fig. 2i**).
6. Attach the μ-needle using the silk adhesive and test the device to ensure proper electrical connection as done previously in Steps 18 and 20 of the PROCEDURE (**Figs. 2j–l** and **6g**,**h**). The device is now ready for injection into a fresh animal starting at Step 24 of the PROCEDURE.

awake locomotor behaviors. Because the only exposed portions of the devices are the metal connector pins, the animals can be group-housed for the duration of their experimental lifetime. However, if one chooses, the pins can be capped by using a dummy connector.

50| The μ-needle should be clear of any components of the device. Remove the adaptor from the cannula holder and sterilize it for reuse (**Fig. 5o**) as described in **Box 2** and **Figure 6**.

Preparation for behavioral testing ● TIMING ~5 d

51| House mice until the time at which proteins would be expected to be expressed. The choice of viral expression system will determine the expression time, and thus the wait time, before behavioral experimentation. This duration will vary from 1 to 6 weeks. For adeno-associated viral expression, typical wait times are 2–3 weeks for expression at cell bodies[1,2,9,11,44].

52| At least 5 d before experimentation, handle the mice to acclimate them to manipulation. In particular, connectors should be fitted to the headstage, and any areas of the body that will be injected should be gently touched in order to

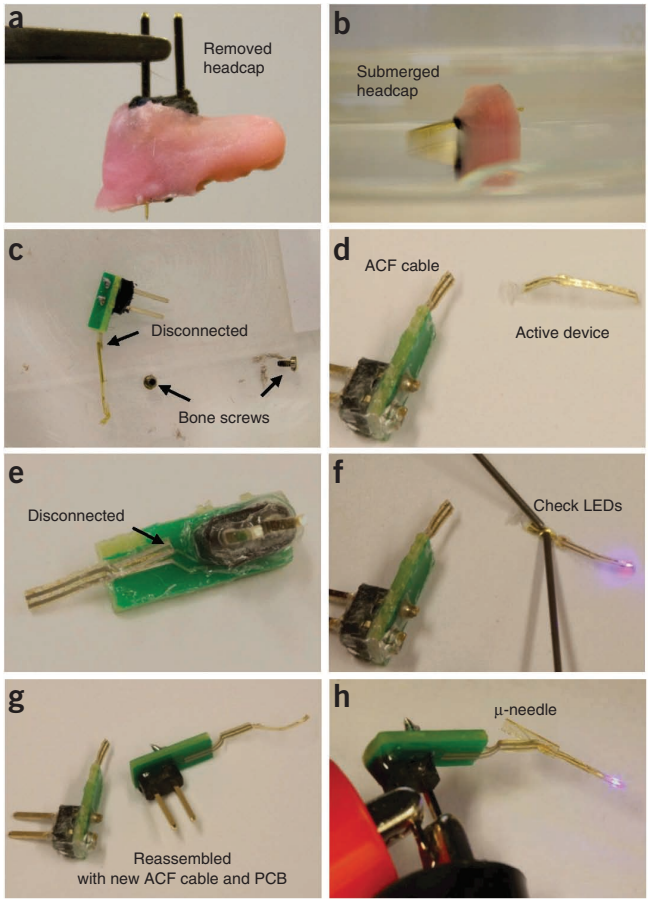

Figure 6 | μ-ILED device recycling and re-fabrication for subsequent use. (**a**) The same headcap from **Figure 5**, after being removed from the animal postmortem and cleaned of biological material. (**b**) The headcap should then be fully submerged in methyl methacrylate. (**c**) After overnight incubation in the stabilized methyl methacrylate monomer, the PCB, connector, μ-ILED device and bone screws will be freely available in the solution. (**d**,**e**) Both connections with the ACF cable will also dissolve, rendering the device inactive. (**f**) The device should be checked for reuse. If it is nonfunctional, the device should be discarded and a new device should be fabricated. (**g**) The working device is reassembled with new ACF cable and PCB. (**h**) The electrical connection through the new ACF cable should be checked after the device is attached to the injection μ-needle again.

© 2013 Nature America, Inc. All rights reserved.

habituate the animal to the manipulations that they will experience during behavioral testing (e.g., the nape of the neck for s.c., the abdomen for i.p., etc.).

53| Also habituate the animals to the method of powering the devices. If a wired approach is used, animals should be connected to the wires and allowed to explore a home-cage environment for at least 20 min once a day for 3 d. If a wireless approach is used, the RF headstage antenna should be connected in the home cage for the same duration.

▲ **CRITICAL STEP** To eliminate locomotor confounds, the animals must be habituated to carrying the added weight of the antennas.

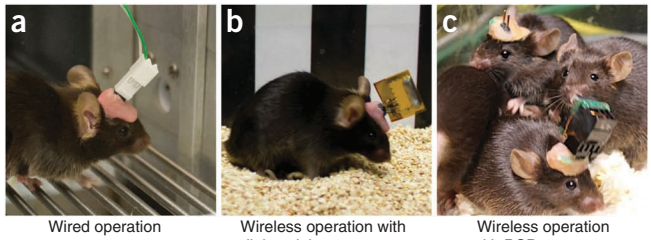

Figure 7 | Expected results after viral and device injection. Once a device is injected, the standard connection allows for temporary coupling multiple means of powering in a variety of behavioral assays. (**a**) A mouse connected for wired powering in a standard operant behavioral chamber. (**b**) The same mouse prepared for wireless powering with the lightweight, flexible power scavenger in a conditioned place preference environment. (**c**) Two mice with implanted devices among cage mates. The mouse in the foreground has a PCB-style RF scavenger for powering in a home-cage environment. All procedures were approved by the Animal Care and Use Committee of Washington University and conformed to US National Institutes of Health guidelines.

54| Perform wired (option A) or wireless (option B) behavioral tests.

▲ **CRITICAL STEP** The timing of the photostimulation will depend on the parameters and goals of the study, but the pulse-generation options are well suited for a wide variety of approaches. Any traditional function generator can either power the devices or provide TTL input into the RF signal generator to modulate the pulse width and frequency of the light pulses. If the photostimulation needs to be contingent on the animal's behavior, this can be achieved by using live video tracking connected to a TTL output (Noldus Ethovision 9.0 with trial and hardware control and I/O box or other) or triggering a TTL signal from IR beam breaks (Med Associates or other).

(A) Wired optogenetic behavioral control ● TIMING variable

(i) Once habituated to the connecting cables, power the devices by using a traditional function generator. The pulse width and frequency of photostimulation should be determined and based on physiologically relevant conditions[7,10,38–40]. The timing of the photostimulation will greatly depend on the parameters and goals of the study.

(ii) Connect the cable to the function generator by using the BNC-to–banana plug adaptor.

(iii) Route the cabling. For most wired behaviors, the best approach is to route the cabling through an electrical rotary joint as described previously[42].

(iv) Carefully scruff the mouse and connect the free end of the cable to the headstage of the animal. Place the animal in the behavioral apparatus (**Fig. 7a**) and perform the desired behavioral test.

(v) After the behavioral test, scruff the animal and remove the cable from the headstage.

(B) Wireless optogenetic behavioral control ● TIMING variable

(i) Connect the function generator to the RF signal generator, the RF signal generator to the RF power amplifier and the RF power amplifier to the panel antenna. Be sure that the power supply is connected to the heat sink (see Equipment Setup) to avoid damaging the amplifier. Connect the power supply to the RF amplifier. It is reasonable to assume that wireless operation of the devices would be compatible with any behavioral assay in which the behavioral apparatus itself does not interfere with the RF signal, but care should be taken to ensure proper powering of the devices in every behavioral apparatus used.

▲ **CRITICAL STEP** To avoid unnecessary powering of the devices, do not engage the power supply until the beginning of the behavioral session.

? TROUBLESHOOTING.

(ii) Carefully scruff the animal(s) and attach the RF scavenging antenna(s). Place the animal(s) in the behavioral apparatus and perform the behavioral test (**Fig. 7b**,**c**).

(iii) After the behavioral test, carefully scruff the animals and remove the scavenging antenna.

(iv) After the final behavioral session, if desired, kill the animals and use their tissue for any manner of post-mortem evaluation[11].

? TROUBLESHOOTING.

? TROUBLESHOOTING

Troubleshooting advice can be found in **Table 1**.

© 2013 Nature America, Inc. All rights reserved.

TABLE 1 | Troubleshooting table.

Step	Problem	Possible reason	Possible solution
14	Failure of the electrical device	Nonuniform coating of BCB passivation on μ-ILED	Spin-coat the BCB again and re-do the process
17, **Box 2** (step 3)	Failure of the ACF cable bonding	Insufficient temperature and/or pressure when bonding	Be certain to apply enough pressure (~1 or 2 MPa) and temperature (150 °C)
24	Device is damaged before or during mounting for surgery	The electrical components are grasped by the cannula holder adaptor	Only grasp the upper, exposed portion of the μ-needle. No portion of the electrical components should be grasped with the cannula holder adaptor. Be careful to apply appropriate pressure so as to avoid crushing the μ-needle
25, 32	Inaccurate tissue targeting	Improperly aligned skull	Follow the instructions provided for your laboratory's stereotaxic equipment for ear bar placement and skull leveling. Species-specific ear bars may be required. If the suture lines for identifying bregma/lambda on the skull are difficult to visualize, a surgical microscope and/or treating the skull with hydrogen peroxide can be a helpful addition. It may be necessary to wait longer after penetration before removal of the μ-needle
33, 36	Headcap falls off in the home cage or during behavior	Insufficient anchoring or cement application	Dental cement is ideal for reusablility, but other adhesives such as VLC one-step adhesive and C&B Metabond offer stronger bonds to the screws and skull surface. Although two screws are normally sufficient, larger PCB interfaces may require more anchor screws
37, 54B(iv)	Little or no expression of the viral construct	Improper handling and injection of the virus	Thaw virus as close in time to the surgery as possible. Keep the virus on ice until the time of injection. Depending on the promoter that drives expression, some systems will not provide sufficient opsin expression. This should be empirically determined before any attempted behavioral experiments
39	Dissolution of silk adhesive during sterilization	Too much exposure to ethanol	Most aqueous solutions will dissolve the silk adhesive. Do not soak the devices in ethanol, as this will promote dissolution of the adhesive. In our experience, rinsing the device with ethanol for ~15 s is sufficient to prevent widespread inflammation in mouse brain tissue[11]. Care should be taken to use appropriate sterilization techniques in higher mammals to avoid immune responses, such as ethylene oxide gas sterilization
54B(i)	Insufficient RF power is reaching the headstage scavenger	The behavioral apparatus is between the panel antenna and the scavenger (in an enclosure)	Connect a freestanding device to the scavenging headstage and place it in the behavioral enclosure. Using the gain on the RF signal generator adjust the RF power until sufficient power is available to power the μ-ILEDs to the desired light output. If problems powering the device persist, consider reducing the distance between the panel antenna and the scavenger
Box 2	Headcap does not fully dissolve	Insoluble dental cement was used, insufficient solvent was used, or there was limited duration of exposure to the solvent	Some dental cements will not dissolve in methyl methacrylate. Consider using the exact recommended cements where possible. If using Jet denture repair, add more solvent or wait longer for the cap to dissolve

● TIMING

Steps 1–22, preparation of μ-ILEDs, deterministic device assembly and fabrication of wireless power harvester: 9 d
Steps 23–50, viral and device injection: 1 d for procedure, 1–6 weeks for expression
Steps 51–54, behavioral experimentation: 5 d for preparation, variable depending on the experiment
Box 1, combining multifunctional sensors and optoelectronics: 1–4 d depending on modalities
Box 2, rescuing the optoelectronics for re-use: 2 d

ANTICIPATED RESULTS

After successful fabrication and implementation of μ-ILEDs, wireless manipulation of intact mammalian neural circuitry is possible. Although our group has demonstrated the feasibility of using these devices to investigate reward-related and anxiety-like behaviors[11], nearly any behavioral assay should be accessible with these devices. In particular, behaviors that require complete freedom of movement such as social interactions, wheel running and home-cage behaviors are now possible (**Fig. 7c**). Users can expect injected devices to function for many months, as we have tested devices up to 6 months after injection and observed that the devices retain their operational functionality[11]. Furthermore, we show here that these devices can be reused in other animals to avoid the lengthy process of remaking new devices for each experiment. Depending on the nature of the experiment, a single panel antenna can power numerous headstage devices. If the stimulation parameters are the same across animals, this approach can greatly increase the experimental throughput for a variety of behavioral assays. Although not presented in detail here, a reasonable extension of this protocol would be to incorporate other existing microscale sensors such as those for pH, blood oxygen, glucose levels or neurochemical detection onto μ-ILED devices[48,49]. In sum, the protocol described here should provide researchers with the ability to use optogenetics to wirelessly control and study intact mammalian neural circuitry in a minimally invasive manner.

13. ABSTRACT (maximum 200 words)

This thesis continues an NPS project related to wireless power transmission for micro air vehicles (MAVs). The conversion of radio-frequency (rf) power into usable direct-current (dc) power is performed by a rectifying antenna, or rectenna. The emphasis of this thesis is the simulation and experimental study of various rectenna designs to determine which best provides high efficiency, stable output power, and lightweight design.

The analysis of rectenna design focuses on four subsystems: (1) the receiving antenna, (2) the matching sections, (3) the rectification, and (4) the post-rectification filter. Based on the findings of this research, the ultimate rectenna design implements a half-wave dipole antenna that performs full-wave rectification with two diodes. The post-rectification filter is implemented by a capacitor to obtain stable dc power. The final design achieved an efficiency of nearly 66% for input power in the range of 200 mW.

ACKNOWLEDGMENTS

I would like to express sincere thanks to my thesis advisor, Professor David C. Jenn, for his patience and encouragement throughout these nine months. He always put aside his precious time to discuss thesis topics with me and gave me strength to keep working on this project. I could not have completed this thesis without the assistance of Professor Jenn.

I would also like to thank Assistant Professor Ric Romero, who was my second reader for this thesis.

I am grateful to the Chung-Shan Institute of Science and Technology for providing this opportunity to study at the Naval Postgraduate School.

Finally, I would like to thank my family for their encouragement and understanding. Their support enabled me to graduate from the Naval Postgraduate School.

THIS PAGE INTENTIONALLY LEFT BLANK

I. INTRODUCTION

A. Background

The concept of wireless power transmission (WPT) dates back to the days of Heinrich Hertz and Nikola Tesla [1], who discovered that energy could be transported by electromagnetic waves in free space. Tesla considered the use of wireless power transmission employing low-frequency transmission, sustained by the earth's natural electromagnetic resonance. His concept is important to later studies of electromagnetic-wave propagation. There has been intense interest in WPT recently for a number of applications. These include remote propulsion of vehicles [2], transmission of solar power from space [3] and wireless battery charging [4]. A related area is energy harvesting, where stray electromagnetic fields from the many systems in the environment are collected and used as a free energy source [5].

Micro-air-vehicle (MAV) propulsion is the main application of interest in this research. MAVs are a category of unmanned air vehicles (UAVs) being developed around the world. The definition of an MAV, according to the Defense Advanced Research Project Agency (DARPA), is a fully functional UAV no larger than 15 cm in length, width, and height [6]. The main reason for using wireless power transmission for military ground-surveillance applications is to achieve unlimited duration of flight without requiring onboard fuel supplies. One application that employs a MAV remotely powered by a small ground station is illustrated in Figure 1.

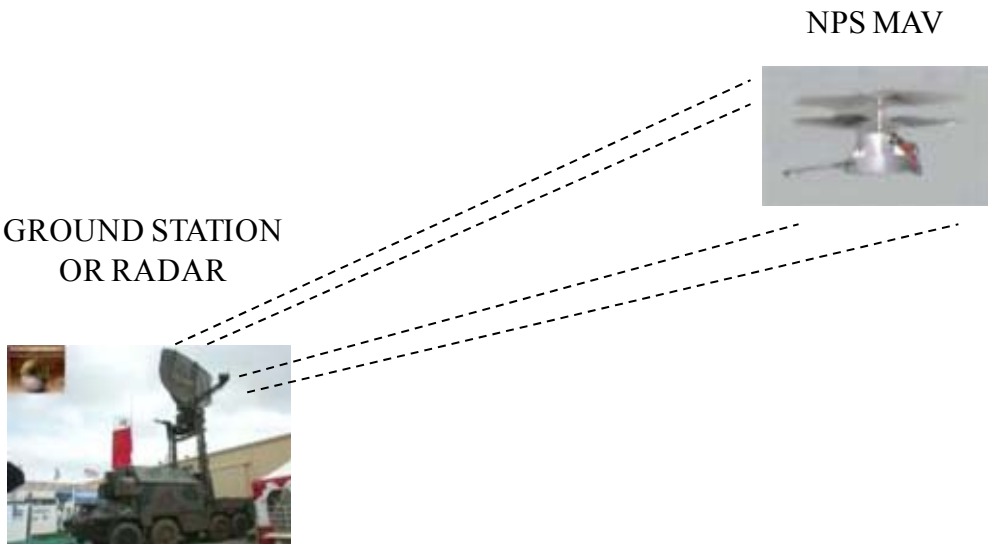

Figure 1. Conceptual powering of an MAV by a ground station (From [6]).

In this thesis, a rectifying antenna (rectenna) system based on studies performed by Tan [6] and Toh [7] was re-evaluated, simulated, and refined. This study also looks at a new antenna design and a full-wave rectifier concept. In order to verify and validate the design of the rectenna model, many tradeoffs were made. Different rectenna designs were investigated, and an improved design was implemented in hardware.

The measured efficiency of the previous NPS rectenna was 26% to 37% [7]. This research changes the circuit design to yield better overall performance. The recommended design changes are shown to yield higher efficiency and lighter weight. The claimed theoretical efficiency of the rectifier designed by Toh [7] was approximately 26-37%, which was insufficient to power a micro air vehicle designed by Tsolis [8].

B. OBJECTIVE

The purpose of this thesis is to verify and analyze the different designs of the rectenna system and make improvements. Since the primary application considered is UAV propulsion, an important requirement is to minimize the antenna and rectifier circuit's size and weight. A new dipole design is presented that is lightweight and compact. A full-wave rectifier circuit is proposed, which increases the output power over that of the half-wave rectifier design.

C. THESIS OUTLINE

This thesis is divided into six chapters. The next five are organized as follows:

Chapter II introduces the development of WPT from the early 1950s through today. References to various WPT studies and applications are also covered in this chapter. An overview of related thesis projects that were conducted at the Naval Postgraduate School is presented.

Chapter III focuses on three different rectenna designs, the components of a rectenna circuit, and evaluation of various circuit designs by using Advanced Design System (ADS) 2009 software from Agilent Technologies. Analysis of the dipole antenna dimensions, Schottky diode, and substrate material are covered in this chapter. Chapter III also discusses the effects of pre- and post-rectification filtering. The design of a rectenna with and without filters is documented, and a comparative study of the performance of the pre-, post-, and no-filter designs analyzed.

Chapter IV discusses the impedance of the rectenna and dipole-antenna array.

Chapter V summarizes the findings of this research and presents conclusions and recommendations for future research.

II. BACKGROUND

A. EARLY EXPERIMENTS WITH WPT

The concept of wireless power transmission (WPT) began in the 1900s. The objective of WPT is to transfer electrical power through space without the need for cables. Conventional communication systems such as radio and cell phones only transmit small amounts of energy, but WPT must transfer a significant amount of power in order to charge a battery or propel vehicles. A generic WPT block diagram is shown in Figure 2. A key component in the receiving system is the rectifying antenna, or rectenna.

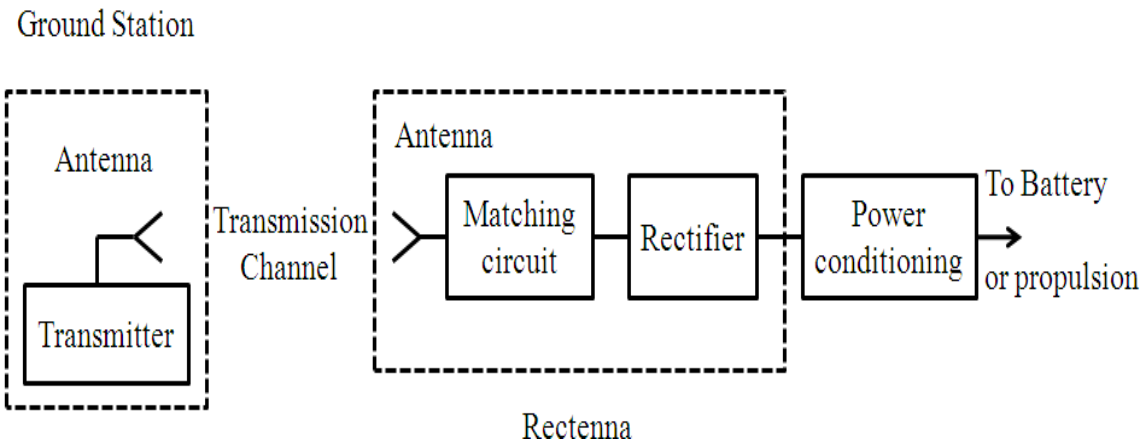

Figure 2. Generic WPT-system block diagram.

Brown conducted wireless power-transmission research in 1963 [1]. In his article, Brown wrote a description of the development of WPT and the milestones along the way. Previously, Tesla carried out numerous experiments to transmit power without a wire at Colorado Springs in 1899 (Figure 3). A gigantic coil was built and fed with 300 kW of low-frequency power in order to produce very long and visible discharges from the sphere, but there is no record of whether any significant amount of power was collected at a distant location. Although Tesla's experiments ended due to lack of land and funding, his concept of efficient, wireless power transmission was important to future research.

Figure 3. Experiment with radio waves for power transmission (From [1]).

In the late 1930s, a further advance in WPT occurred with the invention of the klystron tube, which converted microwave power into dc power by using microwave power tube at one end and dc diode tubes at the other. Advances in the microwave-cavity magnetron led to higher efficiency for WPT applications during World War II.

In the 1950s, two advances were enabled by the invention of the amplifier tube, which created a larger amount of transmitting power [9] to drive an electromagnetic beam, and the focusing of electromagnetic power into a beam for high efficiencies [10]. In May 1963, Raytheon demonstrated the first microwave-power transmission system, which converted 400 W of CW power at the transmitter to 100 W of dc power to drive a motor.

In October 1964, a demonstration of microwave-powered helicopter flight up to 60 ft. above a transmitting antenna was presented (Figure 4). In November of that year, a nonstop, 10-hour hover was demonstrated.

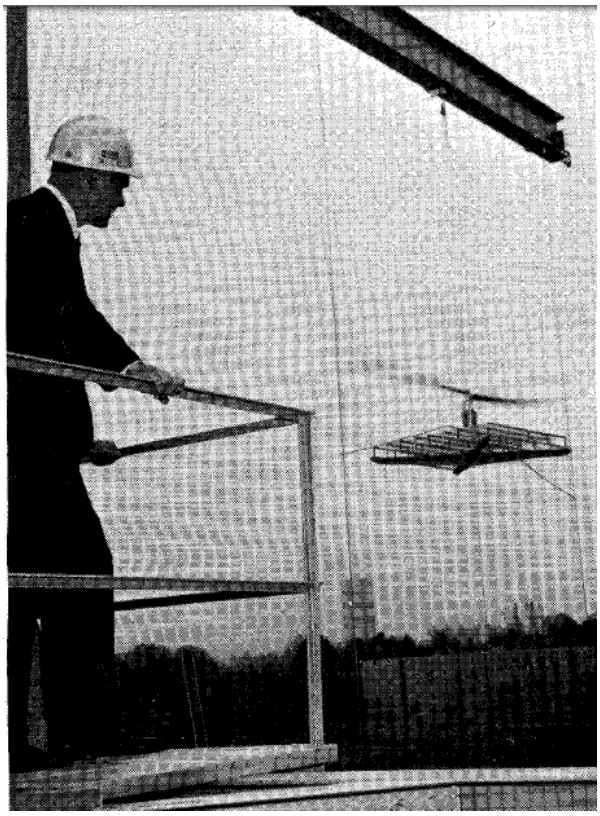

Figure 4. A helicopter powered by WPT (From [1]).

The concept of a solar-power satellite (SPS) introduced in the 1960s also relied on WPT, as illustrated in Figure 5. In the SPS concept, solar energy collected in orbit is converted into microwave power for transmission to a large antenna on ground. With oil consumption increasing over the past years, WPT technology has become an alternative source of energy by transmitting collected solar power from satellites to an earth rectenna station. Solar energy transmitted by WPT is environmentally clean and available 24 hours a day from space by using satellites as collection stations. Although the SPS program ended in 1980, it redirected the design of the transmitter antenna to an active, phased array made from a large number of microwave generators instead of super power tubes.

For ground-based arrays, the low-cost, microwave-oven magnetron could be used directly in the SPS. Pacific Gas and Electric (PG&E) has recently funded a study to design a commercial SPS system [3].

Figure 5. Satellite solar-power model (From [14]).

In the 1990s, the advancement of WPT related to the use of solid-state silicon-based PN junction diodes, which have a high turn-on voltage, and new GaAs Schottky diodes that have fast switching capability for the high-frequency rectification processes. Semiconductor devices were became suitable for achievement of high-rectification efficiency in WPT applications. The first fuel-less plane powered by microwave was produced by Joseph in September 1987 [2]. An array of antennas was used to transmit microwaves onto the plane disc with a dual-polarized rectenna. The airplane flew on beamed microwave for 20 minutes.

B. RECENT DEVELOPMENTS IN WPT

Recently there has been increased activity in WPT. In a September 1999 article by Youn [11], a WPT system achieving a single rectenna conversion efficiency of 75.6% and an overall system efficiency of 33% are described.

Hagerty [12] proposed an array of 64 circularly polarized spiral elements and used a broadband-antenna array to convert more microwave power into dc power. The achievement of 20% efficiency over a frequency range of 2–18 GHz was reported.

A December 2002 survey article on space solar-power (SSP) program research was written by McSpadden [13]. McSpadden gave insight on achieving practical SSP and emphasized three critical components: the transmitter, beam control, and rectennas. Although it was acknowledged that the technology was immature, a strategic roadmap was highlighted for future investigation.

In [14], Goel proposed that a solar-power satellite could be placed in halo orbit to be fixed over the earth's midnight as the earth rotates. The proposed orbit, known as the trans-earth Lagrange point, obviates the need for a rotating joint between the solar array and microwave transmitter, making a simpler design possible.

C. RECENT RESEARCH IN RECTENNAS

In [15], a dual-frequency. printed-diode rectenna system using a GaAs Schottky diode that could achieve 84.4% and 82.7% efficiency at 2.45 and 5.8 GHz, respectively, is reported. The dual-frequency rectenna system is illustrated in Figure 6.

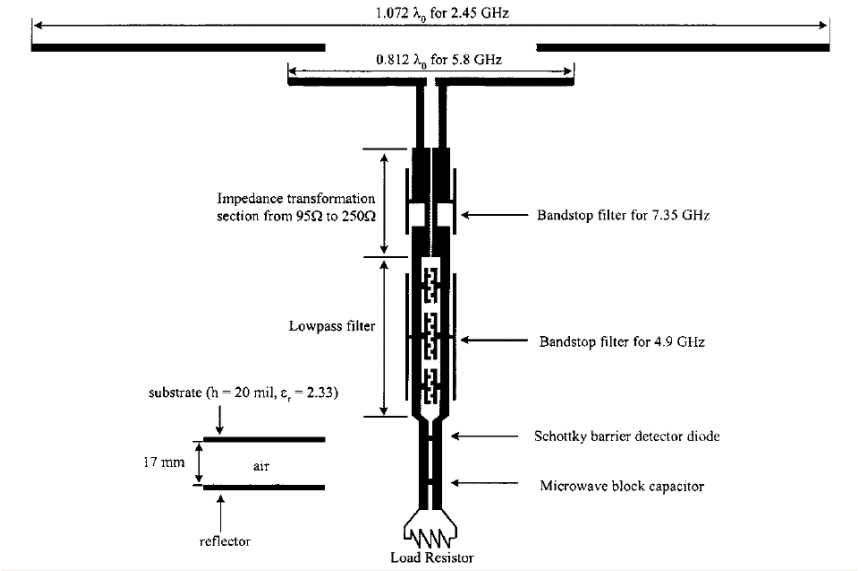

Figure 6. Circuit configuration of the dual-frequency rectenna (From [15]).

Reference [16] by Strassner contains an article on a 5.8 GHz, circularly polarized rectenna design and array. Strassner demonstrated the feasibility of a rectenna array scaled 3 feet wide by 2 feet long and 4 inches tall, with an efficiency of 82% and output power of 7.6 W.

Reference [17] reports a circular-sector antenna using inset feeding in order to exhibit high reflection coefficients at the second and third harmonics generated by the diode. As illustrated in Figure 7, the rectenna can eliminate the need for a low-pass filter (LPF) placed between the antenna and the diode, as well as achieve a conversion efficiency of 77.8% at 2.4 GHz.

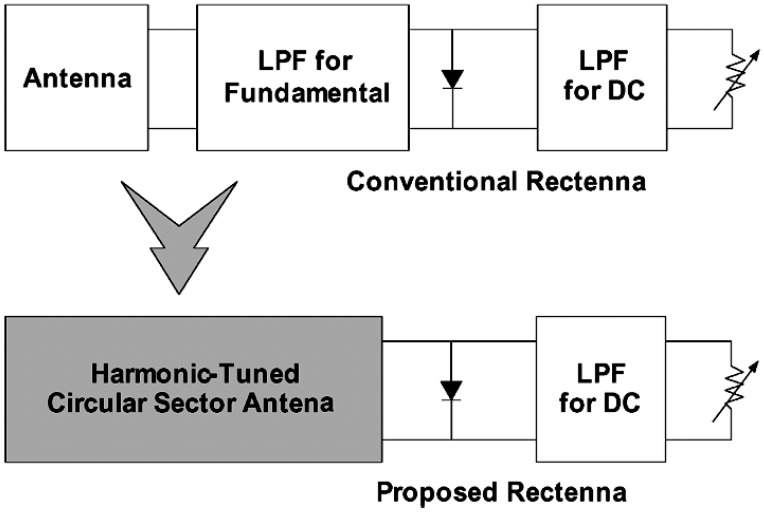

Figure 7. Block diagram of the conventional and the proposed rectenna (From [17]).

In [18], Zbitou reported a monolithic rectifier design with a second diode acting as a variable resistor to achieve an overall efficiency of 65% at 2.54 GHz. He conducted the study using a GaAs, pseudomorphic, high-electron-mobility transistor process to develop a monolithic rectifier to minimize circuit dimensions. The dimension of the rectenna was 1340 μm by 476 μm.

The use of full-wave rectification for rf-to-dc conversion showed that 70.69% rectenna efficiency could be achieved with an input power of 45 mW [19]. The conversion efficiency depends on load resistance, due to the internal resistance of the rectenna system (Figure 8).

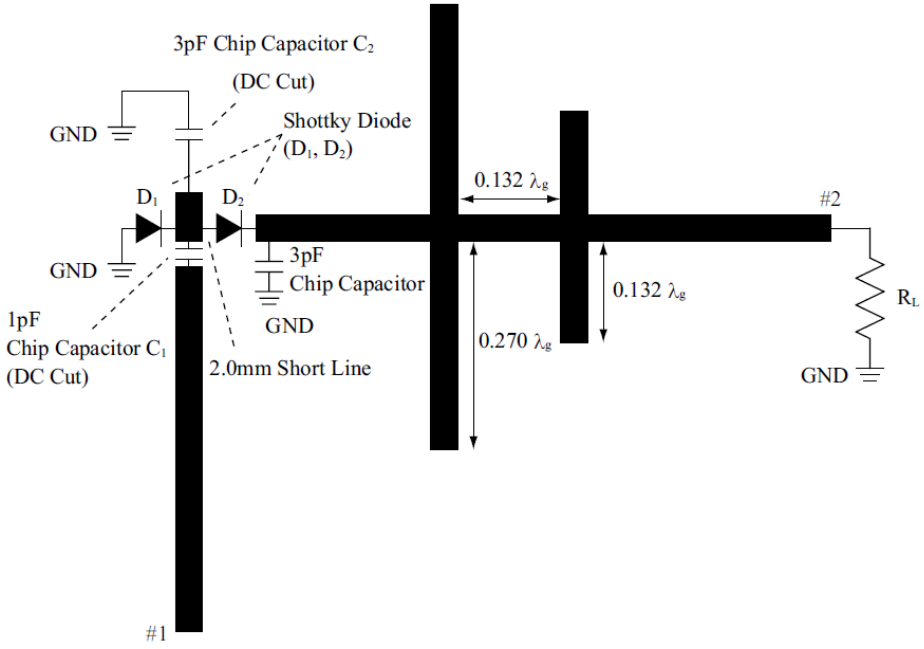

Figure 8. Full-wave rectification (From [19]).

A recent article by Olgun [20] reported that a rectenna system combining a two-stage, zero-bias Schottky diode with a miniature antenna could achieve 70% efficiency at 2.4 GHz. The diodes are in parallel to rf signals, but appear in series for the dc circuit in order to produce doubled voltage. The circuit layout of the rectenna is depicted in Figure 9.

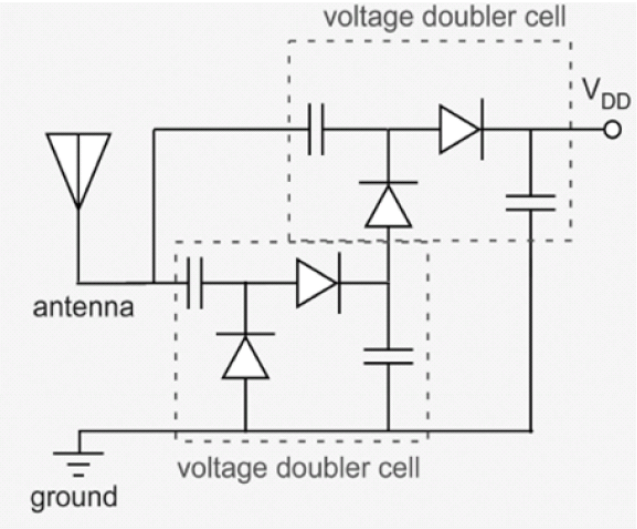

Figure 9. Circuit design of the rectenna (From [20]).

D. PREVIOUS NPS RESEARCH

Students at Naval Postgraduate School have looked into aspects of WPT for MAV propulsion. Vitale [21] utilized a metal semiconductor diode to design a rectification circuit and was able to experimentally determine the scattering parameters (S parameters) of the diode. He highlighted that future research into employing GaAs Schottky diodes for higher rectification efficiency and using a high power source for examining improvement on the MAV antenna design.

Tsolis [8] extended Vitale's work by using Schottky diodes with a patch antenna, but efficiency was verified to be only 7%, due to the mismatch of impedance. Tan [6] investigated various designs of antennas and concluded that a round-patch antenna and sixth-order filters were the better design. He recommended that further analysis into building rectenna to determine the fabrication robustness and conversion efficiency.

Toh [7] improved Tan's design by matching the impedance of the rectenna system. Toh introduced an impedance-matching unit and simulated his design using software. The prototype of the rectenna system was fabricated and tested. The overall efficiency of a single rectenna element varied between 26% and 37%.

E. SUMMARY

In this chapter, the major milestones in the development of WPT were highlighted and a brief history of WPT was covered. Much research has been conducted to determine the feasibility of implementing WPT and its applications, which range from miniaturized versions of remotely powered vehicles to large-scale systems. In the next chapter, rectenna design is addressed in detail.

THIS PAGE INTENTIONALLY LEFT BLANK

III. RECTENNA DESIGN

A. DISCUSSION OF RECTENNA DESIGN

1. General Rectenna Design

A rectifying antenna (rectenna) receives a microwave signal at the antenna and converts it to direct current. It should do this as efficiently as possible and provide a clean, constant, low-ripple voltage. Typically, a rectenna is composed of four components: (1) an antenna, (2) a pre-rectification filter, (3) a rectification diode, and (4) a post-rectification filter [7]. The basic configuration of the previous NPS rectenna systems is depicted in Figure 10.

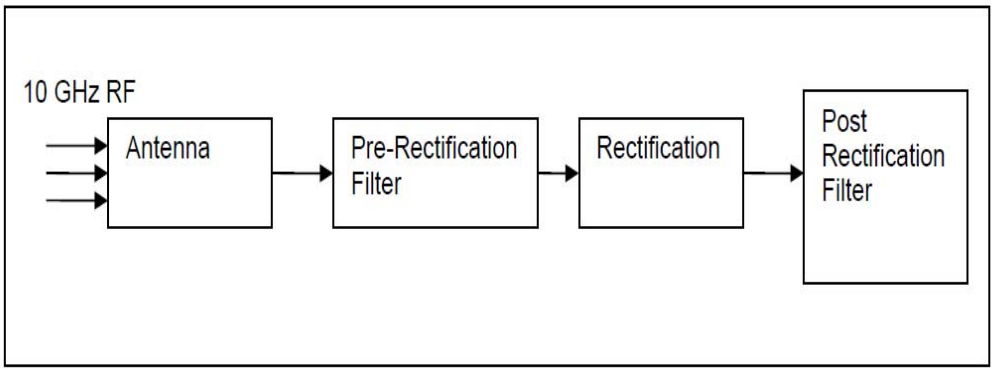

Figure 10. Basic configuration of NPS rectenna system (From [7]).

There are many candidate antenna designs, such as half-wave dipole, horn, parabolic antenna, and microstrip antenna. Some of these can be discarded for this application, due to their weight or size. In reference [8], Tsolis concluded that a circular-patch antenna was preferred, in part due to its capability of reducing the reradiation of harmonics. Figure 11 shows the S_{11} (return loss) response of a circular-patch antenna. Ideally, the return loss of a circular-patch antenna is about 50 dB. In practice, the return loss is likely to be 15 dB to 20 dB. (Return loss is a positive quantity equal to the negative of S_{11} in dB.)

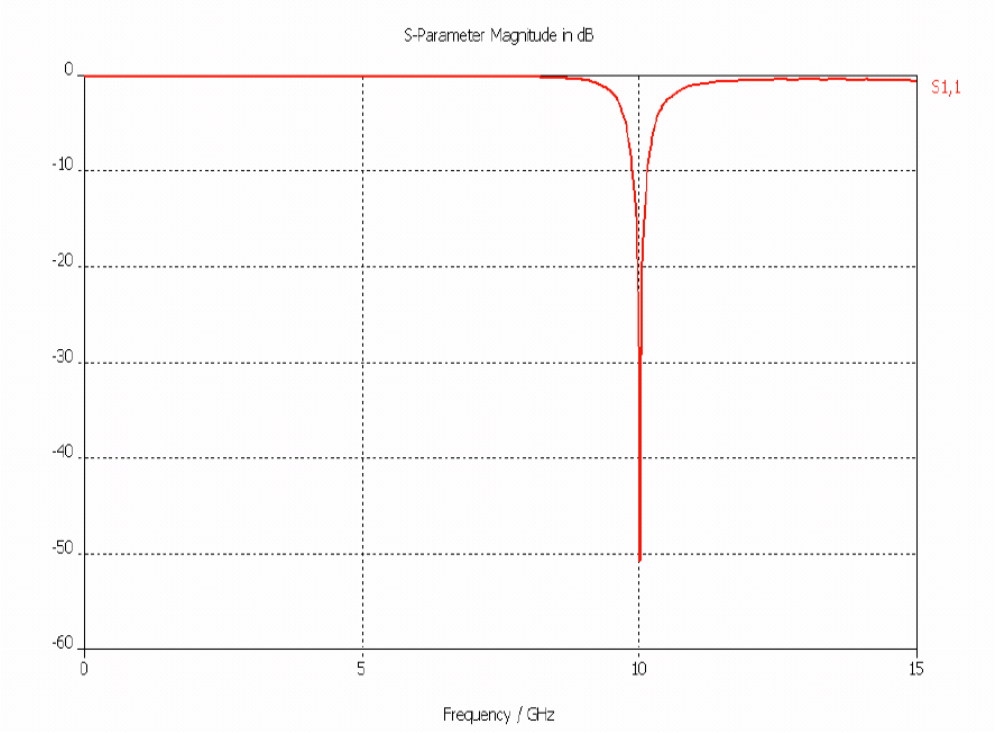

Figure 11. S_{11} frequency response of circular-patch antenna design (From [7]).

The antenna feeds directly into a pre-rectification filter. It allows the 10 GHz operating frequency to pass and prevents interference signals and re-radiation of higher-order harmonics generated by the diode. It also helps provide a constant load impedance for the antenna. Tan [6] selected a sixth-order LPF instead of a fourth-order LPF, due to its better response at 10 GHz. Figure 12 shows that the S_{12} (insertion loss) is 0.078 dB (insertion loss is the negative of S_{12} in dB.)

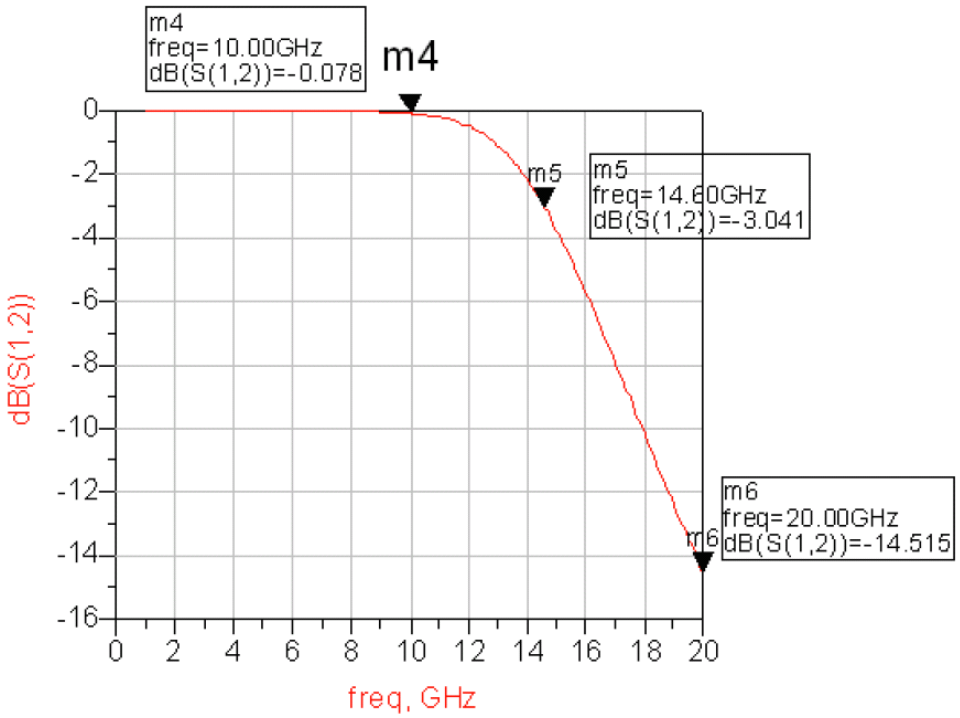

Figure 12. Simulated response of sixth-order low pass filter using ADS software (From [7]).

Rectification is the key function of the rectenna: converting microwave rf energy into dc power. In reference [8], the Schottky diode was used as the rectifying device, due to a high switching capacity that enables it to follow a high-frequency input signal. A commercial Avago HSMS8101 was used in the NPS rectenna system [7], [8]. The S_{21} response of the Schottky diode is depicted in Figure 13. The value of S_{21} is about -0.5 dB at 10 GHz [7].

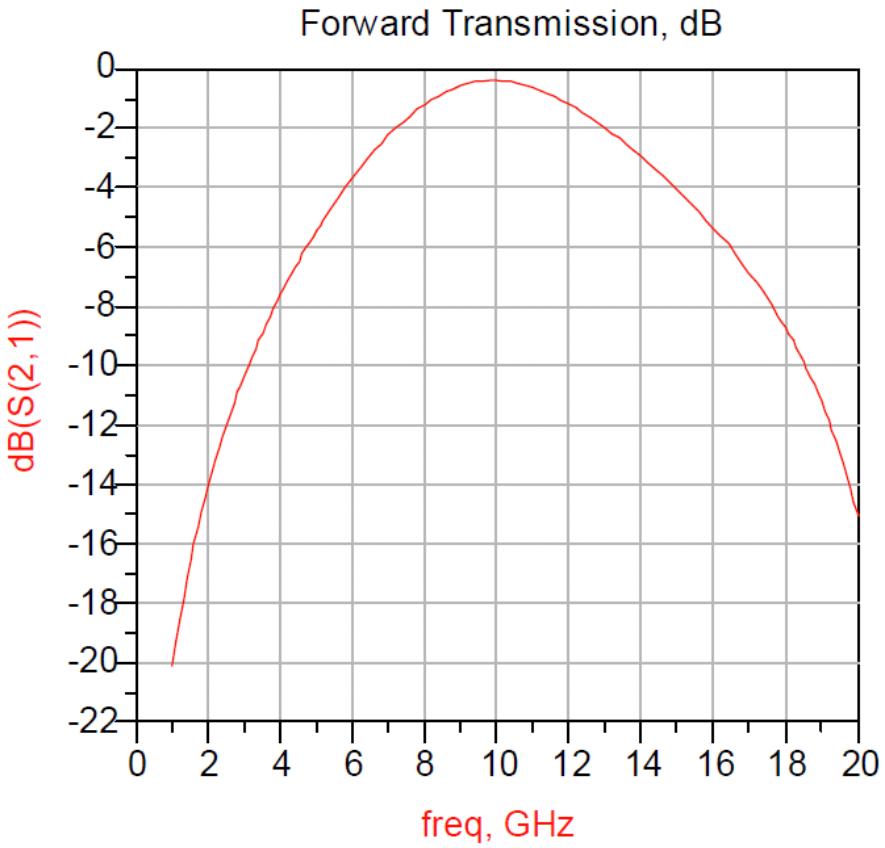

Figure 13. Simulated response of Schottky diode using ADS software (From [7]).

A post-rectification filter is used to extract the dc component and produce a smooth transient for output dc power. Toh [7] developed a post-rectification filter by simply using a 47 pF capacitor in the circuit design.

Tsolis [8] studied the MAV motor prototype DMMK06-10 and measured data for the motor. Toh [7] confirmed the characteristics of the motor given in Table 1. In order to hover the weight of 10 g with 0.952 W, Toh concluded that at least 22 rectenna elements are needed, with each rectenna producing a maximum power of 75 mW. He also implemented a half-wave rectenna and measured the maximum power produced by a single rectenna to be 41.15 mW. In order to hover the MAV, the present research needed to produce more dc power from each rectenna than the previous half-wave rectenna and design a lighter-weight rectenna circuit.

DMMK06-10 Motor's characteristics							
Weight (g)	net	5	10	15	20	25	30
Voltage (V)	5.5	7	8.1	9.9	11.5	14	16
Current (A)	0.1	0.136	0.17	0.22	0.264	0.319	0.357
Resistance (Ω)	54.9	51.4	47.4	45	43.5	43.8	44.8
Power (W)	0.55	0.952	1.3817	2.1780	3.0360	4.4660	5.7120
Round Per Minute	1200	1440	1620	1740	1770	1800	2100

Table 1. Measured data for the MAV motor (From [7]).

2. Antenna Design

In order to obtain a lightweight rectenna design for MAV applications, we discuss possible changes or removal of components of the rectenna. First, we propose using a half-wave dipole antenna instead the original circular-patch antenna to reduce weight. Figure 14 illustrates the structure of the half-wave dipole antenna over a ground plane modeled in CST Microwave Studio. The dipole has a unique design: only one arm is fed by the microstrip line, while the other arm is open. As will be discussed in a later section, this represents the situation that occurs when the dipole is used in a full-wave rectenna.

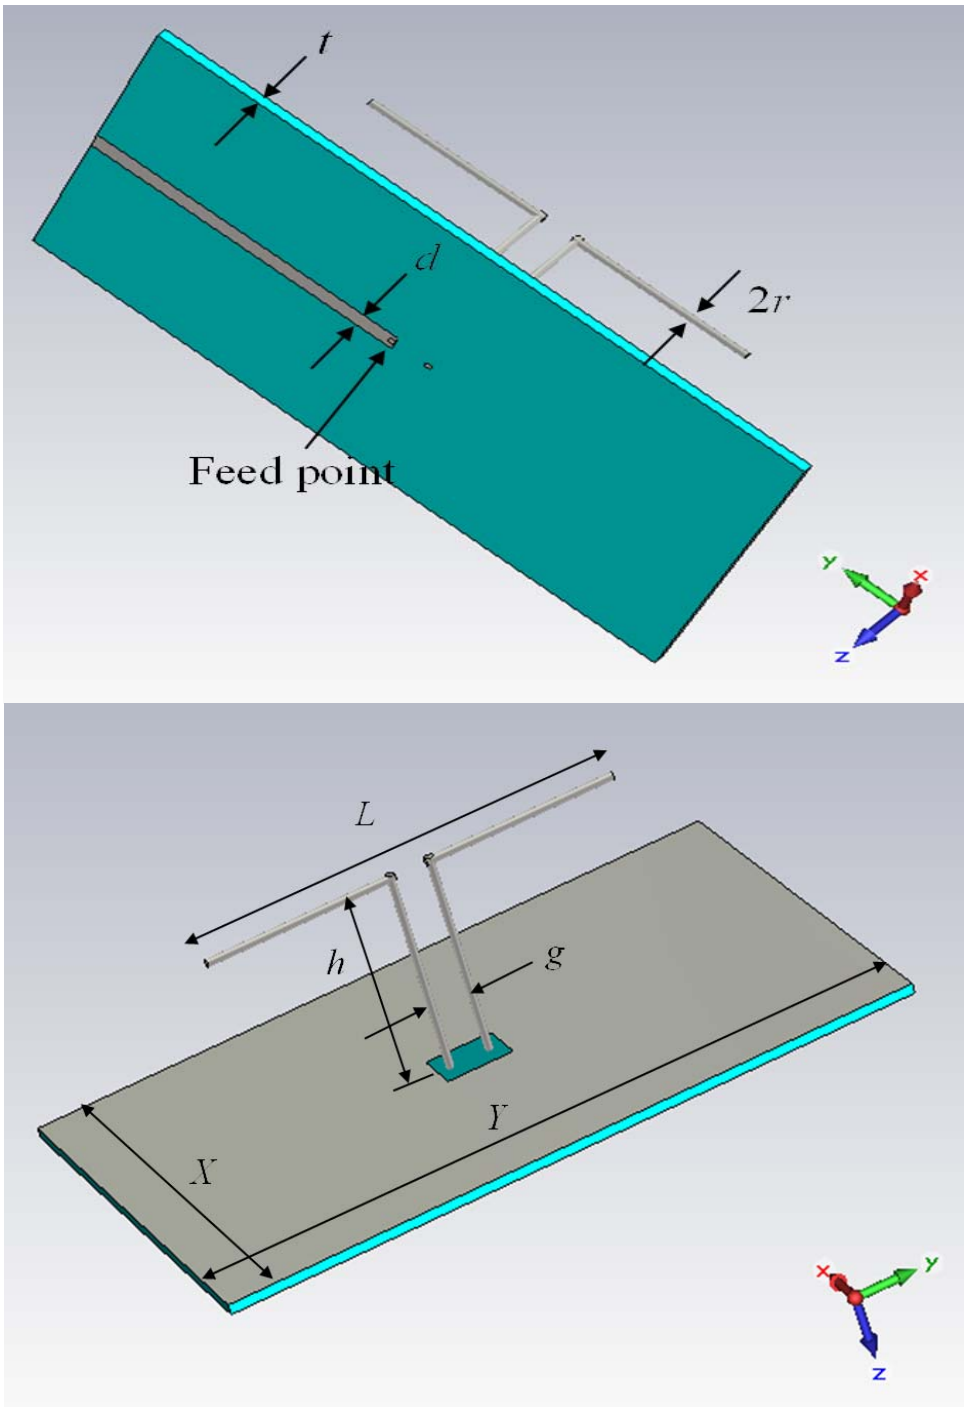

Figure 14. Two views of the half-wave, dipole-antenna structure.

Table 2 lists the design specifications for the data in Figure 15 through 17.

Half-wave dipole's specifications			
Dipole wire radius (r)	0.25	Gap width (g)	1.5
Substrate height (t)	0.508	Dipole height above ground (h)	9
50 ohm line width (d)	1.6829	Sample width (X)	25
Dipole length (L)	25	Sample length (Y)	35

Table 2. Design specifications for the half-wave dipole antenna.

Figure 15 shows the S_{11} response of the half-wave dipole antenna. The return loss is about 23.5 dB at 10 GHz. The impedance of the antenna is 44+j1.6 Ω at 10 GHz as noted on the Smith chart in Figure 16.

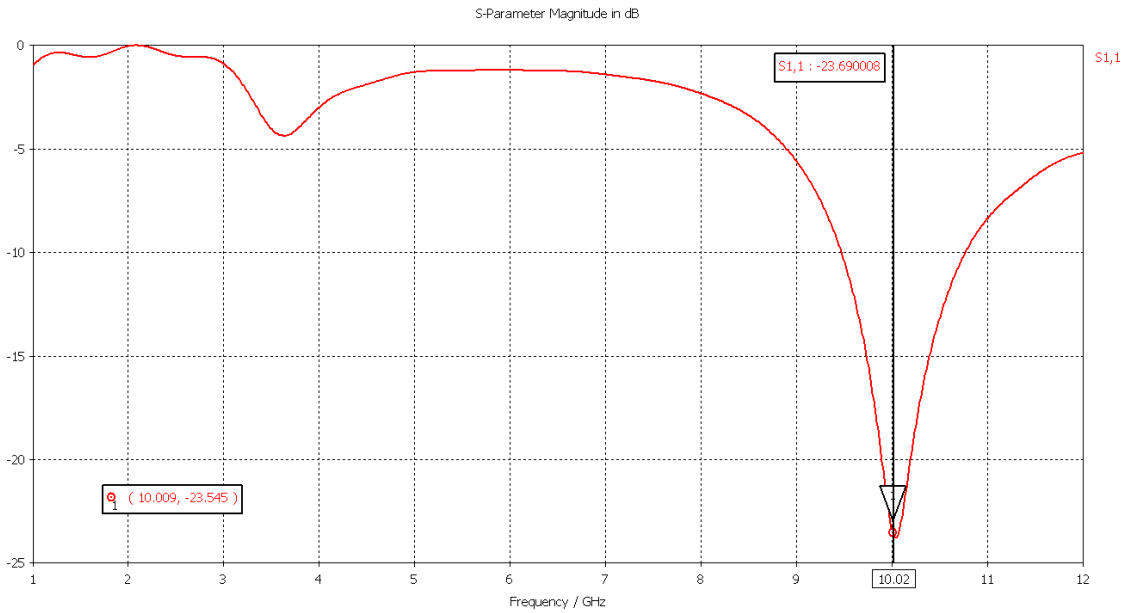

Figure 15. S_{11} frequency response of half-wave, dipole-antenna design.

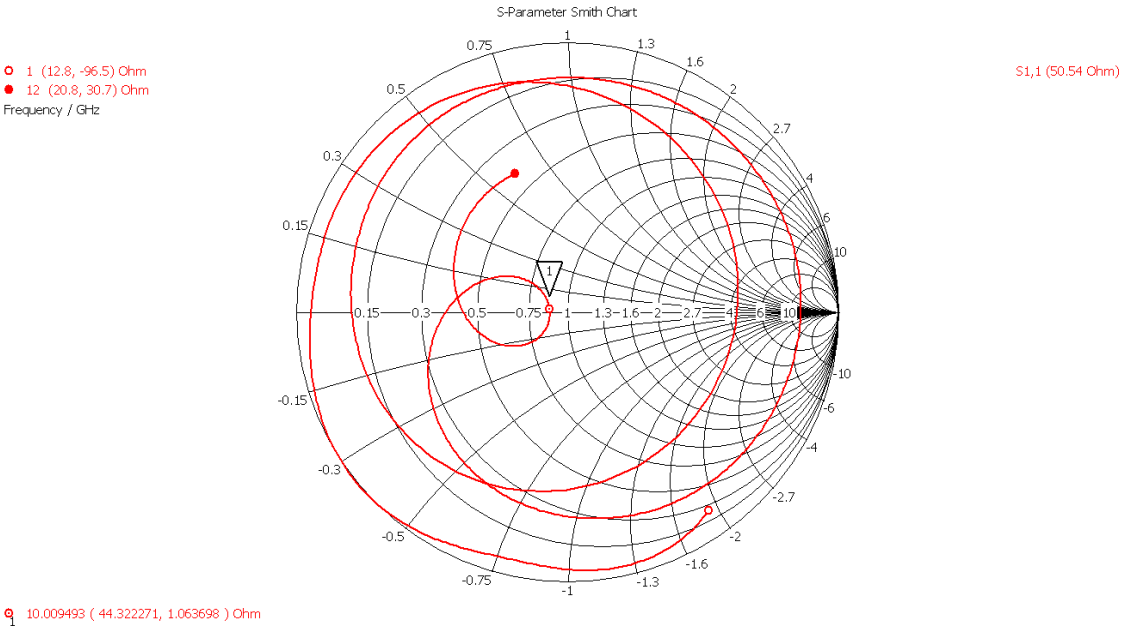

Figure 16. Smith chart of the half-wave, dipole-antenna design**.**

The pattern, gain, and radiation efficiency of the antenna are given in Figure 17. The coordinate system is defined in Figure 14. The pattern plotted is $|E| = \sqrt{|E_\theta|^2 + |E_\phi|^2}$. The pattern gives good coverage over a wide range of angles. The large backlobe is from radiation by the microstrip feed line. It will be shielded in the final design. The return loss and pattern were found to be sensitive to the ground-plane size and dipole height. Smaller ground planes required a higher dipole for a good impedance match. From the simulation, we observe that using a half-wave dipole antenna has acceptable return loss and pattern.

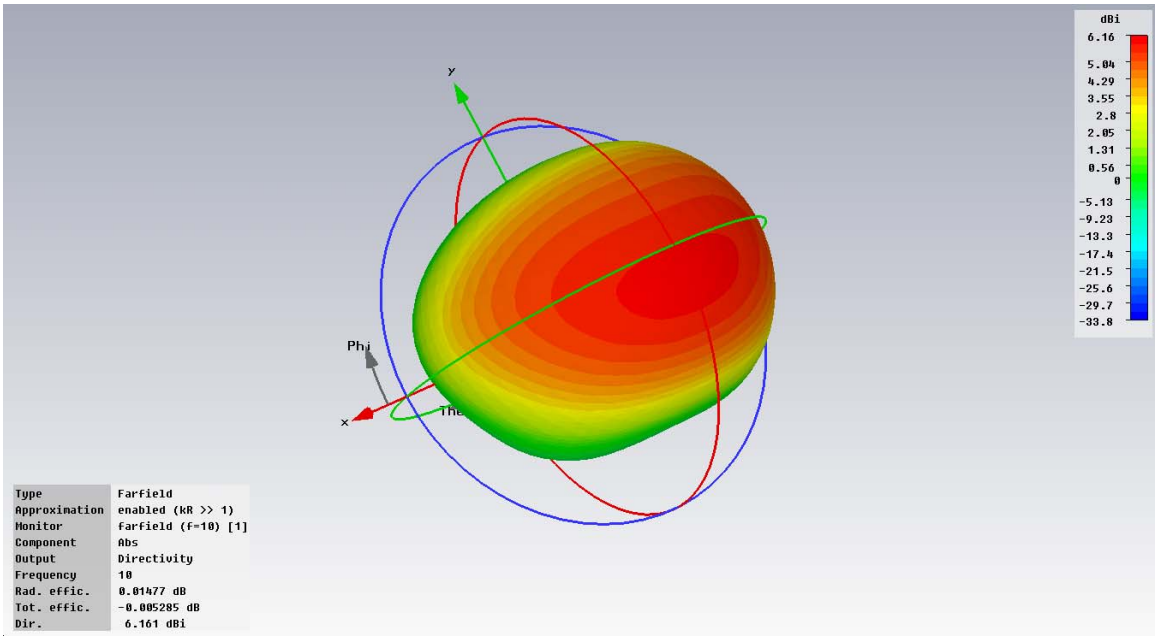

Figure 17. Three-dimensional, far-field radiation pattern of the half-wave, dipole-antenna design.

3. Power Budget

In this section, we introduce the effective area of the transmitting and receiving antennas and calculate the power density in order to obtain the required transmitter power for various distances. Figure 18 shows the geometry.

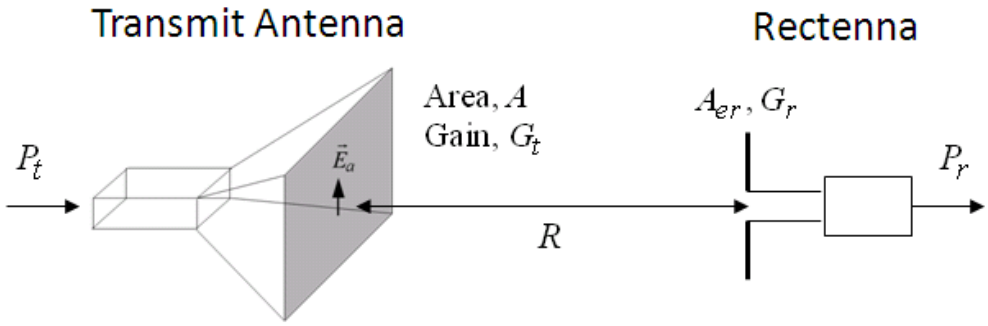

Figure 18. Diagram of the transmit antenna and rectenna.

The effective area of the dipole antenna over a perfect ground plane is calculated using:

$$A_{er} = \frac{G_r \lambda^2}{4\pi} \tag{3.1}$$

where G_r is the gain of the dipole antenna and λ is the wavelength at 10 GHz. From Figure 17, the gain is 6.16 dB = 4.13. Using Eq. (3.1), the effective area of the dipole antenna is 2.96×10^{-4} m^2. The power density W_i transmitted by the horn antenna at distance R can be expressed as

$$W_i = \frac{P_t G_t}{4\pi R^2} = \frac{4\pi P_t \frac{A_{et}}{\lambda^2}}{4\pi R^2} = \frac{P_t A_{et}}{\lambda^2 R^2} \tag{3.2}$$

where P_t is the transmitted power, A_{et} is the effective area of the horn antenna, and R is the distance between transmitting and receiving antennas. The effective area of the horn antenna is the physical area (A) times the efficiency, e_t. Assuming horn dimensions of 3 inches by 4 inches and an efficiency of 0.7, $A_{et} = 0.0054$ m^2, the power P_r received by dipole antenna can be expressed as

$$P_r = W_i A_{er} = \frac{P_t A_{et} A_{er}}{R^2 \lambda^2}. \tag{3.3}$$

Using Equation (3.3), the required transmitting power versus the distance between transmitting and receiving antennas to obtain 200 mW of received power is given in Figure 19. From Figure 19, the transmitted power is 1.35 W for the distance of 30 cm, and the received power will be 200 mW. This analysis assumes the distance R is in the far field of the horn antenna.

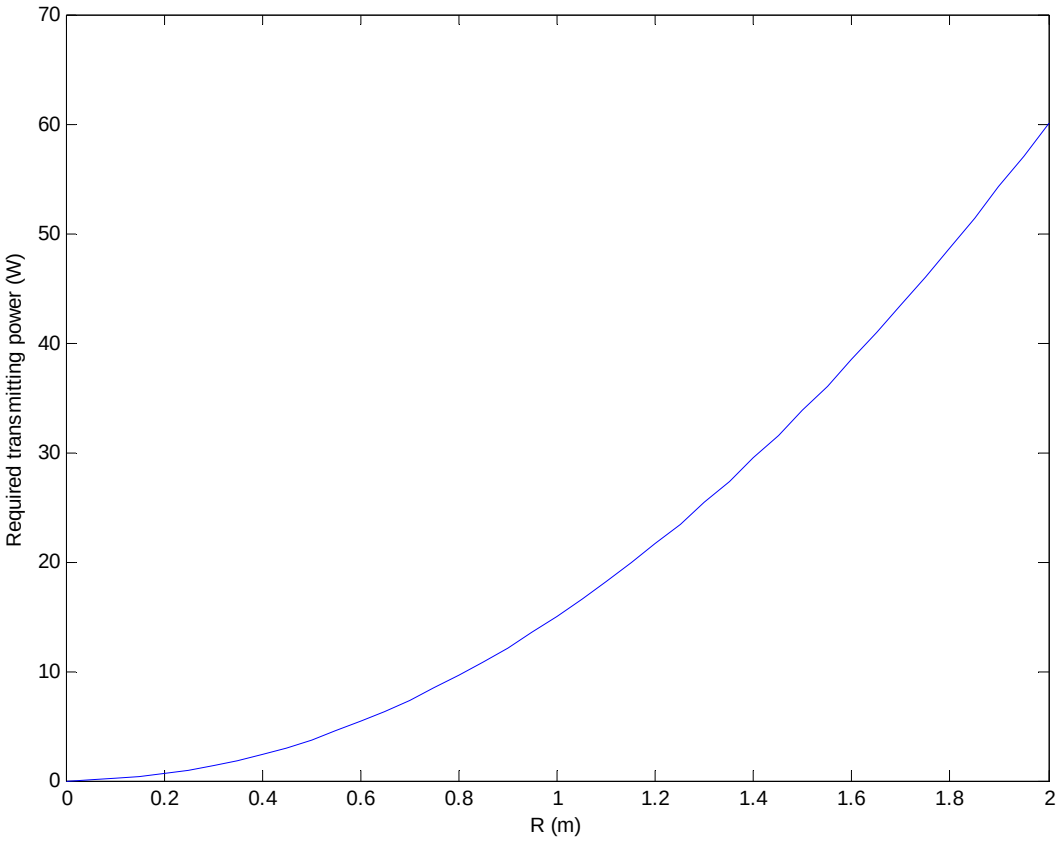

Figure 19. Required transmitting power versus distance with 200 mW received power.

Next, we evaluate the various rectenna configurations by simulating the conversion efficiency and discuss the effect of changing the position of the pre-rectification filter in rectenna design by analyzing the harmonics in the frequency domain.

B. COMPARISON OF DIFFERENT DESIGNS USING ADS

In this section, we simulate the rf-to-dc efficiency of different rectenna designs, such as a half-wave-rectification rectenna, hybrid rectenna, and full-wave rectenna. Agilent ADS2009 is used to evaluate and compare the performance of the various designs. This software provides numerous simulation technologies, covering issues such as electromagnetic-field simulation and frequency and time-domain circuit simulation. To compare performance with the NPS rectenna design, we model the original rectenna circuit of Toh [7] using the HSMS8101 Schottky diode and sixth-order LPF.

1. Half-Wave-Rectification Rectenna Design

The half-wave-rectification rectenna has the advantage of simple circuit layout and ease of fabrication as a microstrip structure [22]. A block diagram of a half-wave-rectification rectenna is depicted in Figure 20.

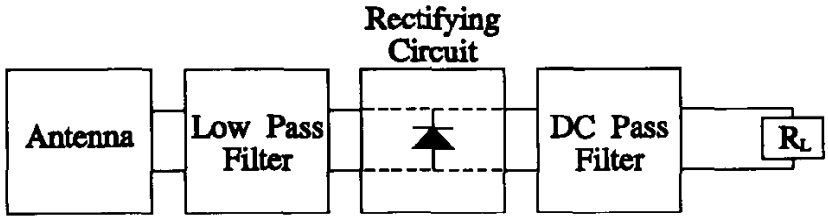

Figure 20. Block diagram of half-wave rectification rectenna (From [22]).

In references [6], [7] a half-wave rectifier design was used. The circuit layout of the rectenna is given in Figure 21.

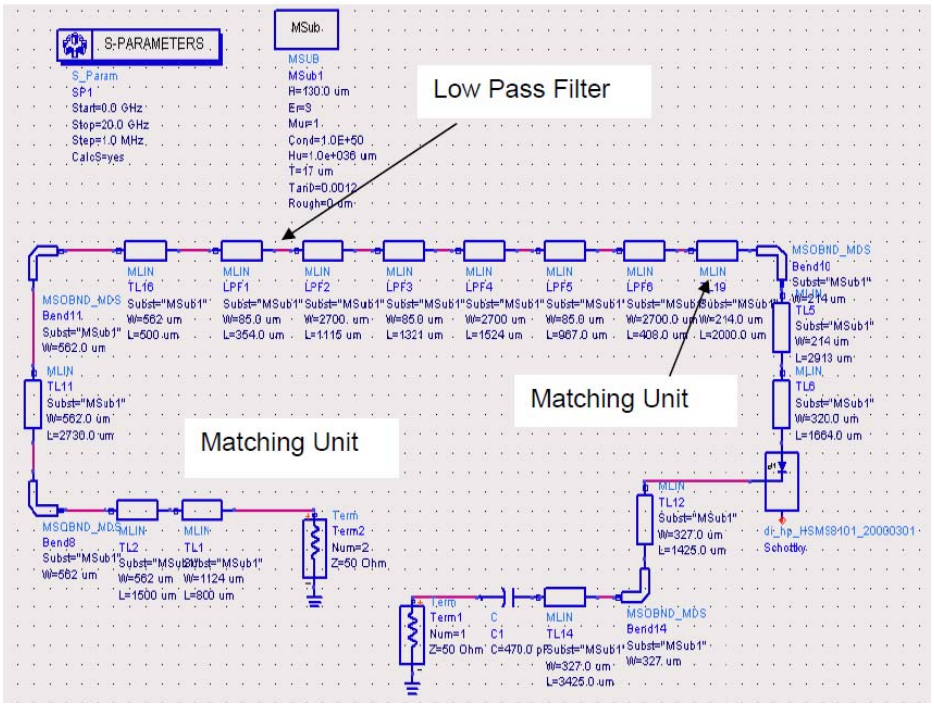

Figure 21. ADS S-parameter circuit model of Toh's rectenna (From [7]).

Toh removed the dc pass filter because it was too small to solder correctly and it was found not to significantly affect output [7]. Omitting this component results in some ripple in the output dc; however, to minimize size and weight, the low-pass filter is possibly a component that can be omitted for some circuit designs. Figures 22 to 24 illustrate three different circuit designs of a half-wave rectenna that will be simulated in ADS. The three half-wave rectifier designs are: (1) with a pre-LPF, (2) with a post-LPF, and (3) without any LPF.

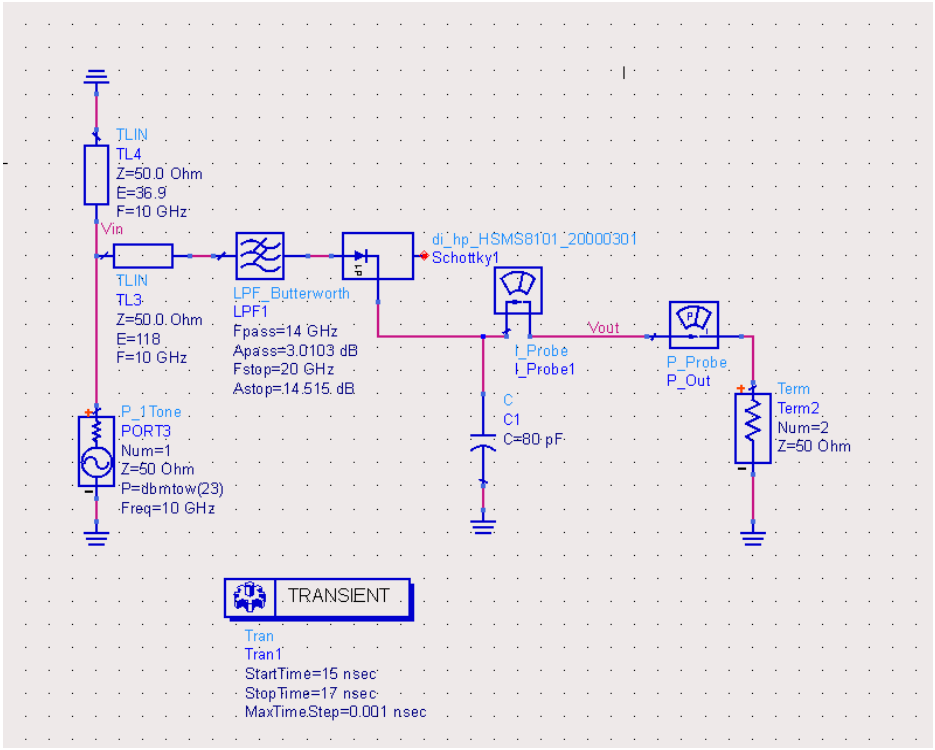

Figure 22. ADS model of a half-wave rectenna design with a pre-LPF.

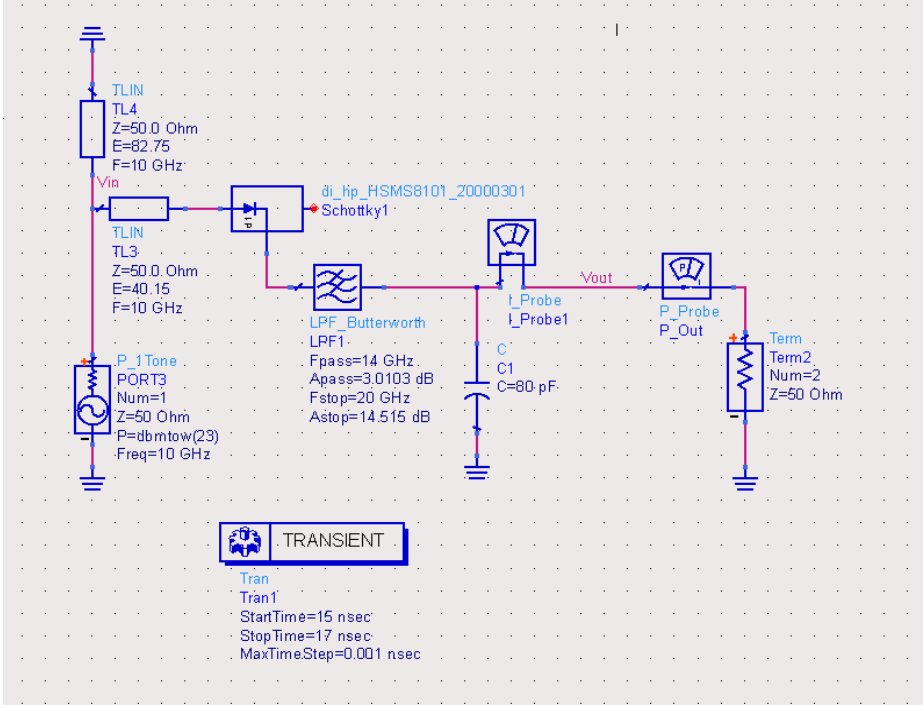

Figure 23. ADS model of a half-wave rectenna design with a post-LPF.

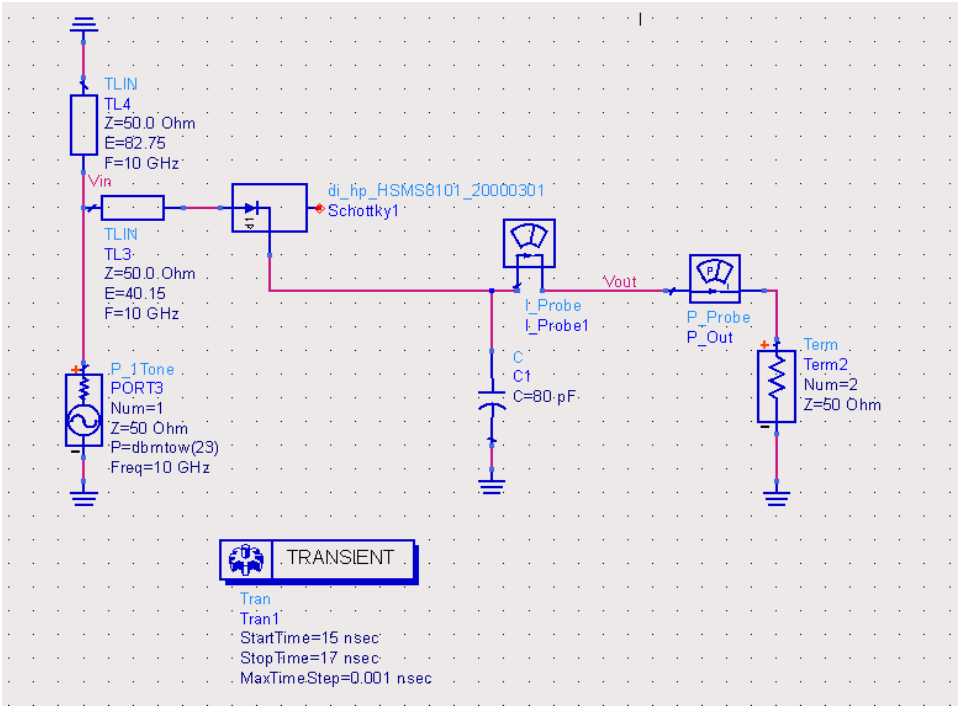

Figure 24. ADS model of a half-wave rectenna design without LPF.

All three designs utilize a capacitor after the diode. In reference [21], Vitale noted that the output voltage when the diode is not conducting is compensated for by the discharge of the filter capacitor. It can be expressed as

$$V_{out}(t) = V_P e^{-t/R_L C} \tag{3.4}$$

where V_P is the peak voltage of the rectified signal, R_L is the load resistance, and C is the filter capacitance. For $R_L C \gg T$, the exponential can be approximated by $\left(1 - T \big/ R_L C\right)$ and the minimum output voltage can be expressed as

$$V_{\min} = V_P \left(1 - \frac{T}{R_L C}\right) \tag{3.5}$$

where T is a full period of the input sinusoid. He also determined that the output dc voltage V_{out} is approximated by the average voltage between the peak voltage and the minimum output voltage

$$V_{out} = V_P \left(1 - \frac{1}{2 f R_L C}\right). \tag{3.6}$$

Figures 25 to 27 illustrate the output dc power produced by the three different circuit designs of a half-wave rectenna that were simulated in ADS.

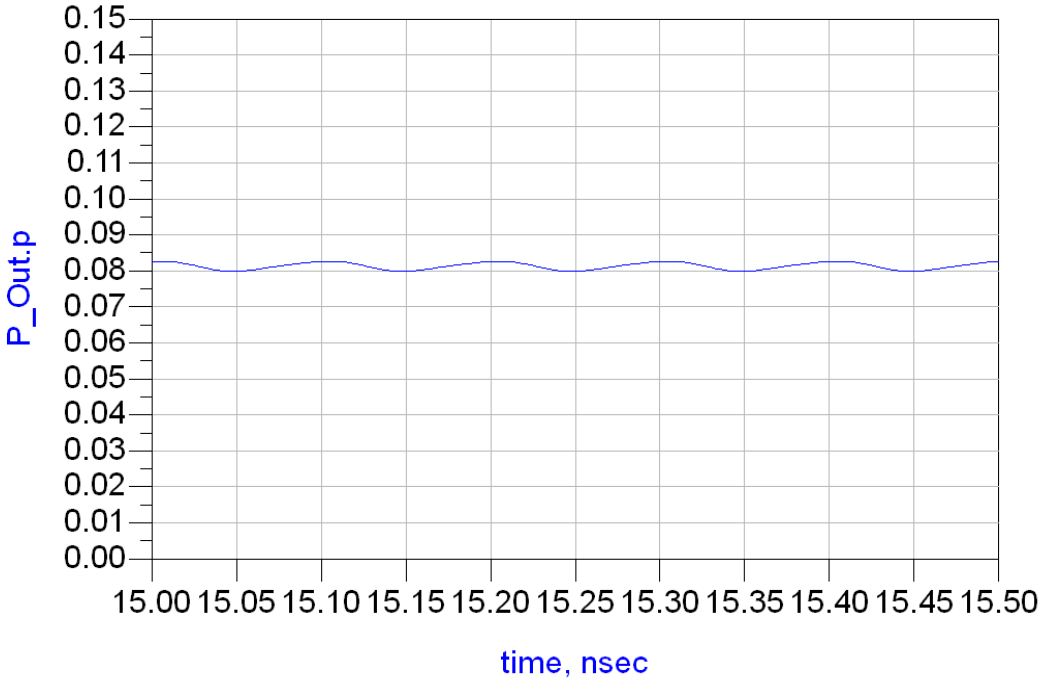

Figure 25. Output power (watts) versus time for a half-wave rectenna design with a pre-LPF.

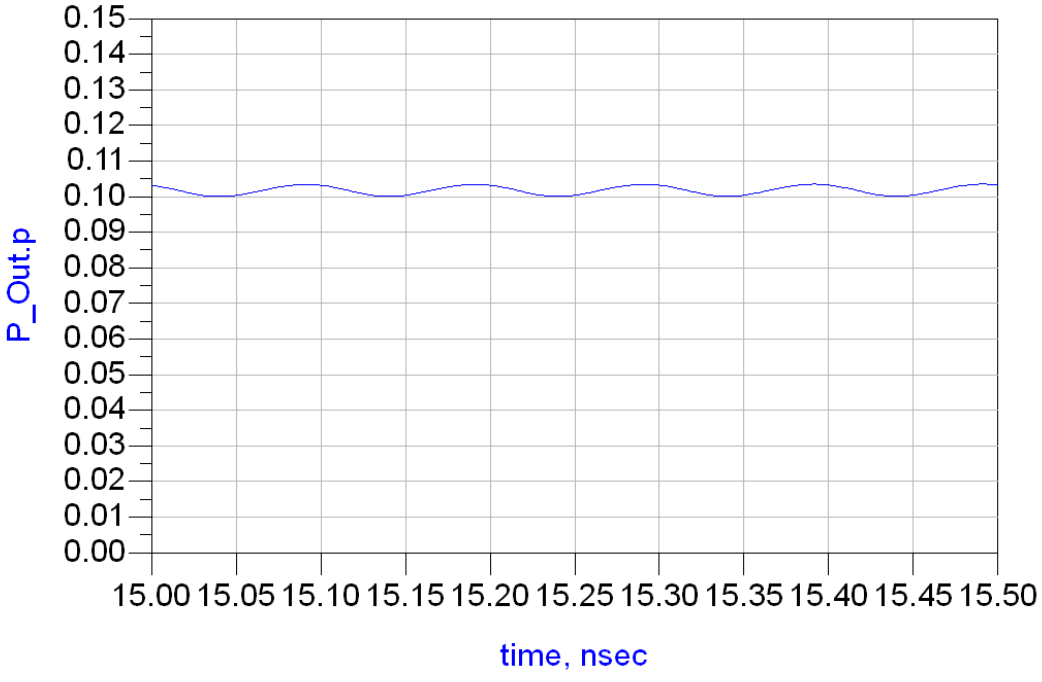

Figure 26. Output power (watts) versus time for a half-wave rectenna design with a post-LPF.

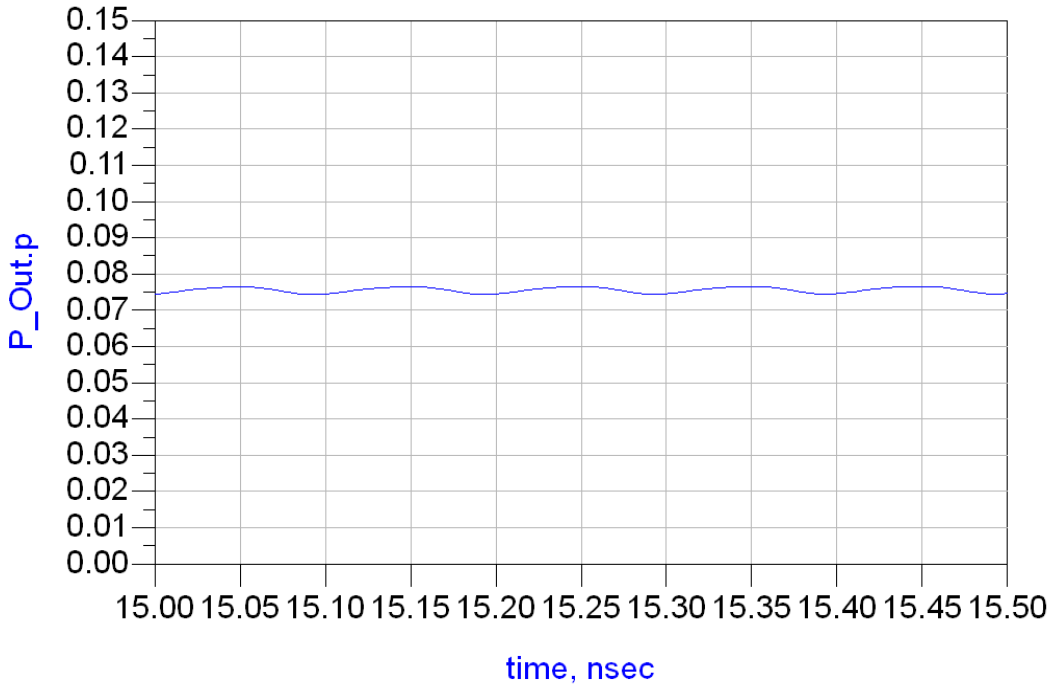

Figure 27. Output power (watts) versus time for a half-wave rectenna design without LPF.

In addition, rf-to-dc conversion efficiency η in percent is calculated as follows:

$$\eta = \frac{(V_{DC}/R_L)}{P_{RF}} \times 100 \tag{3.7}$$

where V_{DC} is dc output voltage, R_L is load resistance, and P_{RF} is microwave input power.

The simulated conversion efficiency of the half-wave rectennas is compared by using Equation (3.7). In Figure 28, the efficiency of the rectenna with post-LPF is higher than those for the pre-LPF and no LPF at their highest power levels. In comparison to the other designs shown in Figure 28, the design with post-LPF is able to convert wireless power to dc power with an efficiency of 54.3% at an input power of 150 mW, but the design with pre-LPF only achieves an efficiency of 45.8% at the same input power. In specific applications with input power smaller than 100 mW, we prefer the half-wave-rectification rectenna with pre-LPF to achieve a high conversion efficiency.

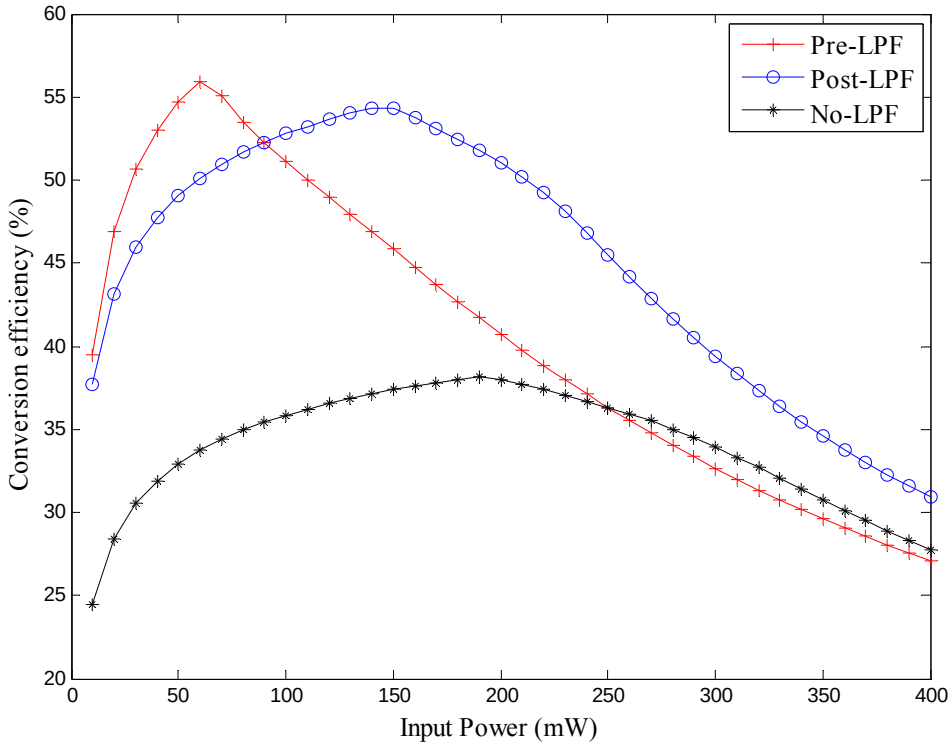

Figure 28. Conversion efficiency of simulated half-wave rectenna designs using ADS.

2. Hybrid Rectenna Design

In reference [18], Zbitou developed hybrid rectenna that achieved a conversion efficiency of 56% at 2.45 GHz. The block diagram of the hybrid rectenna is depicted in Figure 29. The function of the second diode is to provide a variable resistance in series with the load.

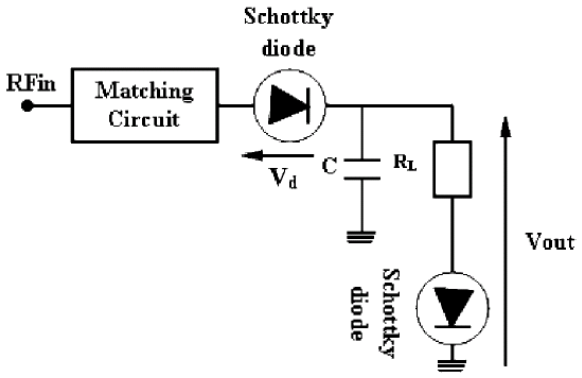

Figure 29. Block diagram of hybrid rectenna (From [18]).

Zbitou considered the dc equivalent circuit of the Schottky diode as a voltage source in series with the junction resistance R_j and that the output voltage of the rectifier can expressed as

$$V_{out} = V_{DC} \frac{R_L}{R_L + R_j} \tag{3.8}$$

where V_{DC} is the dc part of the diode junction voltage and R_j is the junction resistance of the Schottky diode. R_j is obtained by differentiating the diode voltage-current characteristics and is given by [18]

$$R_j = \frac{nKT}{q\left(I_s + I_b\right)} \tag{3.9}$$

where n is the diode ideality factor, K is Boltzmann's constant, q is the electronic charge, I_s is the diode saturation current, I_b is the external bias current, and T is the temperature of the diode in degrees Kelvin. For the HSMS2820 diode, R_j is approximately 1.7 MΩ at ambient temperature, which tends to decrease the value of V_{out}, as evident from Equation (3.8). According to Equation (3.8), an increase in voltage at low power levels can be obtained when a variable resistance, which fluctuates as R_j, is connected in series with R_L. The value of this variable resistor must change with the

rectified current. Thus, Zbitou employed a technique using the same Schottky diode in series with R_L, in the dc portion of the rectifier, to act as a variable resistor (due to its current dependence in the junction resistance).

Three variations of the hybrid circuit are evaluated. Two incorporate an LPF (Figures 30 and 31). The third eliminates the LPF in order to minimize size and weight (Figure 32).

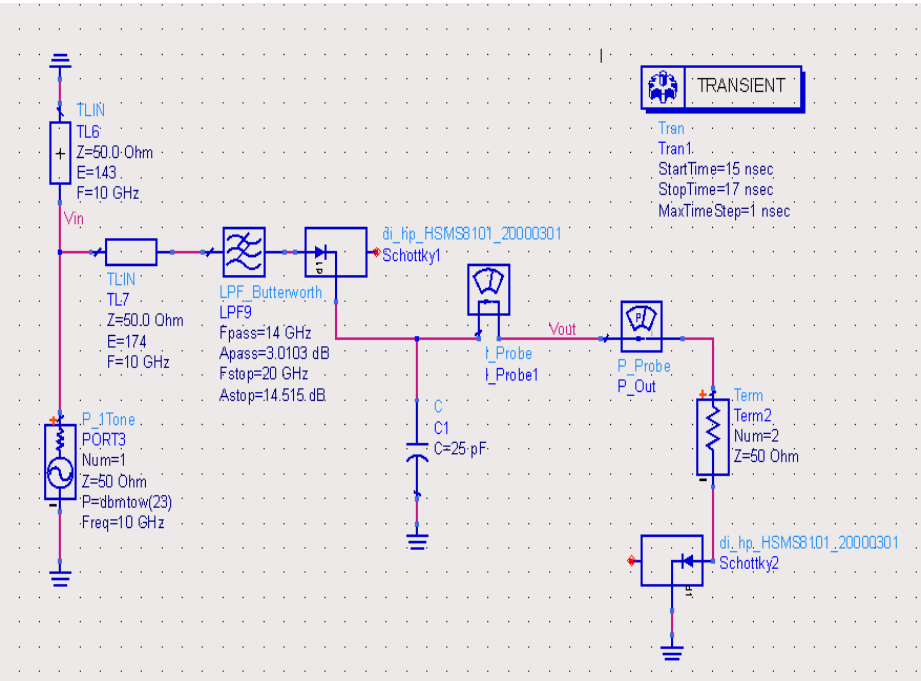

Figure 30. ADS model of a hybrid rectenna design with a pre-LPF.

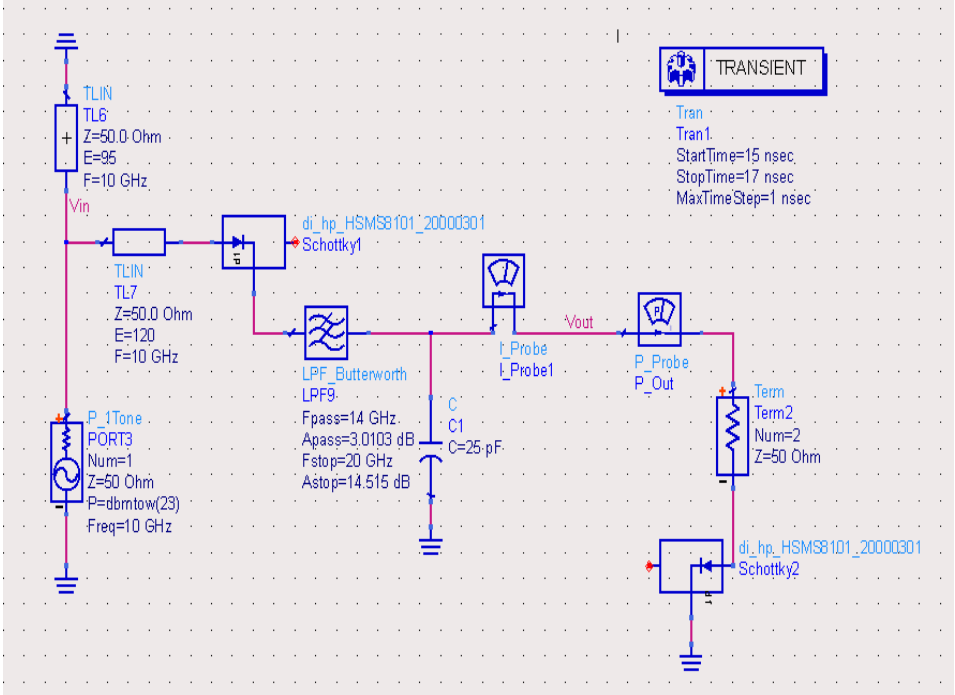

Figure 31. ADS model of a hybrid rectenna design with a post-LPF.

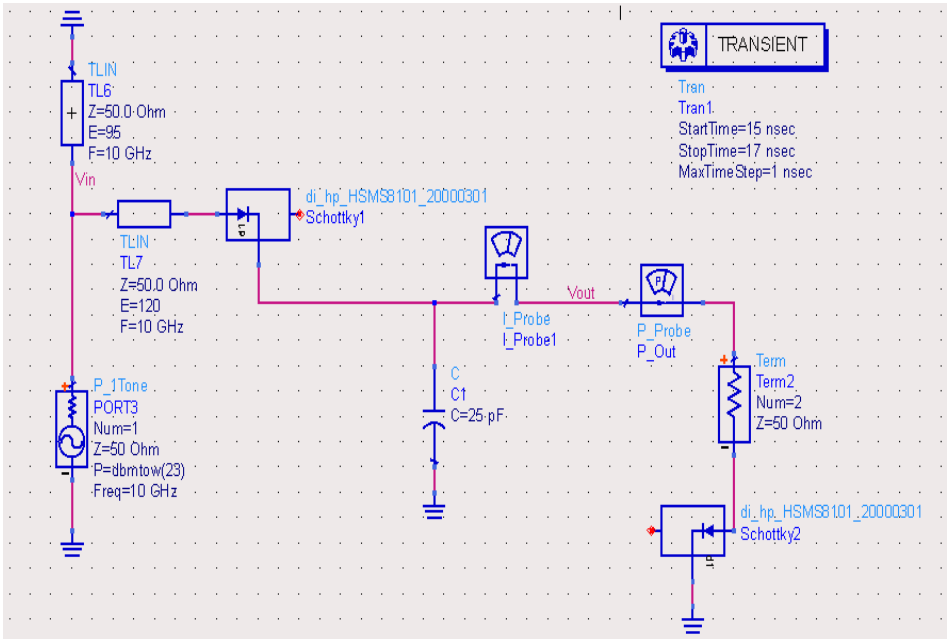

Figure 32. ADS model of a hybrid rectenna design without LPF.

Figures 33 to 35 illustrate the output dc power produced by three different circuit designs of hybrid rectenna that were simulated in ADS.

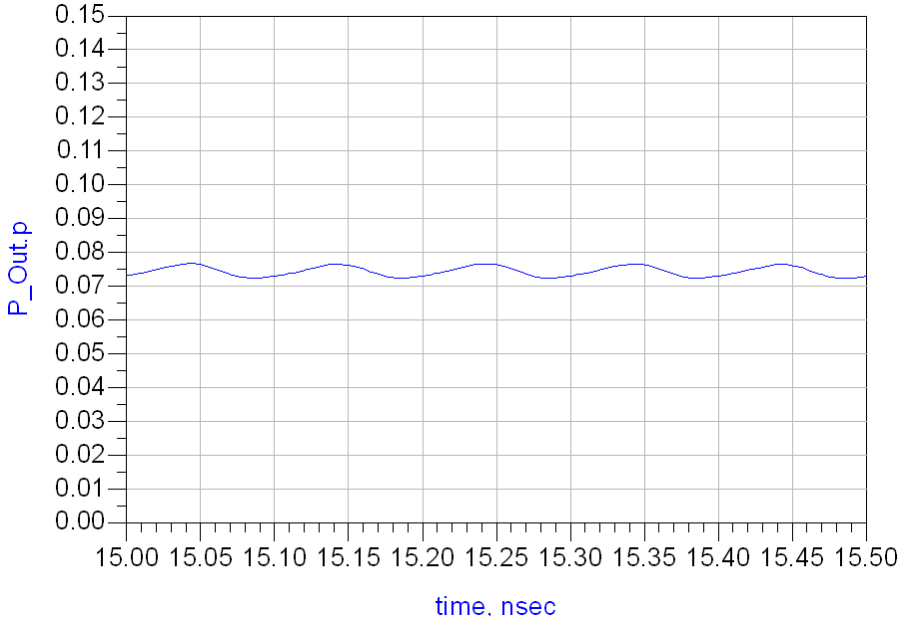

Figure 33. Output power (watts) versus time for a hybrid rectenna design with a pre-LPF.

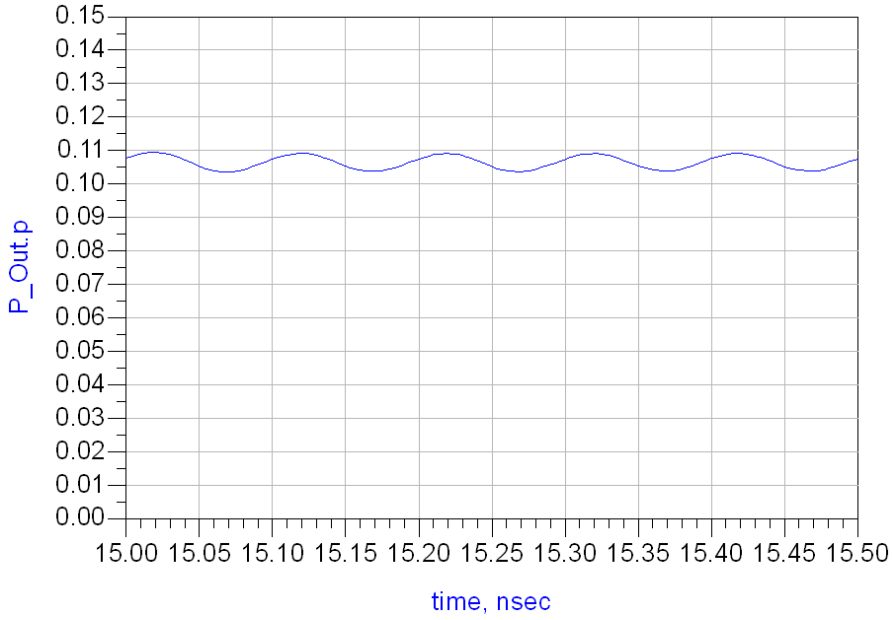

Figure 34. Output power (watts) versus time for a hybrid rectenna design with a post-LPF.

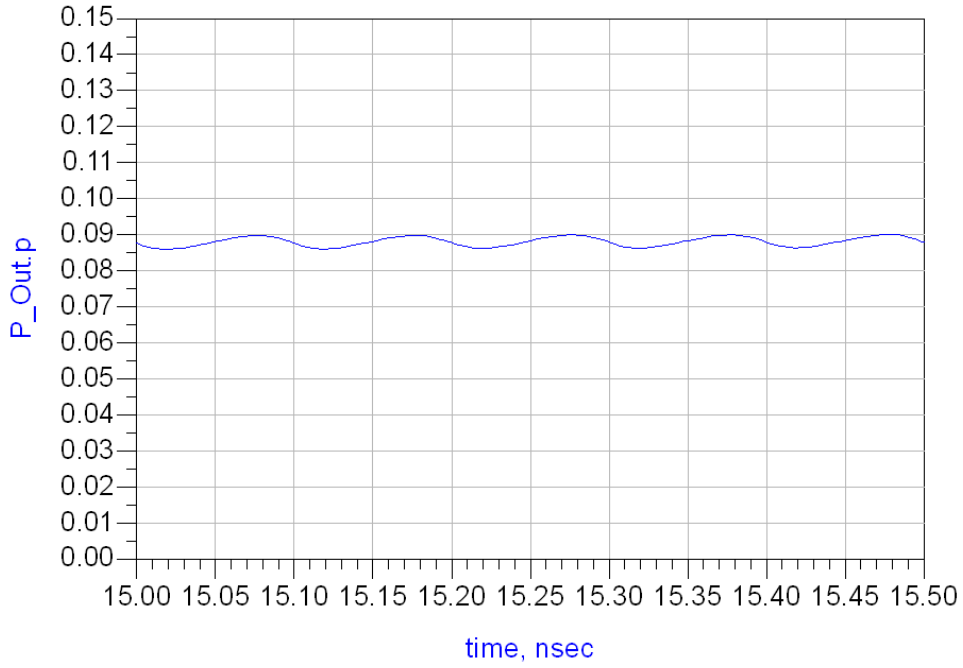

Figure 35. Output power (watts) versus time for a hybrid rectenna design without LPF.

The simulated conversion efficiency of the three hybrid rectenna designs are given in Figure 36. The efficiency of the hybrid rectenna with post-LPF is higher than those with pre-LPF and no-LPF. In comparison to the previous results given in Figure 36, the design with post-LPF is able to convert wireless power to dc power with an efficiency of 61.2% at an input power 140 mW, but the design with pre-LPF only achieves an efficiency of 45% at the same input power.

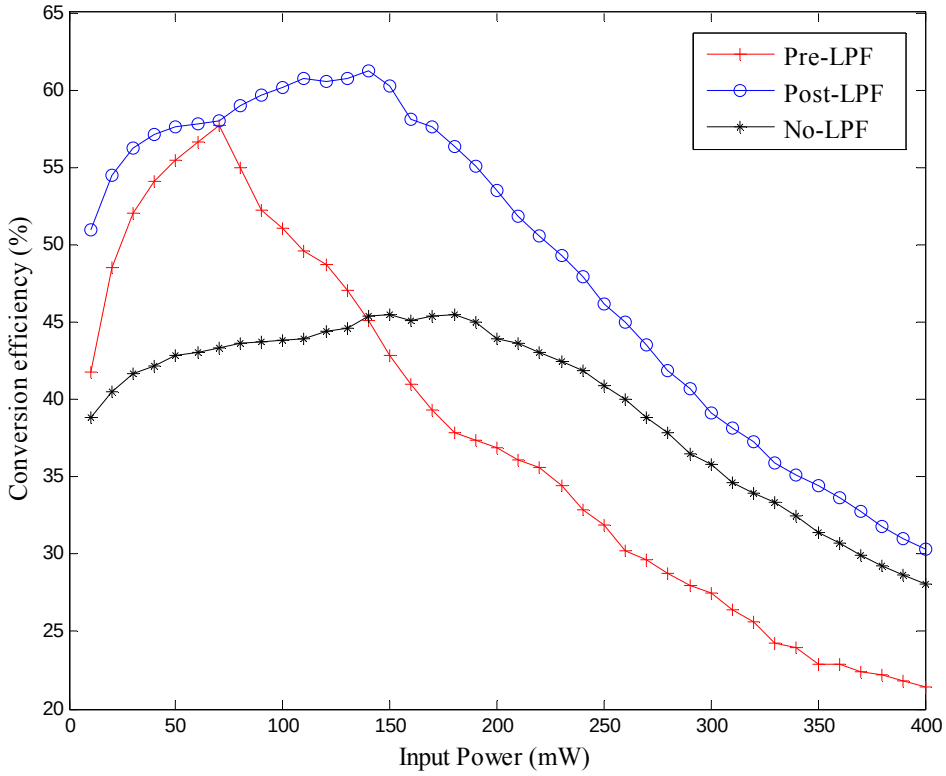

Figure 36. Simulated conversion efficiency of the hybrid rectennas.

3. Full-Wave Rectenna Design

In reference [23], Chiou presented a full-wave rectenna circuit in order to obtain a more stable dc output voltage than that a half-wave rectenna of the same chip area. He demonstrated the feasibility of a rectenna with an efficiency of 53% at an incident radiation power density of 30 W/cm^2 and frequency of 35 GHz. The rectenna comprised a power-receiving linear tapered slot antenna (LTSA), a slot line (SL) to finite-width ground coplanar waveguide (FGCPW) transition, a bandpass filter (BPF), a full-wave rectifier for rf-to-dc conversion, a dc bypass capacitor, and a resistive load. The fabricated rectenna with off-chip lumped elements is depicted on Figure 37.

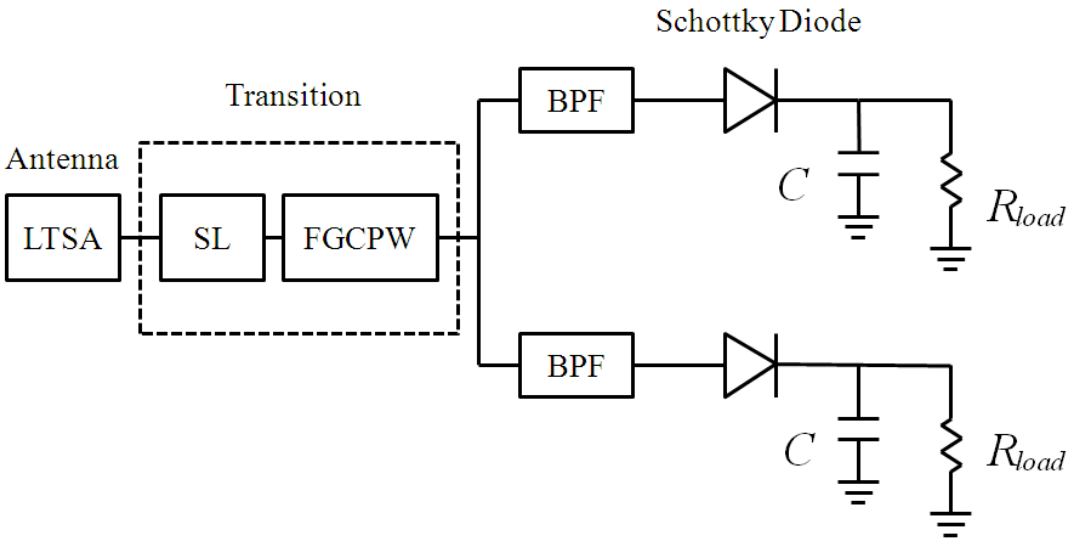

Figure 37. Block diagram of full-wave rectifier (From [23]).

As in the previous circuit, in order to minimize the size and weight, elimination of the low-pass filter is considered. For our design, a microstrip-fed dipole will be used in place of the LTSA. It is a lighter-weight structure that can be tuned to 10 GHz, whereas the LTSA is a broadband structure. Figures 38 to 40 illustrate the three different circuit designs for a full-wave rectenna.

In the ADS model, the antenna is represented by a power source with 50 Ω impedance. The diodes are matched using shorted stubs placed the required distance from the diodes. The stub location and stub length were computed using the standard stub-matching procedure [24]. Then the ADS optimization program was used to adjust the line lengths so the output power was a maximum.

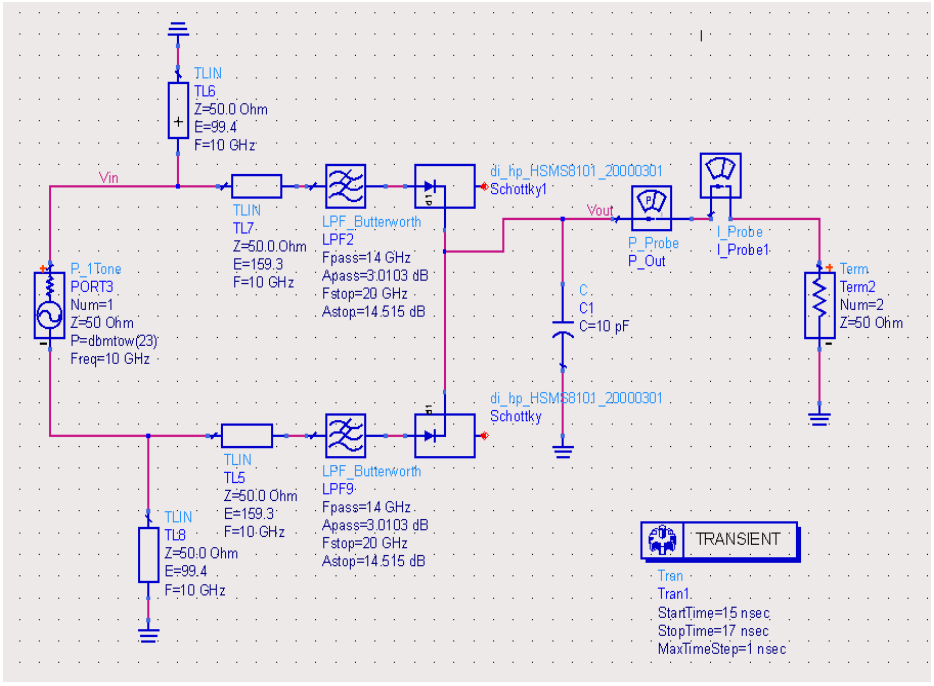

Figure 38. ADS model of a full-wave rectenna design with a pre-LPF.

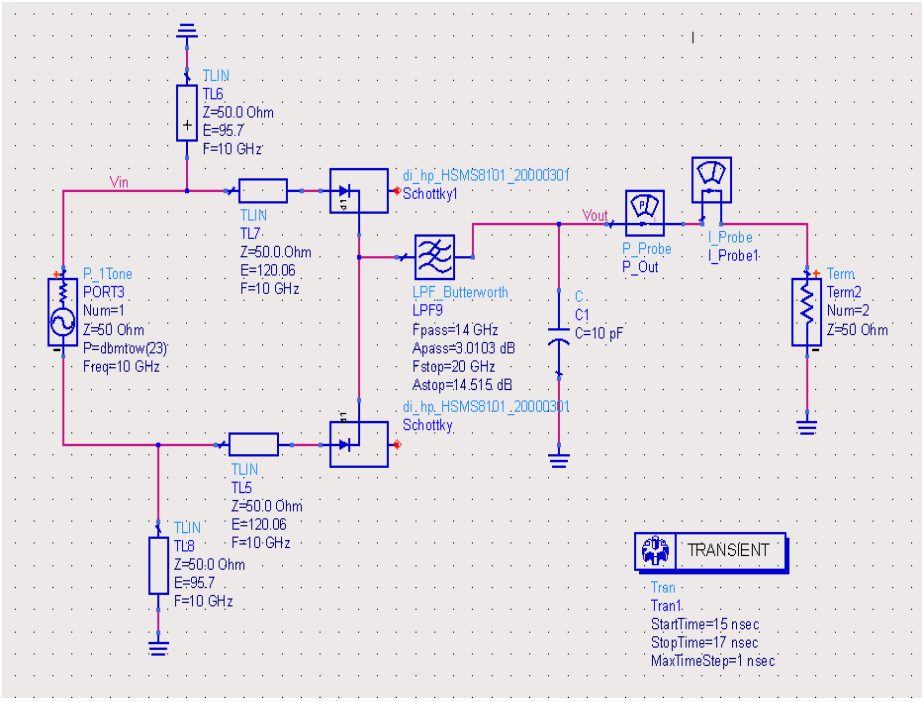

Figure 39. ADS model of a full-wave rectenna design with a post-LPF.

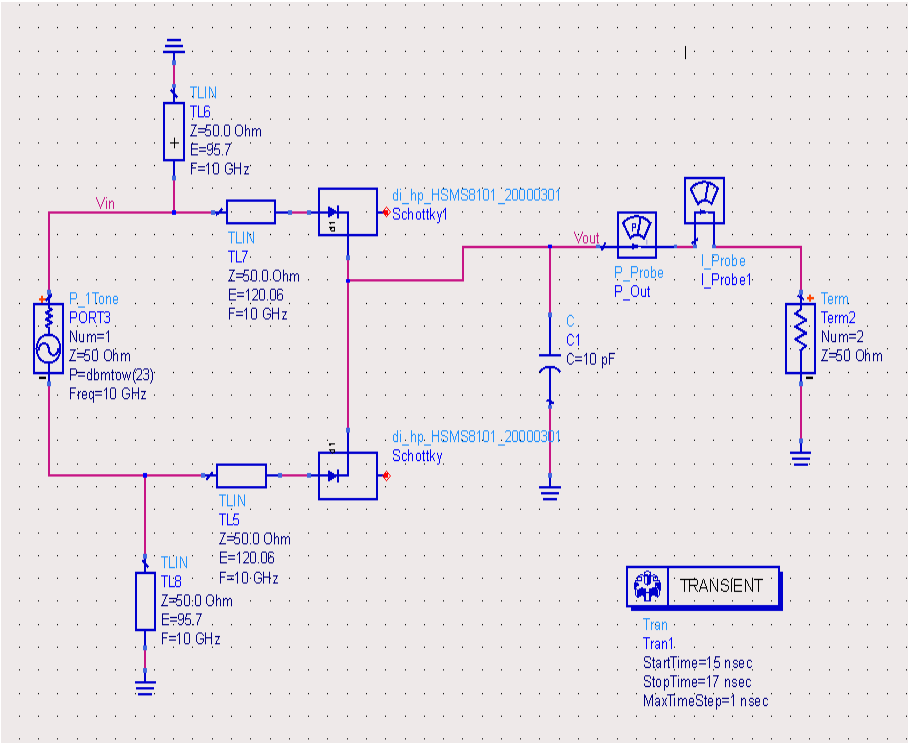

Figure 40. ADS model of a full-wave rectenna design without LPF.

The same method used to obtain Equation (3.4) was applied to the full-wave rectenna for the discharge time. The derivative expression for the output voltage V_{out} becomes

$$V_{out} = V_P \left(1 - \frac{1}{4 f R_L C} \right). \tag{3.10}$$

Equation (3.6) and (3.10) show that the average output voltage of the full-wave rectenna can approach double the half-wave rectenna.

Figures 41 to 43 illustrate the output dc power produced by three circuit designs of the full-wave rectenna that were simulated in ADS.

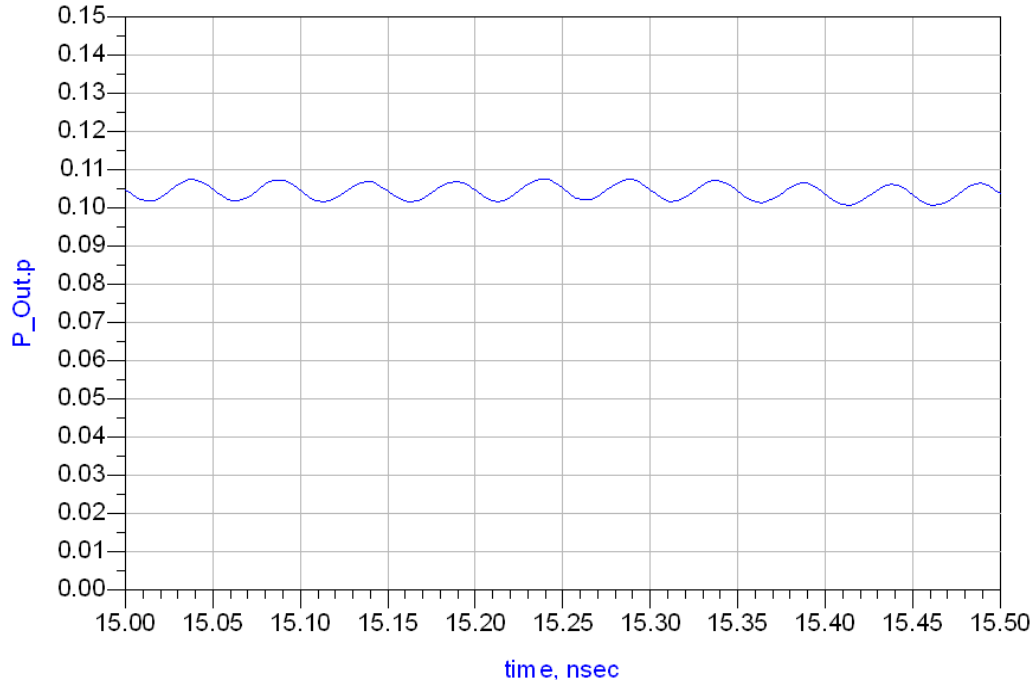

Figure 41. Output power (watts) versus time for a full-wave rectenna design with a pre-LPF.

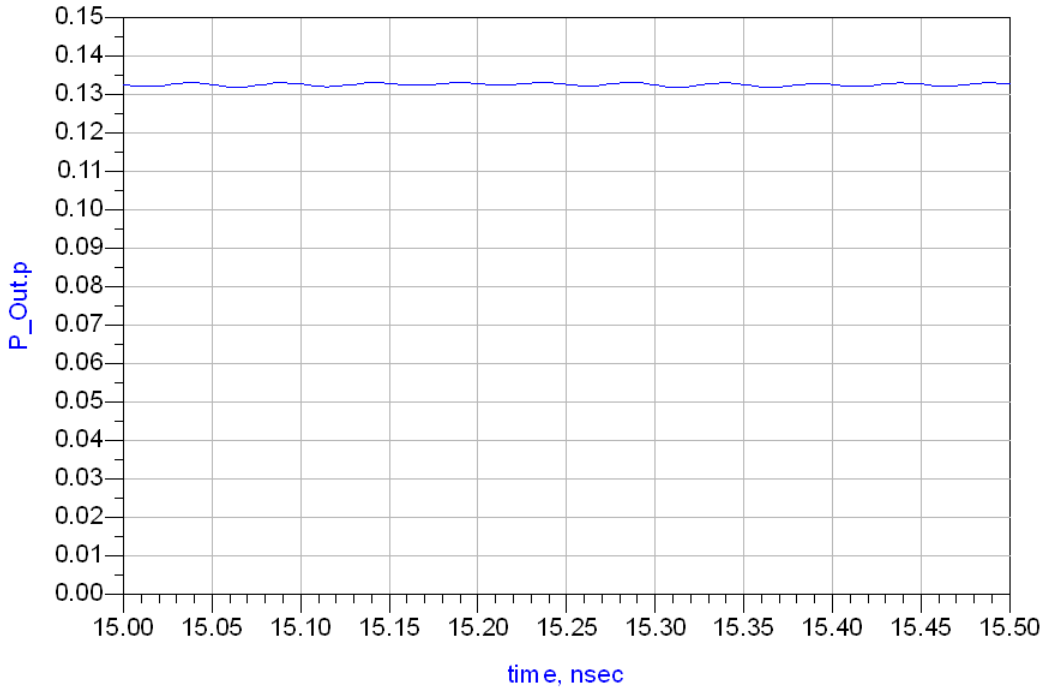

Figure 42. Output power (watts) versus time for a full-wave rectenna design with a post-LPF.

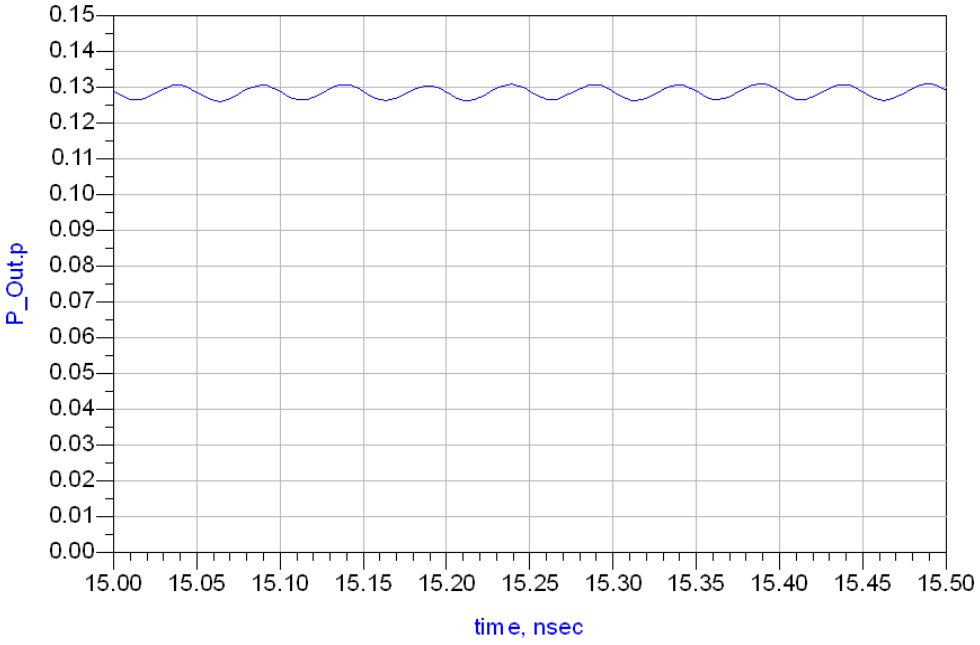

Figure 43. Output power (watts) versus time for a full-wave rectenna design without LPF.

The simulated conversion efficiencies of the three full-wave rectenna designs are given in Figure 44. In Figure 44, the efficiency of the full-wave rectenna with post-LPF and no-LPF are the same and higher than that with pre-LPF. In comparison with the previous results in Figure 33, the design with no LPF is able to convert wireless power to dc power with an efficiency of 68.1% at an input power of 170 mW, but the design with pre-LPF only achieves an efficiency of 56.6% at the same input power.

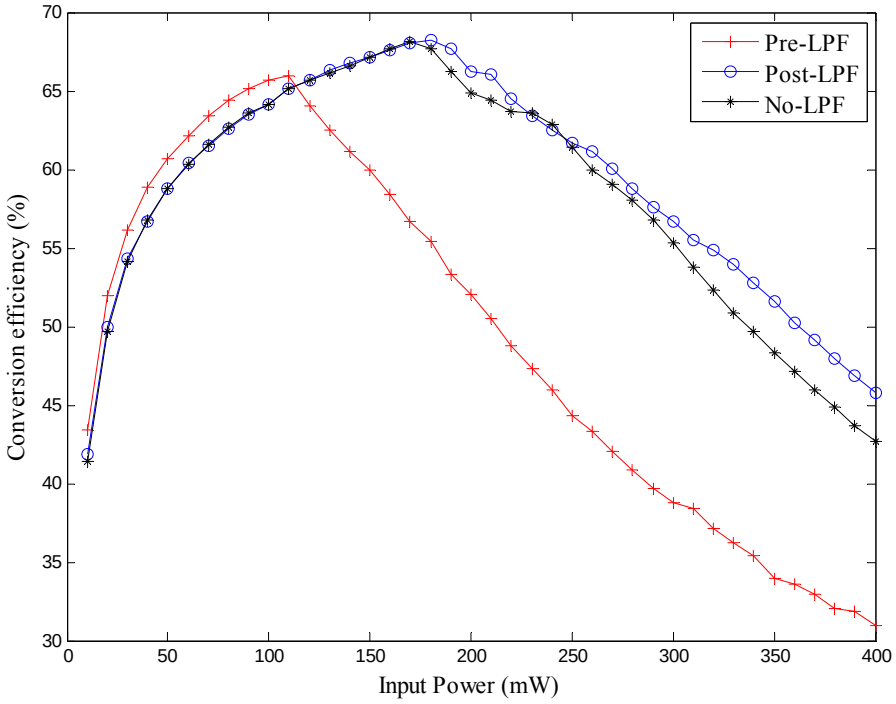

Figure 44. Simulated conversion efficiency of full-wave rectenna using ADS with different LPF.

4. Conclusion

Comparing previous results, we observed that the conversion efficiency of the hybrid rectenna is higher than that of the half-wave rectenna, which confirms the research conducted by Zbitou [18]. In order to hover the MAV, the full-wave rectenna with no LPF is selected to achieve the highest efficiency (68.1%) of the various rectenna designs and obtain more stable dc power than with the half-wave rectenna. The full-wave rectenna with no LPF also provides a lightweight design for the MAV application.

C. EVALUATION OF HARMONIC FREQUENCIES

In reference [12], Hagerty reported that reflected harmonic energy from the input or output side of the diode can alter the voltage across the diode. The diode also begins to bias itself as it produces more dc current, thus moving the dc operating point of the I-V curve in a nonlinear fashion. The diode's harmonic frequency components can possibly be radiated by the antenna, causing interference with other systems. Based on the

properties of the diode at microwave frequencies, we simulate and analyze the radiated harmonics and dc power of different rectenna designs for an input microwave power at 10 GHz. This can be accomplished using the harmonic balance (HB), nonlinear-circuit analysis module of the ADS software.

1. Harmonic Balance Analysis for the Half-Wave Rectenna

Figures 45 to 46 illustrate the harmonic balance of a half-wave rectenna with pre-LPF. The power in the fundamental frequency, the second through fourth harmonics, and the dc power are shown at four locations in the circuit (at the probes highlighted in the figure). These are the same cases shown in Figures 25 through 27, and their voltage and power curves were shown previously.

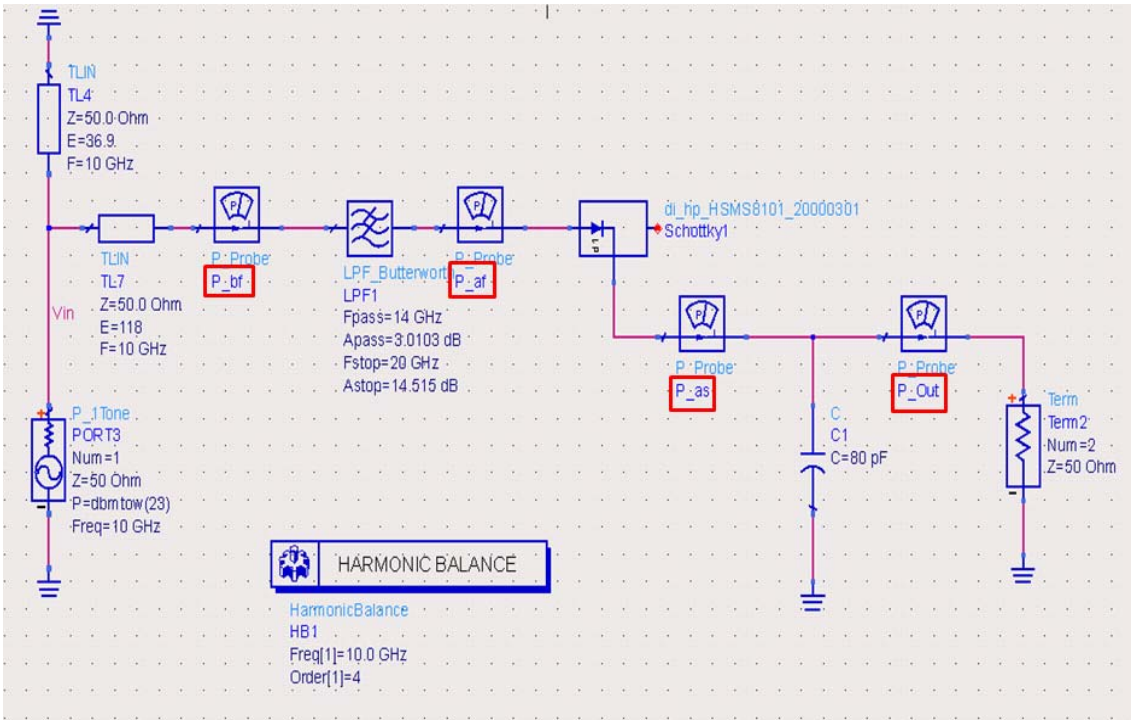

Figure 45. Harmonic balance of configuration in half-wave rectenna with pre-LPF.

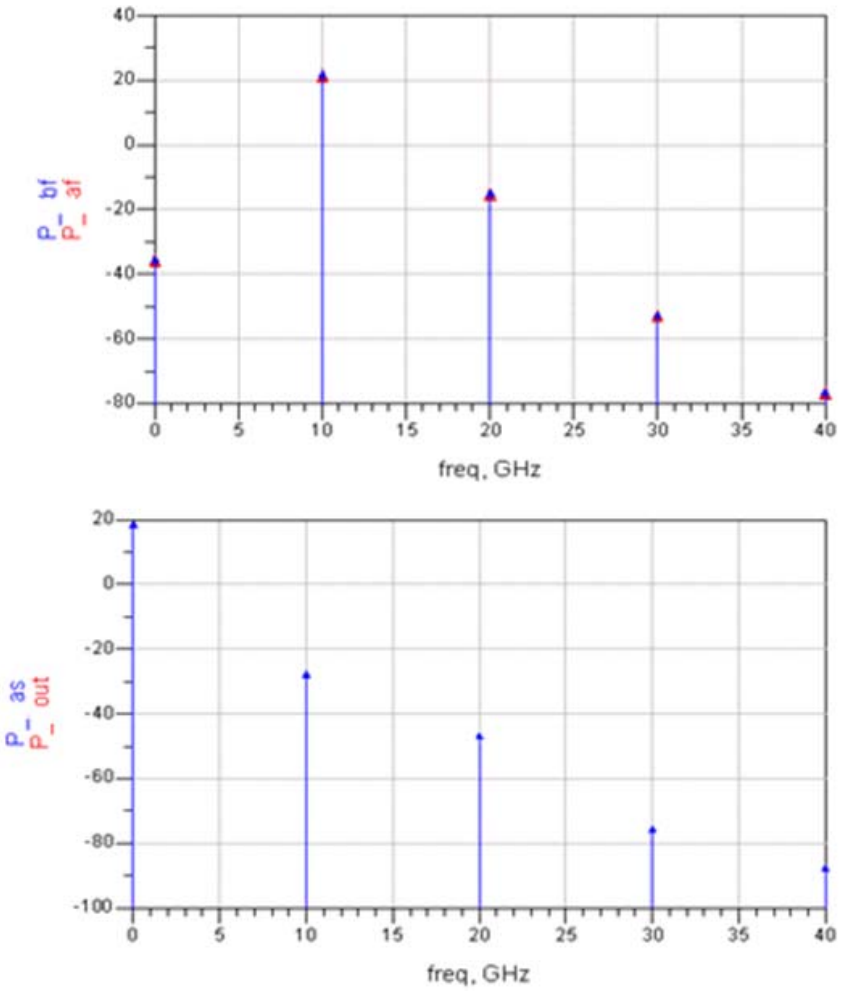

Figure 46. Simulated input power, reradiated harmonic powers, and dc power (in dBm) versus frequency for the half-wave rectenna with pre-LPF.

The simulation results for the power in the harmonics at different nodes in the circuit are given in Table 3. Pbf is the power before the low-pass filter, Paf is the power after the low-pass filter, Pbs is the power after the Schottky diode, and Pout is the power at the output of the circuit. The unit is dBm. Examination of the results in Table 3 shows that the harmonics reflected by diode are eliminated by the low-pass filter. The 80 pF capacitor performs as a dc pass filter to eliminate any leakage of 10 GHz signal. We confirm the above simulation by comparing the dc power of the harmonic balance simulation with that of the transient simulation, and found that the two results agree.

Harmonic balance analysis data for fundamental frequency of 10 GHz (Pin=23 dBm)					
Node	0 Hz	10 GHz	20 GHz	30 GHz	40 GHz
Pbf (dBm)	-34.302	22.887	-13.708	-51.469	-75.358
Paf (dBm)	-34.302	22.887	-13.708	-51.469	-75.358
Pas (dBm)	19.634	-26.804	-45.813	-74.595	-86.818
Pout (dBm)	19.634	-26.804	-45.813	-74.595	-86.818

Table 3. Harmonic balance data for the half-wave rectenna with pre-LPF.

Figures 47 to 48 illustrate the harmonic balance model of the half-wave rectenna with post-LPF and the power probes at different nodes in the circuit.

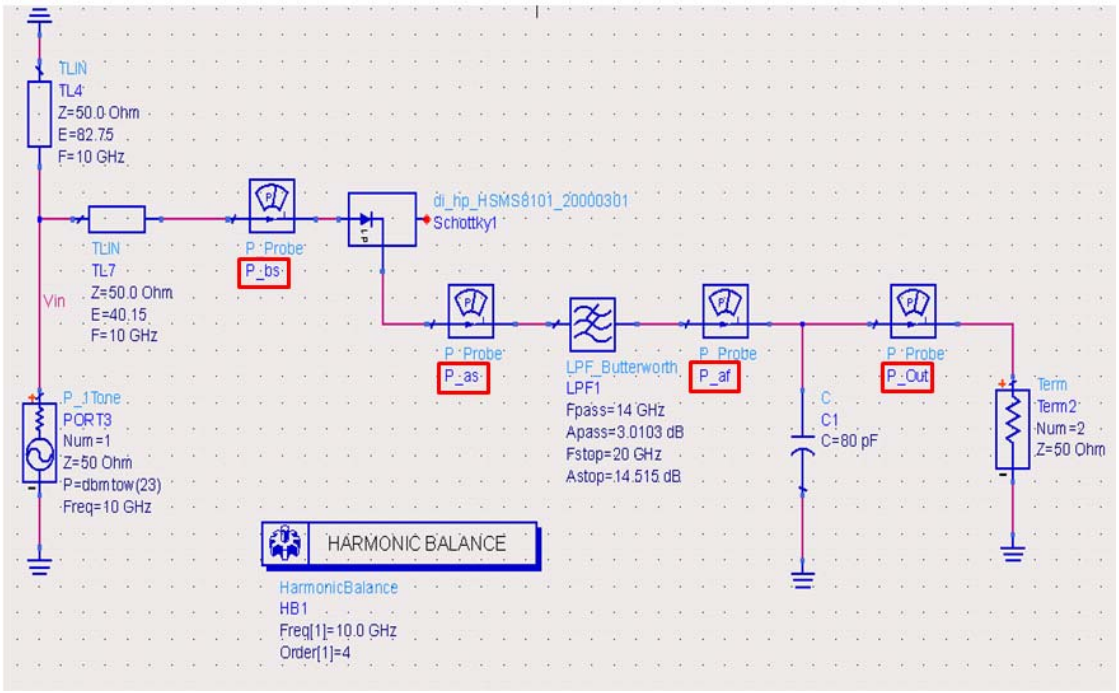

Figure 47. Harmonic balance simulation configuration for the half-wave rectenna with post-LPF.

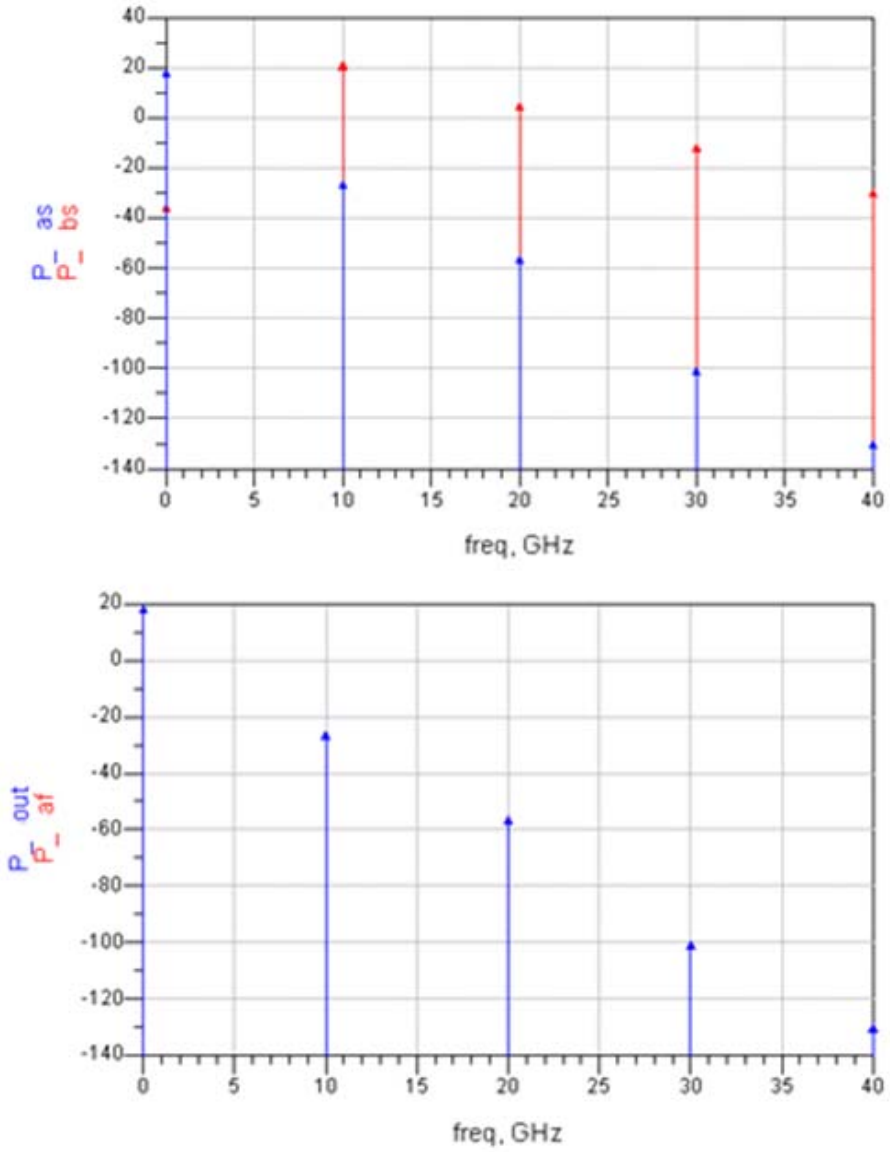

Figure 48. Simulated input power, reradiated harmonic powers, and dc power (in dBm) versus frequency for the half-wave rectenna with post-LPF.

Table 4 is a list of the power in the harmonics at different nodes in the circuit shown in Figure 45. Pbs is the power before the Schottky diode, Pas is the power after the diode, Paf is the power after the low-pass filter, and Pout is the power at the output. A comparison of the results in Table 4 shows that the highest harmonic reflected by diode and reradiated toward antenna was about 6 dBm at 20 GHz; the third and forth harmonics were negligible for this design. The low-pass filter and 80 pF capacitor reduced the

harmonics produced by diode and produced stable dc power. We confirmed the above simulation by comparing the dc power of harmonic balance simulation with the transient simulation, and the results agree.

Harmonic balance analysis data for fundamental frequency of 10 GHz (Pin=23 dBm)					
Node	0 Hz	10 GHz	20 GHz	30 GHz	40 GHz
Pbs (dBm)	-34.555	22.342	5.914	-10.423	-28.589
Pas (dBm)	19.381	-25.154	-55.312	-99.631	-129.019
Paf (dBm)	19.381	-25.154	-55.312	-99.631	-129.019
Pout (dBm)	19.381	-25.154	-55.312	-99.631	-129.019

Table 4. Harmonic balance data for the half-wave rectenna with post-LPF.

Figures 49 to 50 illustrate the harmonic balance of the half-wave rectenna without LPF and the power in the fundamental frequency, harmonics, and dc at different nodes in the circuit.

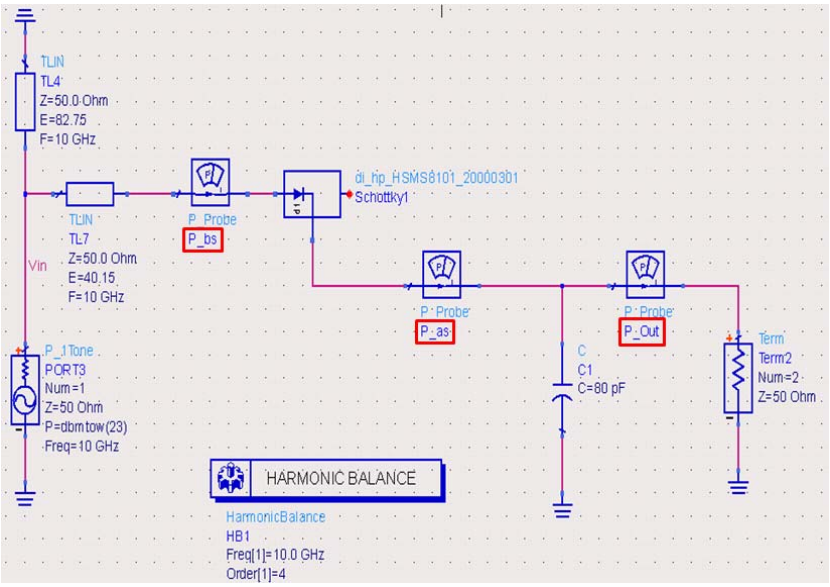

Figure 49. Harmonic balance simulation configuration for the half-wave rectenna without LPF.

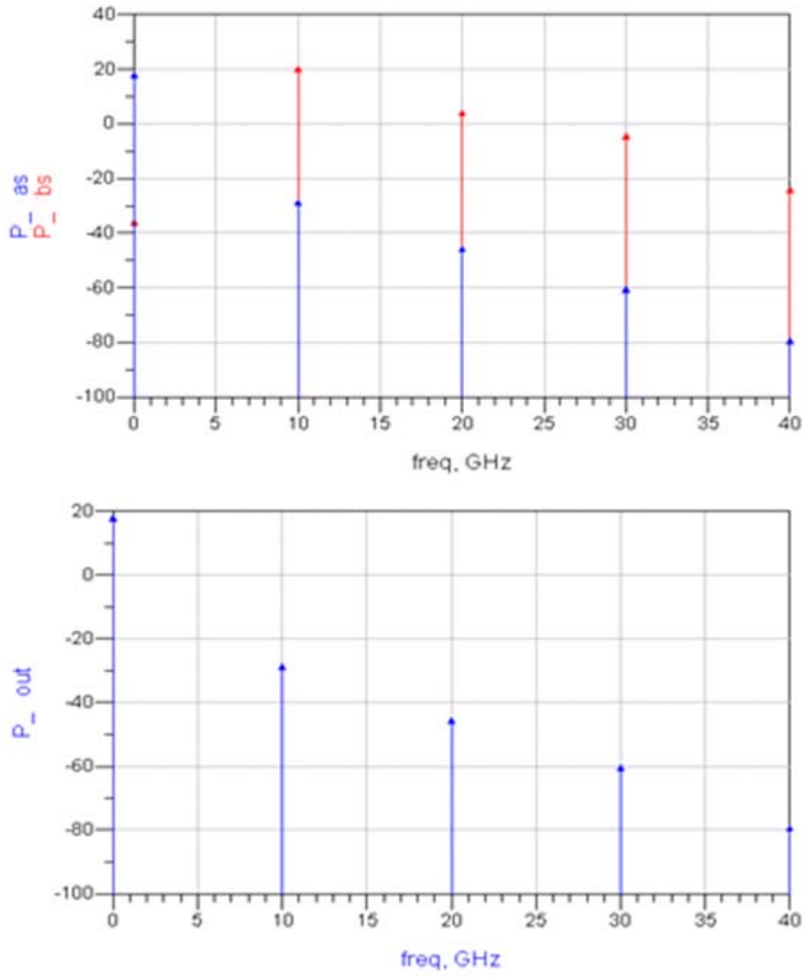

Figure 50. Simulated input power, reradiated harmonic power, and dc power (in dBm) versus frequency for the half-wave rectenna without LPF.

Table 5 is a list of the power in the harmonics at different nodes in the circuit. Pbs is the power before the Schottky diode, Pas is the power after the diode, and Pout is the power at the output. In comparison to the results in Table 5, the highest harmonic reflected by diode and reradiated toward antenna was about 5 dBm at 20 GHz, but the third and fourth harmonics were small and acceptable for our design. The 80 pF capacitor reduced the harmonics produced by diode and produced stable dc power. We confirmed the above simulation by comparing the dc power of the harmonic balance with the transient simulation, and the results agree.

Pas (dBm)	18.876	-27.815	-44.730	-59.540	-78.615
Pout (dBm)	18.876	-27.815	-44.730	-59.540	-78.615

Table 5. Harmonic-balance data for the half-wave rectenna without LPF.

2. Harmonic Balance Analysis for the Full-Wave Rectenna

Figures 51 to 52 illustrate the harmonic balance of a full-wave rectenna with pre-LPF and the power in the fundamental frequency, harmonics, and dc at different nodes in the circuit.

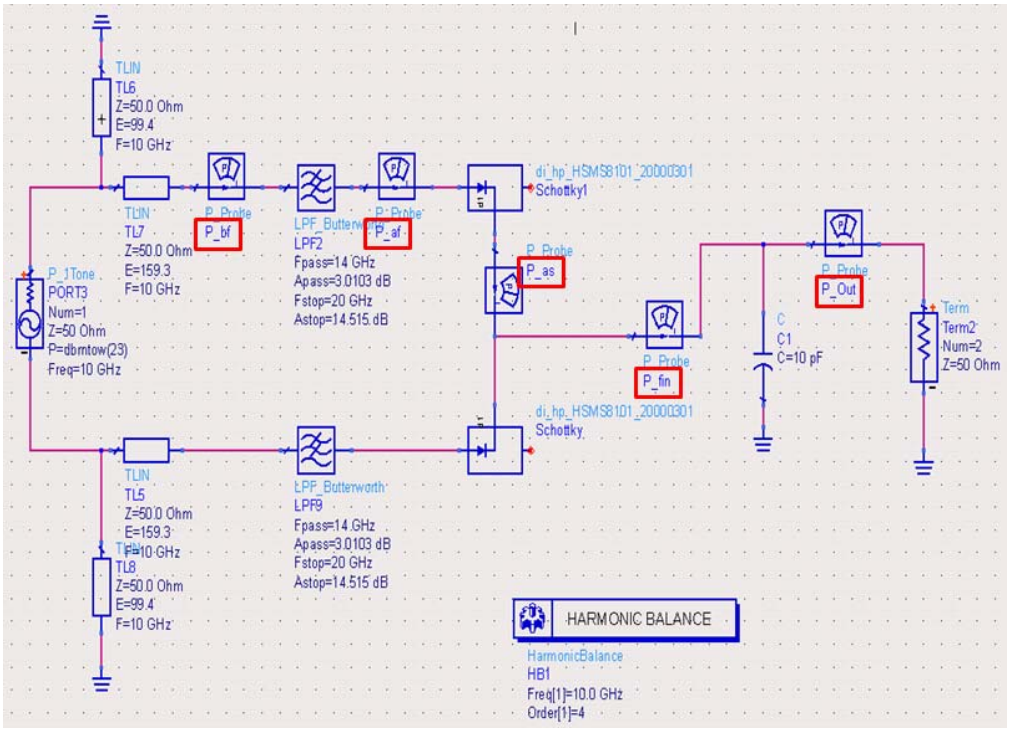

Figure 51. Harmonic-balance simulation configuration for the full-wave rectenna with pre-LPF.

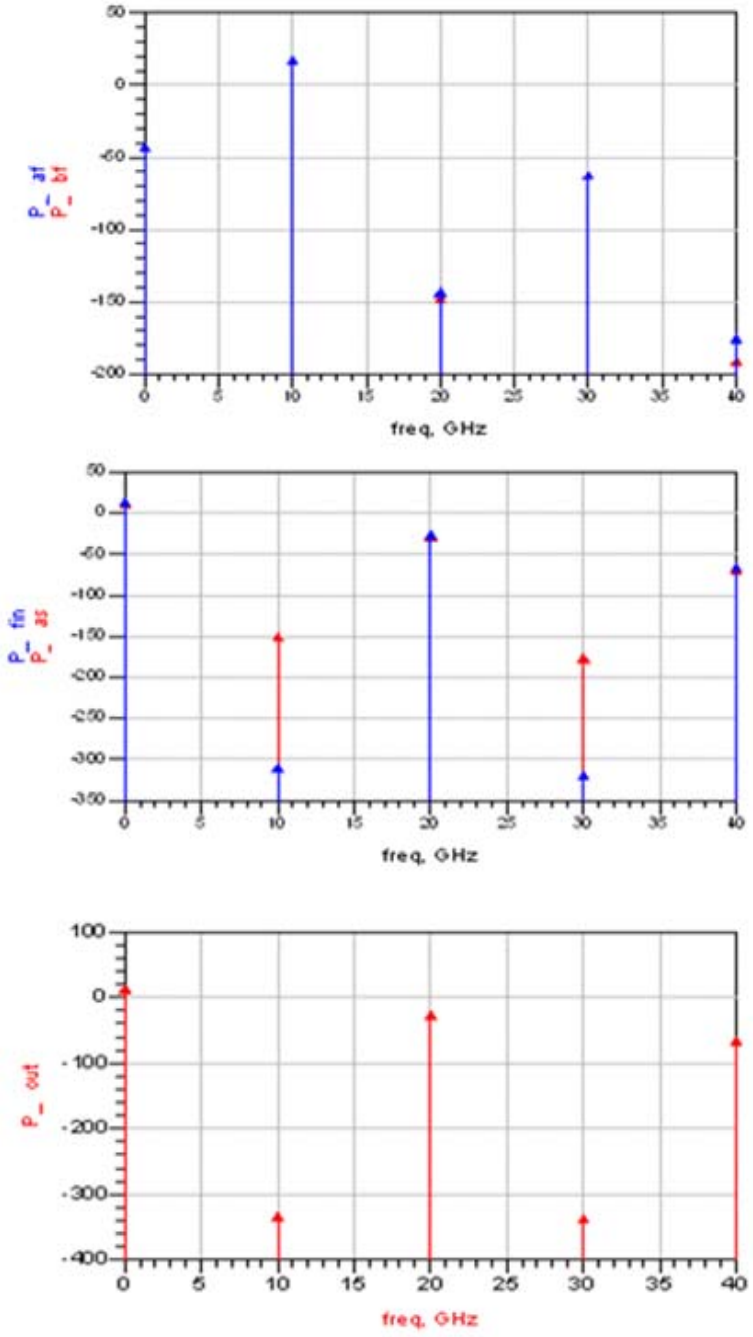

Figure 52. Simulated input power, reradiated harmonic power, and dc power (in dBm) versus frequency in full-wave rectenna with pre-LPF.

The power in the harmonics at different nodes in circuit is given in Table 6. Pbf is the power before the lowpass filter, Paf is the power after LPF, Pas is the power after the Schottky diode, Pfin is the combined power after the two diodes and Pout is the power at

the output of the circuit. The harmonics reflected by diode were eliminated by the low-pass filter. The full-wave architecture essentially eliminates the frequencies of 10 GHz and 30 GHz at the output. The 10 pF capacitor performs as a dc pass filter to eliminate the frequencies 20 GHz and 40 GHz. These simulation results were compared to the transient simulation, and the results agree.

Harmonic balance analysis data for fundamental frequency of 10 GHz (Pin=23 dBm)					
Node	0 Hz	10 GHz	20 GHz	30 GHz	40 GHz
Pbf (dBm)	-40.149	19.934	-145.177	-59.528	-188.391
Paf (dBm)	-40.149	19.934	-140.204	-59.528	-172.270
Pas (dBm)	16.797	-145.791	-23.490	-170.867	-63.062
Pfin (dBm)	19.808	-304.622	-20.480	-313.664	-60.051

Table 6. Harmonic balance data for the full-wave rectenna with pre-LPF.

Figures 53 to 54 illustrate the harmonic balance of the full-wave rectenna with post-LPF and the power in the fundamental, harmonics, and dc at different nodes in circuit.

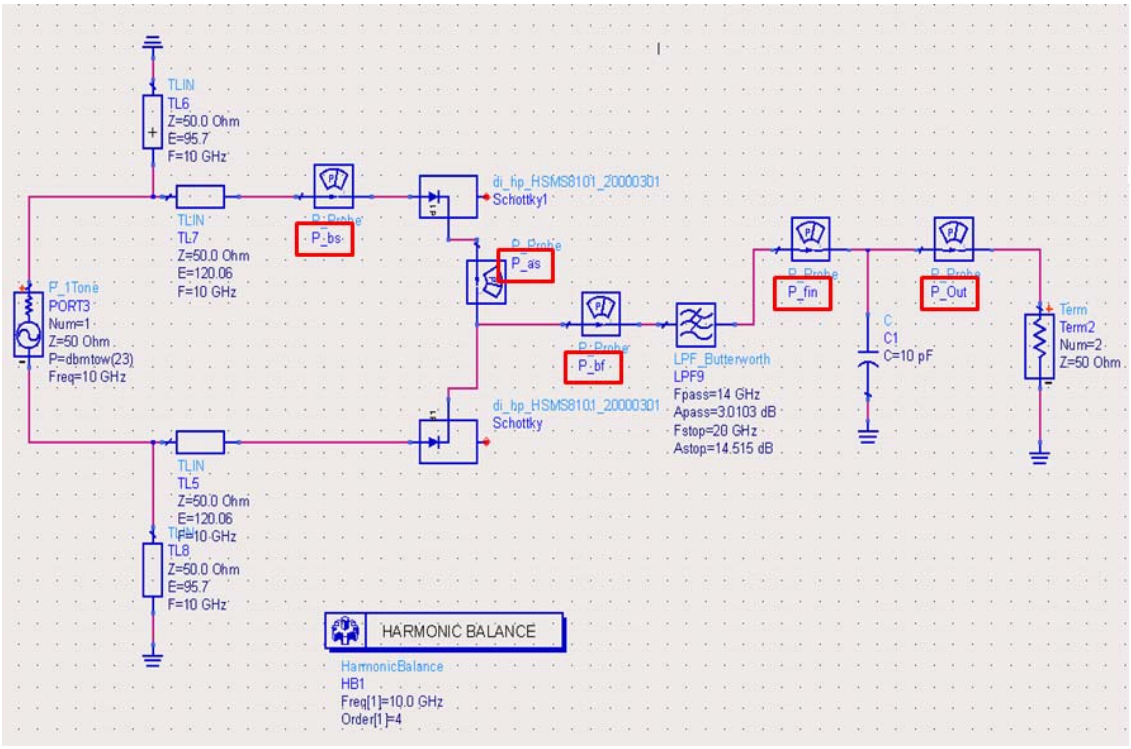

Figure 53. Harmonic-balance simulation configuration for the full-wave rectenna with post-LPF.

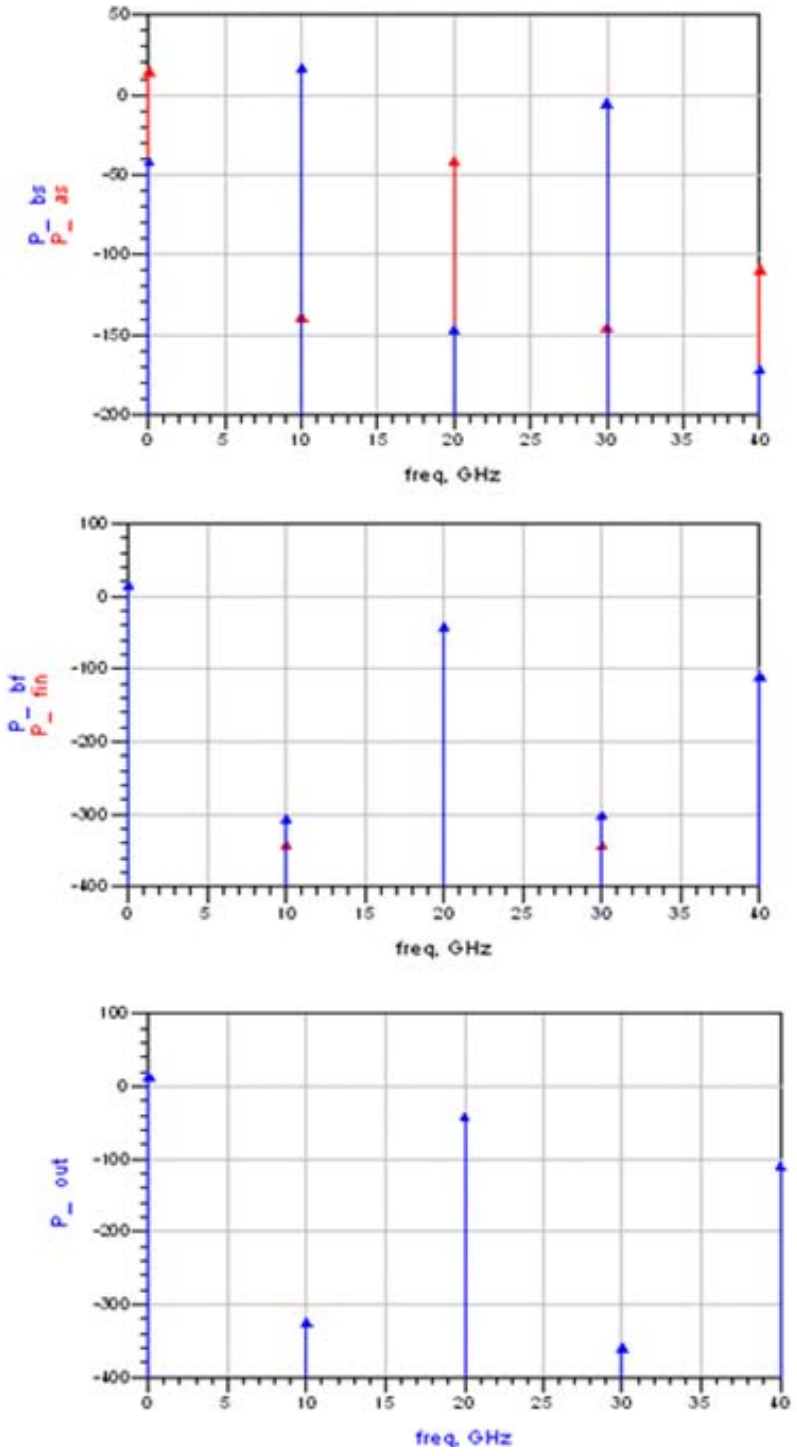

Figure 54. Simulated input power, reradiated harmonic power, and dc power (in dBm) versus frequency for the full-wave rectenna with post-LPF.

The power in the harmonics at different nodes in the circuit is given in Table 7, where Pbs is the power before the Schottky diode, Pas is the power after the diode, Pbf is the combined power of the two diodes and measured before the LPF, Pfin is the power after LPF, and Pout is the power at output. In comparison to the results of Table 7, the highest harmonic power reflected by the diode was -2 dBm at 30 GHz and there was negligible power at 10 GHz after the diode for the full-wave design. The full-wave architecture also eliminates the frequency of 30 GHz after the diode. The 10 pF capacitor performs as dc pass filter to eliminate the frequency of 20 GHz and 40 GHz. The simulation results were compared to the transient simulation, and the results agree with each other.

Table 8. Harmonic-balance data for the full-wave rectenna without LPF.

3. Findings

After comparing the three half-wave rectenna designs, we conclude that the half-wave rectenna with pre-LPF has better performance due to its limitation of harmonics back toward the antenna and slightly higher efficiency, albeit not much. The half-wave rectenna only converts at best half of the microwave energy, but the full-wave rectenna ideally converts all power, due to its architecture. We also observe that the full-wave rectenna without LFP converts more dc power than other designs and the full-wave rectifier design eliminates the fundamental frequency and third harmonic frequency at the output. In order to have a lightweight rectenna, the full-wave rectenna without LFP is selected. In the next chapter, we discuss the impedance of the full-wave rectification rectenna without LPF and optimize the impedance matching unit.

THIS PAGE INTENTIONALLY LEFT BLANK

IV. RECTENNA IMPLEMENTATION

A. RECTENNA IMPEDANCE DESIGN

Chapter III presented the simulation results for several different rectenna designs. We conclude that the full-wave rectenna without LPF meets the MAV requirement because of its higher conversion efficiency and constant output power. This chapter discusses the impedance matching of the rectenna and the circuit design and layout.

1. Full-Wave Rectenna Design

The full-wave rectenna design with the final optimized circuit and dielectric material is shown in Figure 57. The simulated output dc power, voltage, and current of full-wave rectenna are shown in Figure 58. The output power of the rectenna is 131 mW for an input power of 23 dBm, and the voltage oscillates from 2.55 V to 2.53 V.

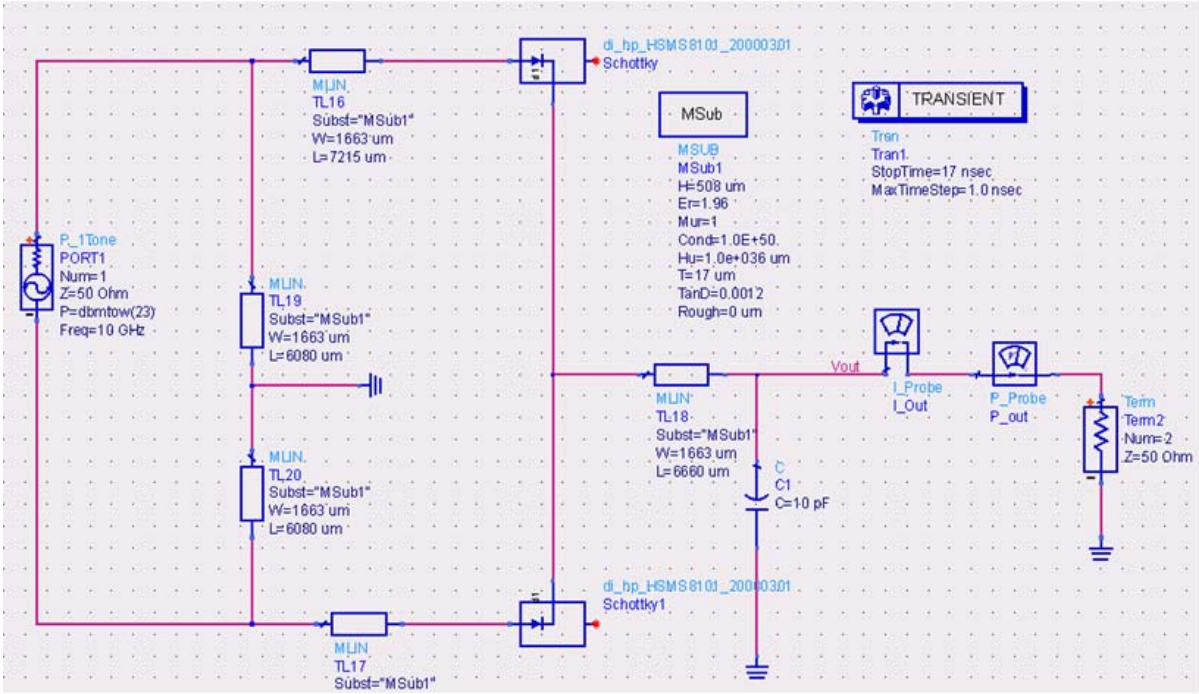

Figure 57. Final circuit design of full-wave rectification rectenna.

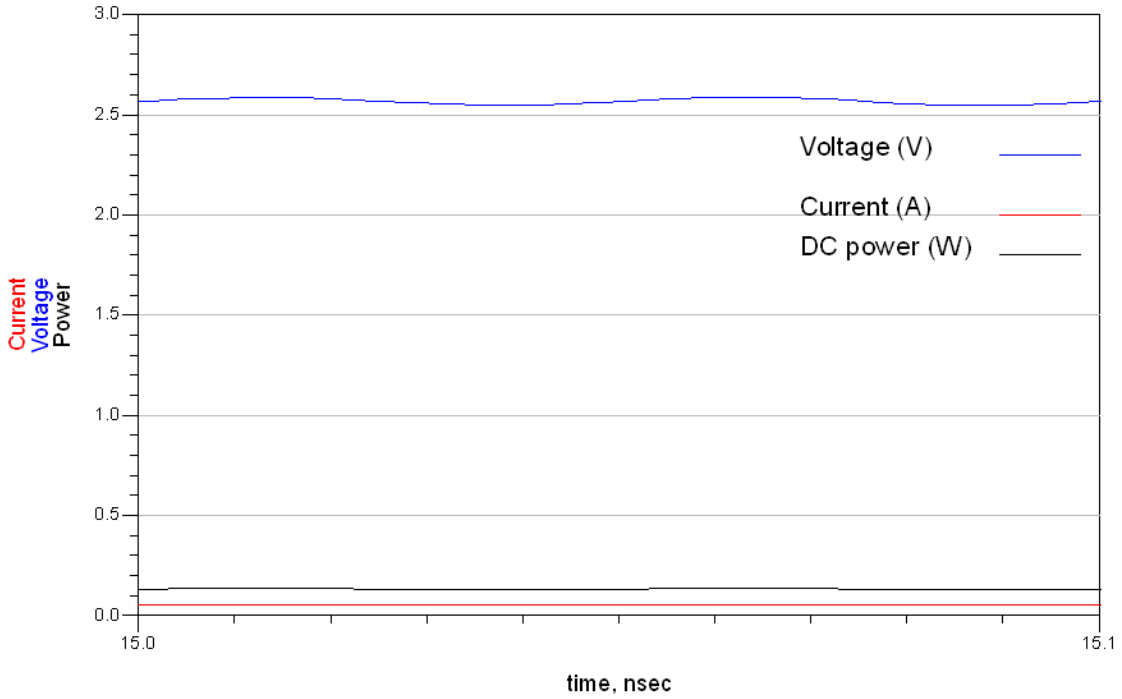

Figure 58. Simulated output power, voltage, and current-versus-time for the full-wave rectenna with a 23 dBm input.

2. Performance of Full-Wave Rectenna Impedance Design

The simulated conversion efficiency of the full-wave rectenna as a function of input power is shown in Figure 59. The full-wave design is able to convert microwave power to dc power with an efficiency of 65.9% at an input power of 200 mW. The simulated output power of the full-wave rectenna design is shown in Figure 60. The full-wave design is able to produce 132 mW at an input power of 200 mW. In addition, the full-wave input–output characteristic is nearly linear, from 20 mW to 200 mW. From 200 mW to 400 mW of input power, the output begins to saturate. As a result, we prefer using the full-wave rectenna design for MAV application at an input power of 200 mW because it achieves the highest efficiency. However, to obtain this high power output requires a very large power density at the antenna, as observed in Figure 19.

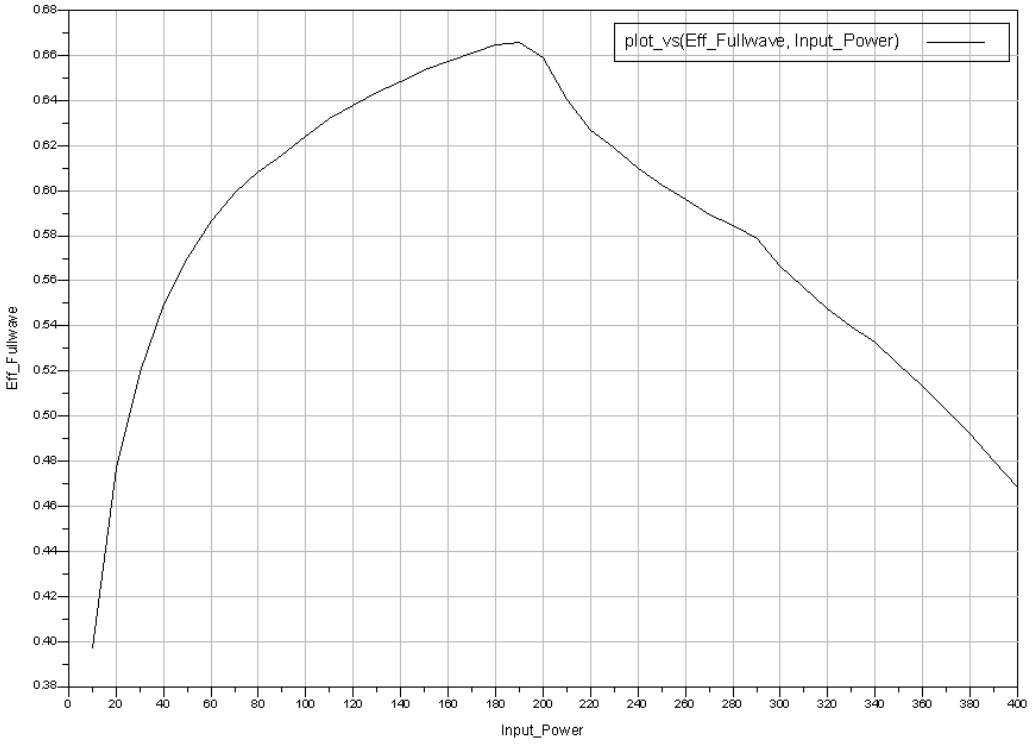

Figure 59. Conversion efficiency of final full-wave rectenna design.

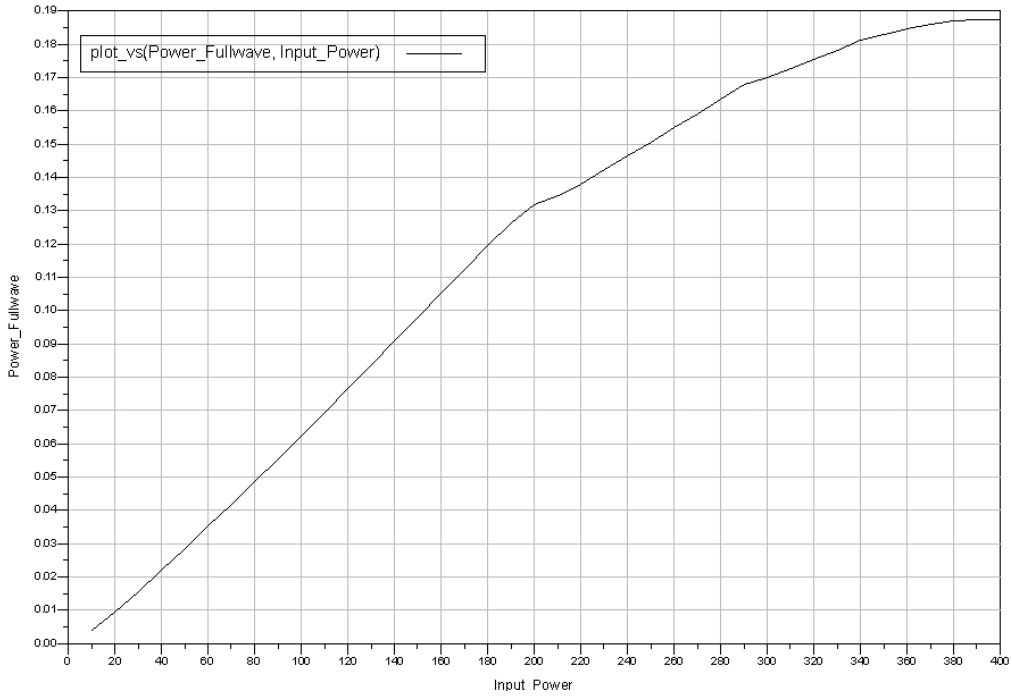

Figure 60. Output power (watts) of final full-wave rectenna design.

B. CIRCUIT LAYOUT AND TUNING

1. Circuit Design Layout

The final circuit-design layout is shown in Figure 61. In Figure 61, the full-wave rectenna includes a matching unit, two diodes, and one capacitor. Based on the ADS simulation, the HSMS 8101 has an S_{22} characteristic impedance of 4.7 + j40 Ω. In order to have a compact circuit design to reduce the size and weight of the printed circuit board (PCB), we bend the impedance-matching unit. The length of ℓ and d are the same values as those in the ADS model in Figure 57. The calculation of the length of L_0 is discussed in the next section. For lightweight design, we select a dielectric constant of 1.96 for the substrate. The properties of the dielectric material are listed in Table 9.

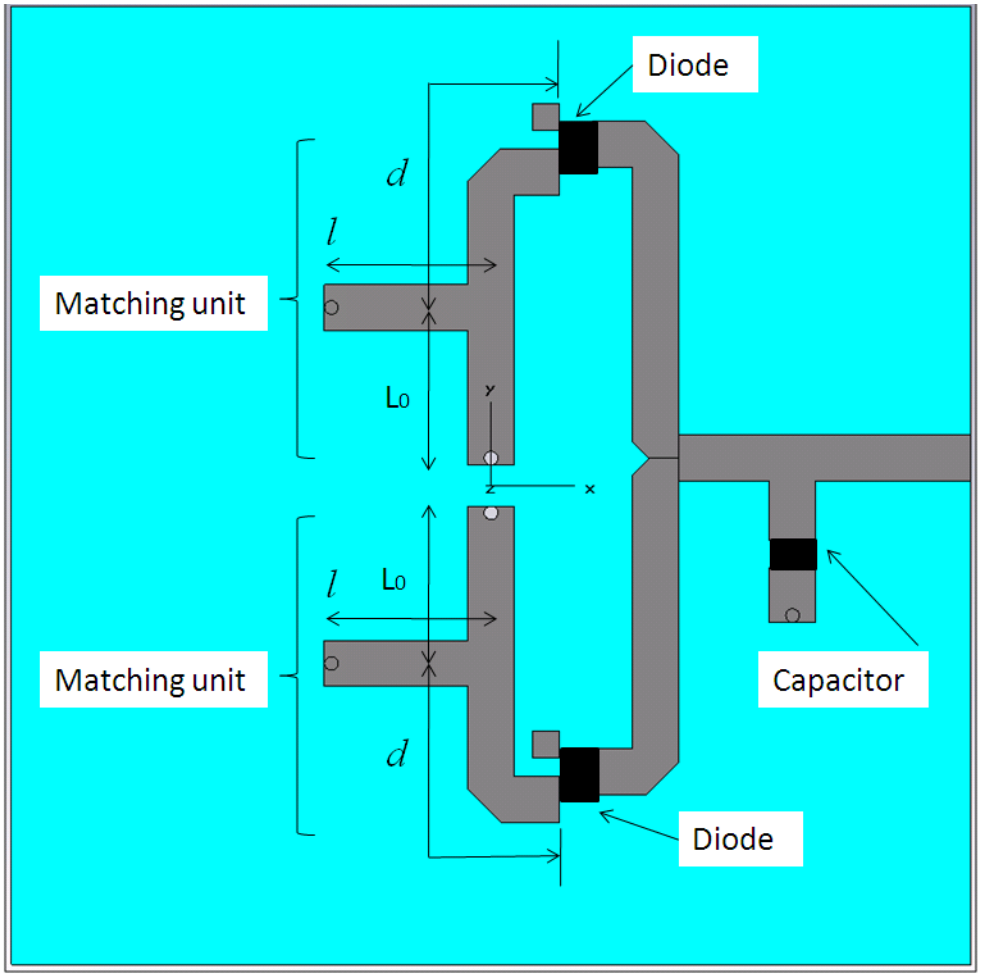

Figure 61. Final circuit layout of the full-wave rectenna modeled in CST.

Dielectric Material	Duroid 5880LZ from Rogers Corporation
Dielectric Constant ε_r	1.96 ± 0.04
Loss Tangent, $\tan\delta$	0.0019 @ 10 GHz
Substrate Height, h	0.508 mm microstrip circuit
Copper Thickness	0.5 oz or 17 μm

Table 9. Properties of Rogers Duroid 5880LZ.

2. Calculation of the Matching Unit

Figure 62 shows the portion of the circuit between an antenna terminal and the diode. As seen in Figure 61, the circuit occurs at both dipole terminals. When a sinusoidal voltage is applied at the terminals, one diode will conduct, appearing as a complex impedance. The values of ℓ and d have been chosen to match the conducting diode to the 50 Ω characteristic impedance of the line. This was done using the ADS parameter sweep.

In order for the dipole to be matched at the conducting diode side, the other side must present an open circuit at the antenna terminal. Therefore L_0 must be chosen so that the combination of the open circuit at the diode (d) and its matching stub (ℓ) present an open circuit at the antenna terminal.

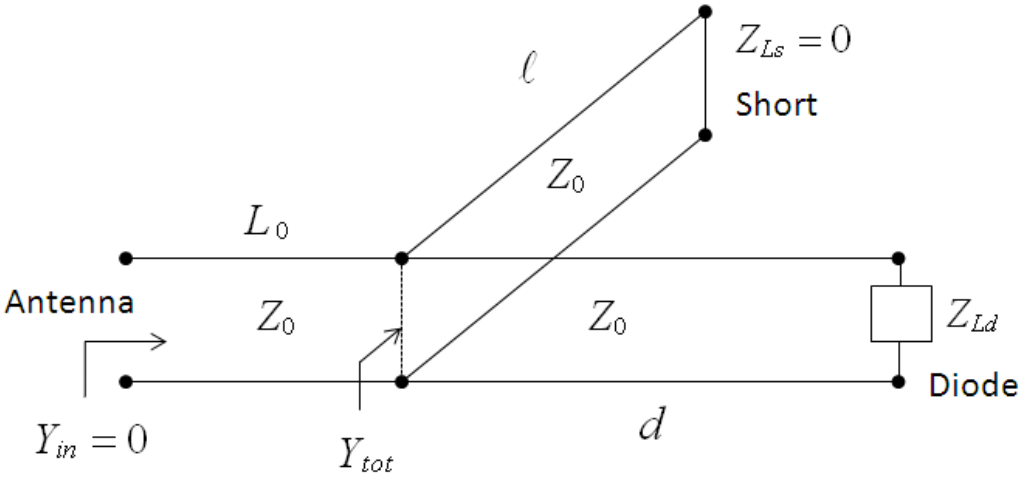

Figure 62. Circuit diagram showing the stub position.

The impedance of the shorted transmission line ℓ at the junction can expressed as

$$Z_{ins} = Z_0 \frac{Z_{Ls} + jZ_0 \tan(\beta\ell)}{Z_0 + jZ_{Ls} \tan(\beta\ell)} = jZ_0 \tan(\beta\ell) \tag{4.1}$$

and the admittance is

$$Y_{ins} = \frac{1}{Z_{ins}} = \frac{1}{jZ_0 \tan(\beta\ell)} \tag{4.2}$$

where Z_0 is 50 Ω and Z_{Ls} is approximately 0 Ω. In addition, the impedance of the transmission line d at the junction can be expressed as

$$Z_{ind} = Z_0 \frac{Z_{Ld} + jZ_0 \tan(\beta d)}{Z_0 + jZ_{Ld} \tan(\beta d)} = \frac{Z_0}{j \tan(\beta d)} \tag{4.3}$$

where

$$Z_{Ld} = \begin{cases} 4.7 + j40 & \text{conducting} \\ \infty & \text{nonconducting} \end{cases} \tag{4.4}$$

and its admittance at the junction is

$$Y_{ind} = \frac{1}{Z_{ind}} = \frac{j \tan(\beta d)}{Z_0}. \tag{4.5}$$

The total admittance at the junction is

$$Y_{tot} = Y_{ins} + Y_{ind} = \frac{-j}{Z_0 \tan(\beta \ell)} + \frac{j \tan(\beta d)}{Z_0}. \tag{4.6}$$

The impedance looking into the junction must be transformed through a distance L_0.

$$Z_{in} = Z_0 \frac{Z_{tot} + jZ_0 \tan(\beta L_0)}{Z_0 + jZ_{tot} \tan(\beta L_0)} = \frac{1}{y_0} \frac{1 + jy_{tot} \tan(\beta L_0)}{y_{tot} + j \tan(\beta L_0)} \tag{4.7}$$

where $y_{tot} = \frac{Y_{tot}}{Y_0}$. Therefore

$$Y_{in} = \frac{1}{Z_{in}} = \frac{y_{tot} + j \tan(\beta L_0)}{1 + jy_{tot} \tan(\beta L_0)}. \tag{4.8}$$

The maximum power from the antenna occurs when Y_{in} equals to 0, therefore

$$y_{tot} + j \tan(\beta L_0) = 0 \tag{4.9}$$

or

$$L_0 = \frac{1}{\beta} \tan^{-1}\left(j \frac{Y_{tot}}{Y_0} \right). \tag{4.10}$$

This is the initial value of the length of the stub L_0 which is a function of Y_{tot}. The length of this stub depends on the length of matching lines ℓ and d.

The parameter sweep in CST was used to fine-tune the value of L_0. Figure 63 shows the CST model of the circuit with one terminal of the dipole connected to a 50 Ω line and the other diode open, to simulate a nonconducting half cycle. Figure 64 shows the best match at 10 GHz obtained with the parameter sweep. The value of L_0 is 4.226 mm, which was used in the final design. The radiation pattern for the circuit of Figure 63 is shown in Figure 65.

V. SUMMARY, CONCLUSIONS AND RECOMMENDATIONS

A. SUMMARY

This thesis evaluated different rectenna designs for wireless power transmission for MAV applications using the ADS simulation software. The first and second chapters covered the history of WPT and research performed previously at NPS. Various rectification circuit designs and antennas were simulated using Agilent ADS software and CST Microwave Studio. A shorted stub microstrip tuner was introduced for impedance matching. The dipole-antenna array was selected to reduce the weight of the rectenna in order to hover a MAV.

A full-wave rectenna without low-pass filter was selected to reduce the weight of the rectenna element yet achieve high conversion efficiency. In addition, a harmonic balance analysis was conducted in order to compare the influence of the harmonics on various circuit designs. The full-wave rectenna circuit was simulated to verify performance, and the conversion efficiency is about 65%. The length of matching units were calculated and optimized in Microwave Studio in order to lay out the circuit.

B. RECOMMENDATIONS

The result of this thesis shows that the improved full-wave rectanna converts more dc power than a half-wave rectenna, as verified by simulation. A dipole antenna was used instead of a circular-patch antenna in order to reduce the weight of the rectenna system. The conversion efficiency of the rectenna can be improved, however, and some recommendations follow.

1. Using High-Power Transmitter and High-Gain Antenna

The performance of the WPT can be further enhanced by complementing it with a high-power transmitter and high-gain antenna to increase the power-density incident on the rectenna array.

2. Building a Hardware Prototype

Upon the successful design of the dipole antenna and rectifier circuit using CST Microwave Studio, it is necessary to build a prototype of the full-wave rectenna to measure the output dc voltage and current and determine the realized efficiency.

3. Running Simulations for an Array

The MWS simulation should be done for an array of dipoles to assess the effect of mutual coupling. The array element may need to be returned to compensate for the mutual coupling.

4. Reducing Polarization Loss

The dipole is linearly polarized, and therefore loss of signal will occur if the MAV antenna is orientated in a cross-polarized direction in flight. A circularly polarized antenna should be considered to reduce the polarization loss factor.

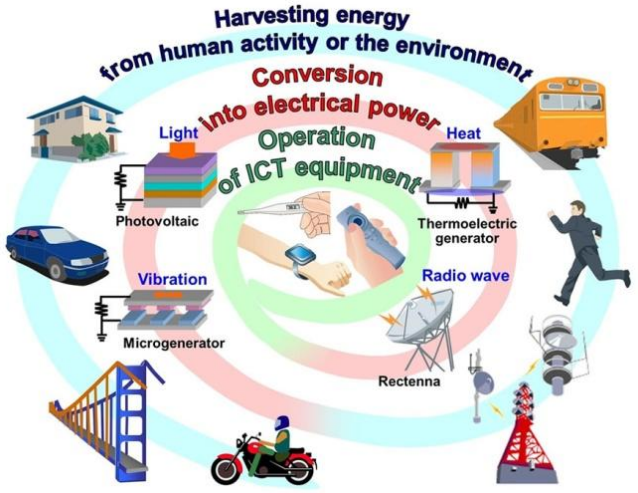
Energy Harvesting

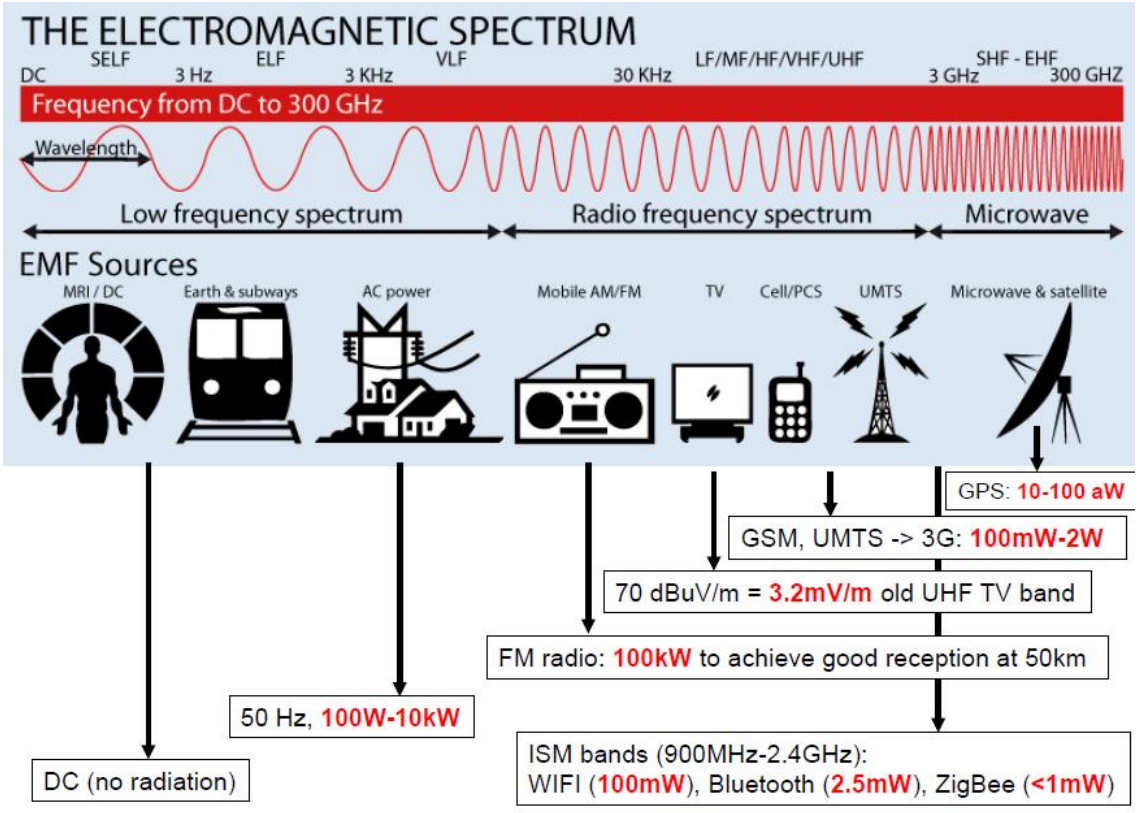
Energy Harvesting

Energy harvesting is the process by which energy is derived from external sources (e.g. solar power, thermal energy, wind energy, salinity gradients, and kinetic energy), captured, and stored for small, wireless autonomous devices.

Energy harvesters provide a very small amount of power for low-energy electronics. The energy source for energy harvesters is present as ambient background and is free. For example, temperature gradients exist from the operation of a combustion engine and in urban areas, there is a large amount of electromagnetic energy in the environment because of radio and television broadcasting.



Energy Harvesting



Energy Harvesting

- Examples of small-scale energy harvesters are:
- Wristwatches powered by kinetic energy (called automatic watches) where the movement of the arm is used. The arm movement causes winding of its mainspring. A newer design uses movement of a magnet in the electromagnetic generator instead to power the quartz movement. The motion provides a rate of change of flux, which results in some induced EMF on the coils. The concept is simply related to Faraday's Law.
- Photovoltaics is a method of generating electrical power by converting solar radiation (both indoors and outdoors) into direct current electricity using semiconductors that exhibit the photovoltaic effect. Conventional photovoltaic power generation employs solar panels composed of a number of cells containing a photovoltaic material.
- Thermoelectric generators consist of the junction of two dissimilar materials and the presence of a thermal gradient. Large voltage outputs are possible by connecting many junctions electrically in series and thermally in parallel. Typical performance is 100-200 μV/K per junction. These can be utilized to capture mW of energy from industrial equipment, structures, and even the human body. They are typically coupled with heat sinks to improve temperature gradient.

Energy Harvesting

- Micro wind turbine are used to harvest wind energy readily available in the environment in the form of kinetic energy to power the low power electronic devices such as wireless sensor nodes. When air flows across the blades of the turbine, a net pressure difference is developed between the wind speeds above and below the blades. This will result in a lift force generated which in turn rotate the blades.
- Piezoelectric crystals or fibers generate a small voltage whenever they are mechanically deformed. Vibration from engines can stimulate piezoelectric materials, as can the heel of a shoe, or the pushing of a button.
- Special antennas can collect energy from stray radio waves, this can also be done with a Rectenna and theoretically at even higher frequency EM radiation with a Nantenna.
- Even power from keys pressed during use of a portable electronic device or remote controller, using magnet and coil or piezoelectric energy converters, may be used to help power the device.

Energy Harvesting

- Low power has been the most important electronic design criterion for at least the last ten years. Thanks to Moore's Law, semiconductor power levels have dropped dramatically, often consuming milliwatts in run mode and nanowatts in standby mode. As a direct result, ultra-low-power wireless sensorless networks finally became possible and their adoption has been dramatic. Now, sensors stand alone in remote or hard-to-reach areas to warn of building and bridge stresses, air pollution, forest fires, pending landslides, worn bearings, and wing vibration. Low-power wireless sensor networks are at the heart of numerous industrial, medical, and commercial applications.

- However, off-grid, as well as portable sensor nodes, rely on batteries for power and face the same problem as cell phones. In such cases, it is advisable to prolong battery life by harvesting environmental energy sources – most often available as light, heat, vibration, motion, or ambient RF. If a device's energy requirement is low enough and battery replacement would be difficult or expensive, it may be possible to rely exclusively on harvesting ambient energy sources for power. The combination of ultra-low-power MCUs and energy harvesting have given rise to a wealth of applications that previously were not possible.

Energy Harvesting

- The energy harvesting market is large and growing rapidly. According to analysts, energy harvesting was a $0.7 billion market in 2012 and is expected to exceed $5 billion by 2022; by then 250 million sensors will be powered by energy harvesting sources. The market for thermoelectric energy harvesting alone will reach $865 million by 2023.

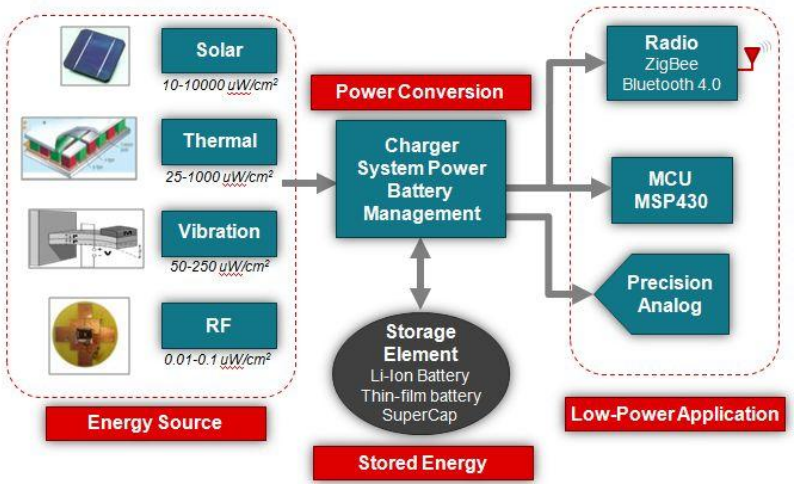
Source	Source Power	Harvested Power
Light		
Indoor	0.1 mW/cm²	10 µW/cm²
Outdoor	100 mW/cm²	10 mW/cm²
Vibration/Motion		
Human	0.5m at 1 Hz	
	1m/s² at 50 Hz	4 µW/cm²
Machine	1m at 5 Hz	
	10m/s² at 1 kHz	100 µW/cm²
Thermal		
Human	20 mW/cm²	30 µW/cm²
Machine	100 mW/cm²	1-10 mW/cm²
RF		
GSM BSS	0.3 µW/cm²	0.1 µW/cm²

Energy Harvesting

Solar

There is hardly a home or office that does not have at least one solar-powered calculator – actually, a calculator with a coin-cell battery and a small front panel photovoltaic (PV) cell to top it up. These polycrystalline silicon or thin-film cells convert photons to electrons with a typical efficiency of about 15 to 20% for polycrystalline and 6 to 12% for thin film cells. Since the power available from indoor lighting is typically only about 10 µW/cm², their usefulness depends on the size of the module plus the spectral composition of the light.

Small solar cells are frequently used in consumer and industrial applications, including toys, watches, calculators, street lighting controls, portable power supplies, and satellites. Since light sources tend to be intermittent, solar cells are used to charge batteries and/or supercapacitors to provide a stable energy source.



Energy Harvesting

Piezoelectric

Piezoelectric transducers generate electricity when stressed, which make them good candidates for vibration sensors when they are used in energy harvesting modules that detect motor bearing noise and the vibration of aircraft wings. The Midé Volture™ V-20W Vibration Energy Harvester employs a cantilever that attaches to a piezoelectric crystal. When vibrations set the cantilever in motion it generates an AC output voltage that is rectified, regulated, and stored in a supercapacitor or thin-film battery.

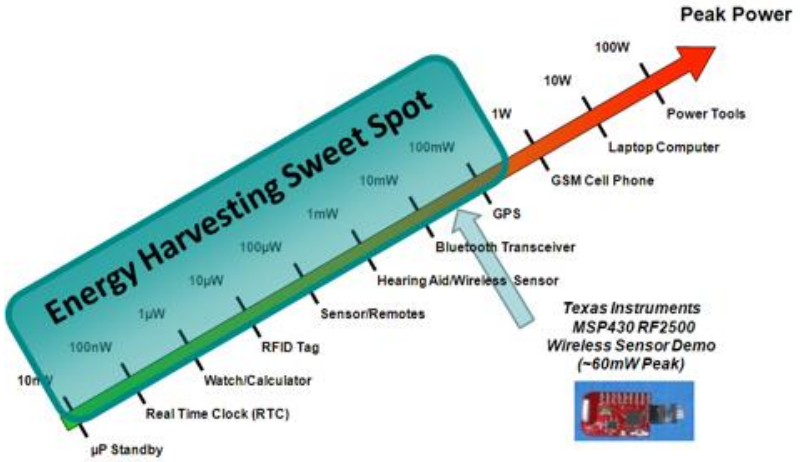
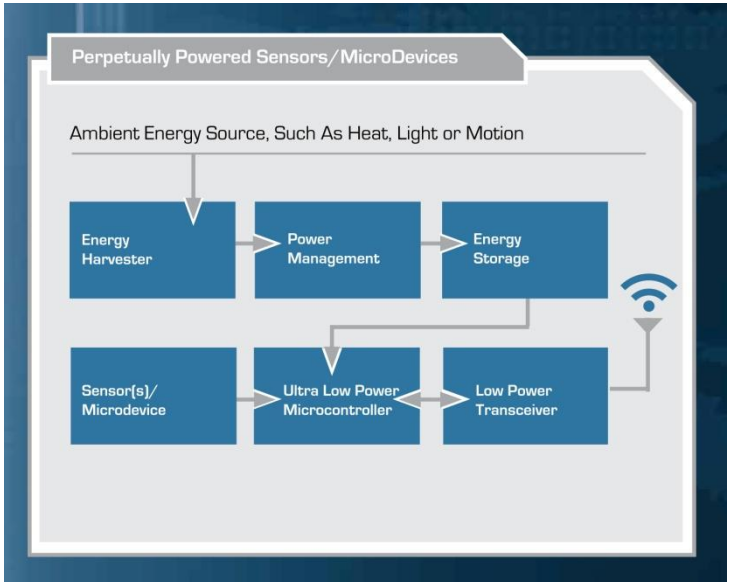
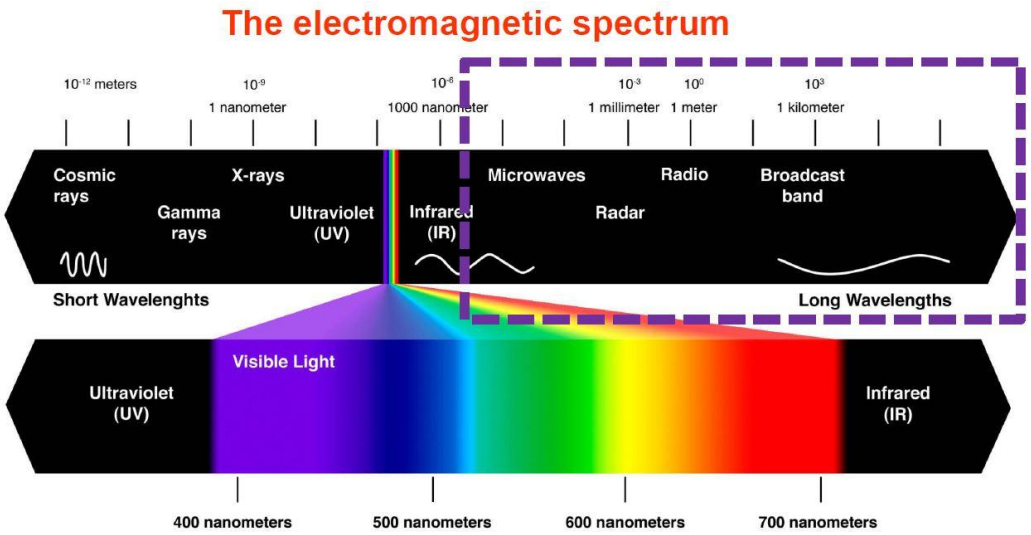
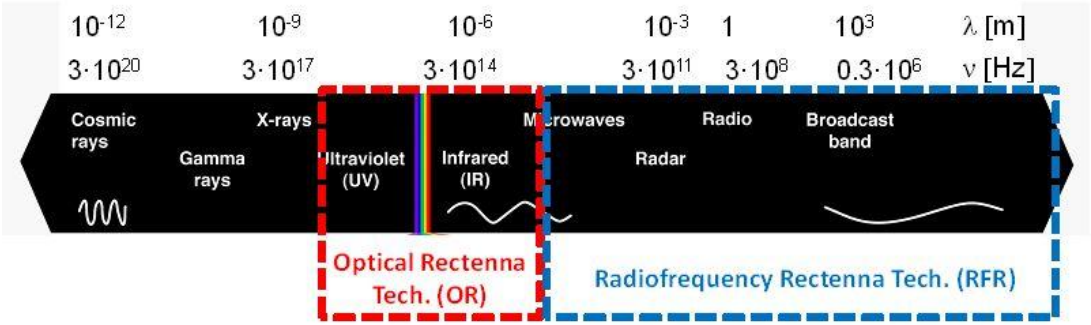
Energy Harvesting





RF Energy Harvesting





RF Energy Harvesting

Radio Frequency - RF

RFID works by rectifying a strong local signal aimed directly at the sensor.

When harvesting RF ambient energy it must be taken into account that RF energy is generally very low, therefore:

– Direct-power at close range to a transmitter

– Energy accumulation for longer range

are needed. Simple battery-recharge is possible but a system level approach is required for optimal implementation. Key system elements are reported below:

- Harvester
- Antenna
- Storage
- MCU
- Sensors

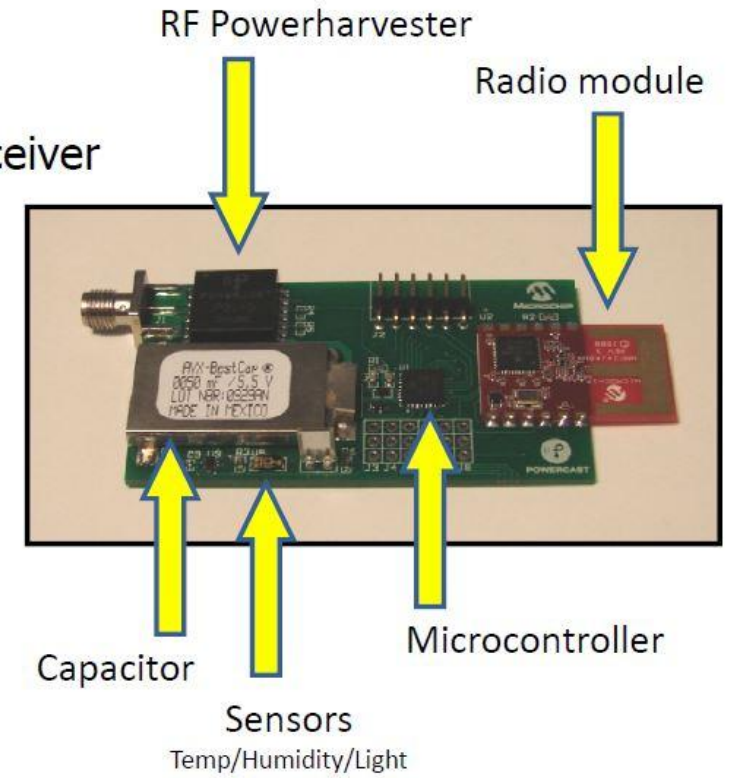
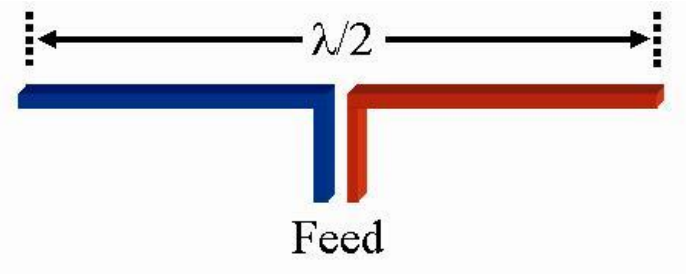
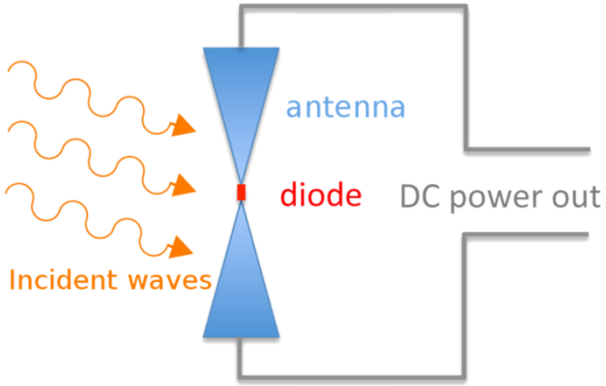
- Discrete sensors: Temp, Humidity, Light
- Wireless protocol: MiWi™ P2P



RF Energy Harvesting

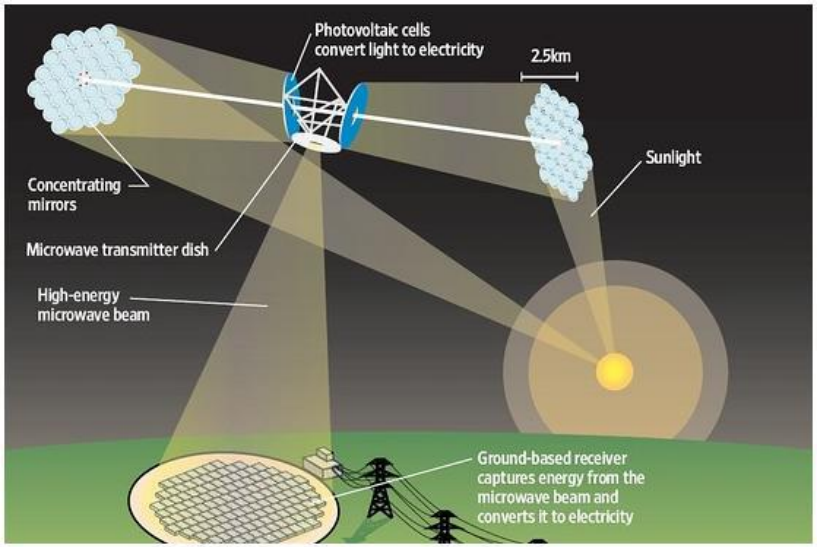
- The RF energy harvester is typically called **rectenna**, i.e. **rect**ifying ant**enna**, a special type of antenna that is used to convert electromagnetic energy into direct current electricity. This component is used in wireless power transmission systems that harvest power by radio waves. A simple rectenna element consists of a dipole antenna with an RF diode connected across the dipole elements. The diode rectifies the AC current induced in the antenna by the microwaves, to produce DC power, which powers a load connected across the diode. Schottky diodes are usually used because they have the lowest voltage drop and highest speed and therefore have the lowest power losses due to conduction and switching. Large rectennas consist of an array of many such dipole elements.





RF Energy Harvesting

- The invention of the rectenna in the 1960s made long distance wireless power transmission feasible. The rectenna was invented in 1964 and patented in 1969 by US electrical engineer William C. Brown, who demonstrated it with a model helicopter powered by microwaves transmitted from the ground, received by an attached rectenna. Since the 1970s, one of the major motivations for rectenna research has been to develop a receiving antenna for proposed solar power satellites, which would harvest energy from sunlight in space with solar cells and beam it down to Earth as microwaves to huge rectenna arrays. A proposed military application is to power drone reconnaissance aircraft with microwaves beamed from the ground, allowing them to stay aloft for long periods.



RF Energy Harvesting

Now the interest has turned to using rectennas as power sources for small wireless microelectronic devices. The largest current use of rectennas is in RFID tags, proximity cards and contactless smart cards, which contain an integrated circuit (IC) which is powered by a small rectenna element. When the device is brought near an electronic reader unit, radio waves from the reader are received by the rectenna, powering up the IC, which transmits its data back to the reader.

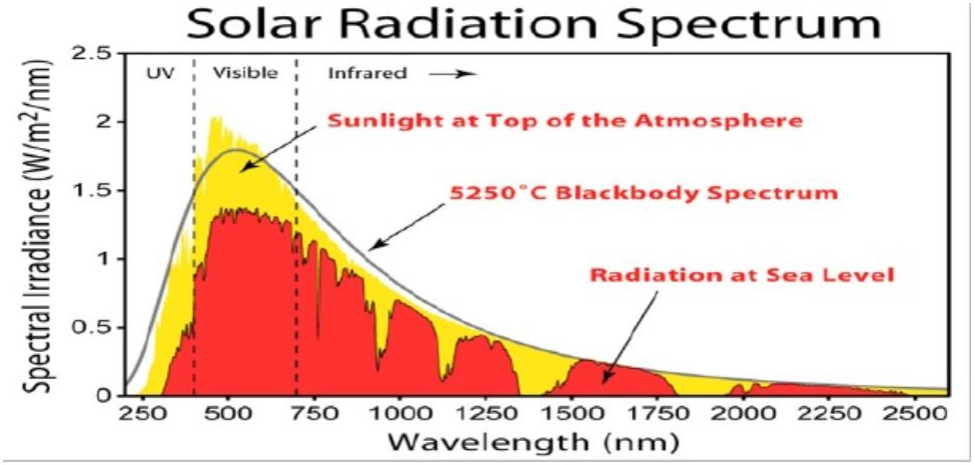
Advanced Solar Harvesting

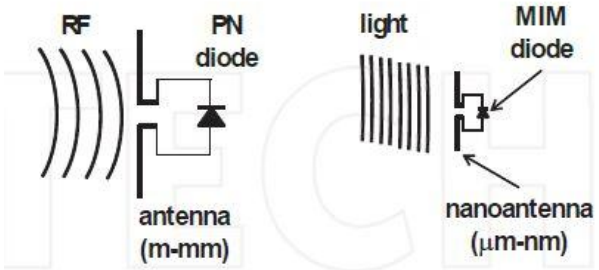
New strategies for solar energy harvesting employing other devices than solar cells, are currently under study. To this end, the nantenna or nano-antenna is the key element for capturing the optical energy. Nano-antennas are resonant metallic structures that confine the optical energy into small volumes in an efficient way by inducing a high-frequency current in its structure. In other words, the nantenna is a very small rectenna (the size of a light wave), fabricated using nanotechnology, which acts as an "antenna" for light, converting light into electricity.

A single nanoantenna reaches a high light-absorbing efficiency if compared to conventional photovoltaic devices. It is hoped that arrays of nantennas could be an efficient means of converting sunlight into electric power, producing solar power more efficiently than traditional solar cell-based systems.

A nantenna is an electromagnetic collector designed to absorb specific wavelengths that are proportional to the size of the nantenna. Currently, **Idaho National Laboratories** has designed a nantenna to absorb wavelengths in the range of 3–15 μm. These wavelengths correspond to photon energies of 0.08-0.4 eV. Based on antenna theory, a nantenna can absorb any wavelength of light efficiently provided that its size is optimized for that specific wavelength. Ideally, nantennas would be used to absorb light at wavelengths between 0.4–1.6 μm because these wavelengths have higher energy than far -infrared (longer wavelengths) and make up about 85% of the solar radiation spectrum.

Advanced Solar Harvesting





Advanced Solar Harvesting

The nanoantennas target mid-infrared rays, which the Earth **continuously** radiates as heat after absorbing energy from the sun during the day. In contrast, traditional solar cells can only use visible light, rendering them idle after dark. Infrared radiation is an especially rich energy source because it also is generated by industrial processes.

Prototype IR nanoantennas have been realized as tiny gold squares set in a specially treated form of polyethylene, thus appearing as light and flexible sheets. Theoretical efficiency as high as 80% has been found and real-life tests are under development. Traditional solar cells rely on a response mechanisnm that only works for up to 20% of the visible light they collect. Scientists have developed more complex solar cells with higher efficiency, but these models are too expensive for widespread use. If technical hurdles on super-fast rectifiers can be overcome, nanoantennas have the potential to be a cheaper, more efficient alternative to solar cells.

Besides, the nanoantennas also have the potential to act as cooling devices that draw waste heat from buildings or electronics without using electricity. Since objects give off heat as infrared rays, the nanoantennas could collect those rays and re-emit the energy at harmless wavelengths. Such a system could cool down buildings and computers without the external power source required by air-conditioners and fans.

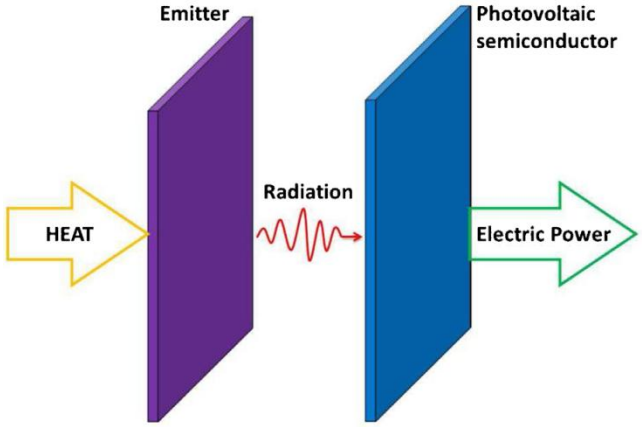
Thermophotovoltaic Harvesting

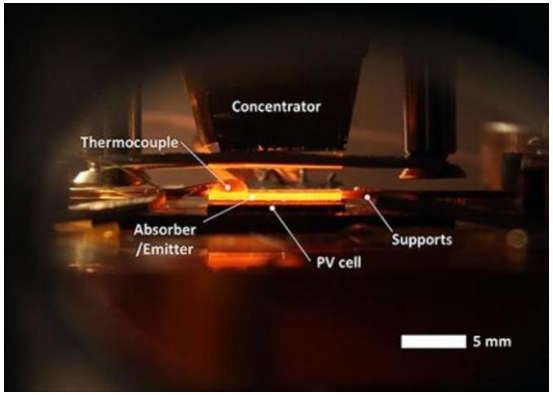
A new approach to harvesting solar energy, developed by MIT researchers, could improve efficiency by using sunlight to heat a high-temperature material whose infrared radiation would then be collected by a conventional photovoltaic cell. A conventional silicon-based solar cell “doesn’t take advantage of all the photons”. This occurs because converting the energy of a photon into electricity requires that the photon’s energy level match that characteristic of the photovoltaic (PV) material called bandgap. Silicon’s bandgap responds to many wavelengths of light, but misses many others.

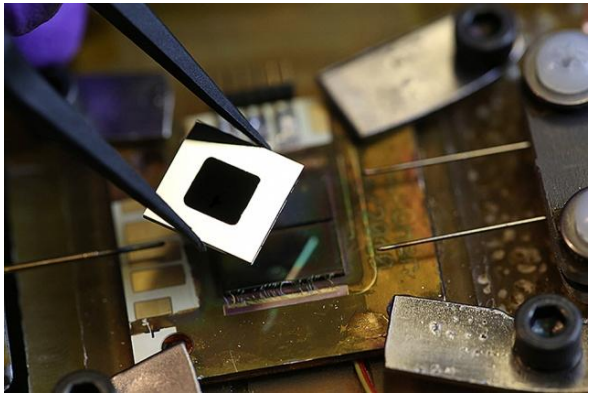
To address that limitation, the research team inserted a two-layer absorber-emitter device — made of novel materials including carbon nanotubes and photonic crystals — between the sunlight and the PV cell. This intermediate material collects energy from a broad spectrum of sunlight, heating up in the process. When it heats up, as with a piece of iron that glows red hot, it emits light of a particular wavelength, which in this case is tuned to match the bandgap of the PV cell mounted nearby.



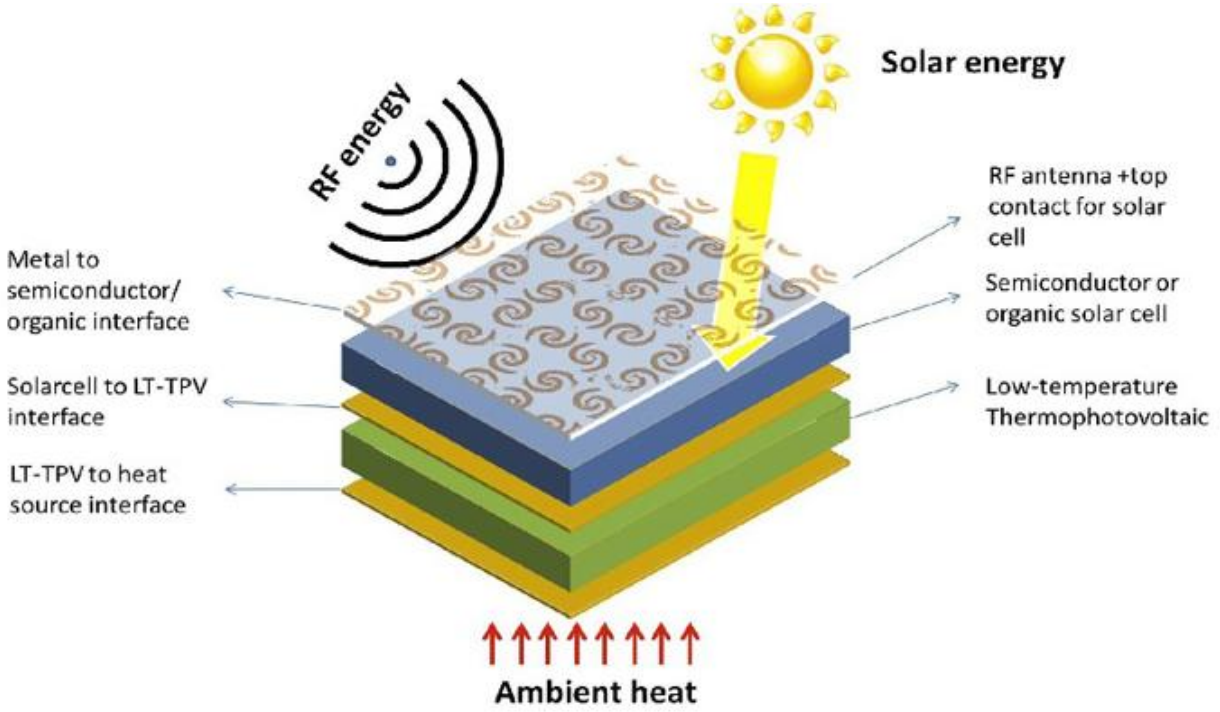
Thermophotovoltaic Harvesting

Such a system, therefore, combines the advantages of solar photovoltaic systems, which turn sunlight directly into electricity, and solar thermal systems, which can have an advantage for delayed use because heat can be more easily stored than electricity. The new solar thermophotovoltaic systems, they say, could provide efficiency because of their broadband absorption of sunlight; scalability and compactness, because they are based on existing chip-manufacturing technology; and ease of energy storage, because of their reliance on heat.





Future of Energy Harvesting



A monolithic energy harvester device, combining solar photovoltaic, thermophotovoltaic, RF and vibration energy harvesting.

Energy Harvesting Using a Cheap Easy-to-Fabricate FM Rectenna

*Mohi El-deen Ahmad**
**Alexandria University Egypt, Marine Engineering Department*
email: mohey_d2005@yahoo.com

Abstract- **Energy harvesting techniques are emerging as environmental friendly energy sources, which form a promising alternative to existing energy resources. These include rectennas, solar cells, harvesting human energy and wind power. GHz/THz rectennas already exist and have some characteristics such as small size and wideband. These rectennas have a lot of disadvantages such as power fading, complicated design procedure and high fabrication technology. Thus, the present paper suggests using FM rectennas to solve these problems and by using fractals we will keep the advantages.**

The present paper discusses the design and implementation of a rectenna prototype operating in the FM range. Using Fractal antennas (which offer broadband/multiband operation) and simple tricks from circuit design, God's willing, proves to be a successful strategy for obtaining useful power from a cheap easy to fabricate rectenna that can be even made in home by interested users. The paper includes theoretical discussion, simulation results and practical prototype results.

Keywords: **rectennas, fractals, rectifying circuits, antennas, energy harvesting.**

I. INTRODUCTION

Energy harvesting techniques are emerging as environmental friendly energy sources, which form a promising alternative to existing energy resources. These include energy harvesting from rectennas, passive human power, wind energy and solar power.

Energy harvesting from human power is used to generate useful power by portable equipments are wearable devices in which digital systems are integrated in everyday personal belongings, like clothes, watch, glasses, etc. Human body can be considered as a storehouse of energy. There exist two possibilities: power can be scavenged from the user's everyday actions or can be intentionally generated by the user. This method has a lot of advantages. It allows the decrease in both size and power consumption of complex digital systems.

The power harvesting can be stored in capacitors, rechargeable batteries, etc. The disadvantages of this method arise because the portable products are powered by rechargeable batteries and they will remain as the main source for this kind of consumer products. However the disadvantage of batteries is the need to rather place or recharge them periodically. Typical candidate applications are extracting power from pedaling which can generate power up to 1.6 mJ, from typing which can generate pewer up to 2 mJ with every push of the button of 15 N and power from body heat which can recoverable 2.8-4.8 W of power.[1]

Another method to harvest energy is offshore wind energy where researchers are developing new technologies to provide electricity offshore. The new Spar-WARP wind machine developed by ENECO can produce and store clean, safe electricity offshore in many areas where there is sufficient wind speed. Most offshore areas provide good sites for wind technology. A good land site usually has mean wind speeds of 13 to 17 mph, while typical offshore mean wind speeds range from 15 to 20 mph [2].

The WARP, which stands for Wind Amplified Rotor Platform, is designed to further amplify wind by as much as 50 to 80 percent, and has many advantages for providing electricity in offshore areas. It can be installed in any depth of water—on a foundation in shallow water or on a floating platform tethered to the bottom by cable in deep water.

A third method to harvest energy the solar power may be used. Solar energy is an environment energy available to power portable devices. A photovoltaic system generates electricity by the conversion of the sun's energy into electricity.

Photovoltaic systems are found from the Megawatt to the milliwatt range producing electricity for a wide range of applications: from wristwatch to grid-connected PV systems.

The examples of consumer products that contain PV solar cells are: calculators, radios, headphones, laptops, battery chargers, etc. [1]

Moreover, we can use solar rectennas to harvest solar power but those rectennas are operating at GHz/THz and have a lot of disadvantages such as power fading, complicated design procedure and high fabrication technology. Thus, it has been suggested to use FM rectennas operating at FM range of frequencies using fractal antennas not to harvest solar power but to harvest electromagnetic waves instead of all those energy harvesting techniques because those FM rectennas are simpler and cheaper to construct. To maintain rectennas advantages, fractal antennas are used. DC-up converter circuits can be used to raise the voltage harvested by the rectenna.

The organization of the remaining of the paper is as follows. In section II, we will explain the rectenna concept and offer a brief literature survey which shows the efforts of some researchers. Section III explains fractal antennas and especially Sierpinski triangle fractals. This section will show the complete rectenna design applied of a fractal antenna called FRACTENT [5]. Finally in section IV the simulation and the practical results of complete rectenna are given including steps of constructing the cheap simple prototype. Simulations are performed using NEC2 software and P-SPICE software.

II. RECTENNA CONCEPT AND A BRIEF LITERATURE SURVEY

A rectenna is a device that can harvest microwave energy. It can be constructed using an antenna, rectifier circuit, smoothing circuit. A basic rectenna is shown in Fig.1. [1]

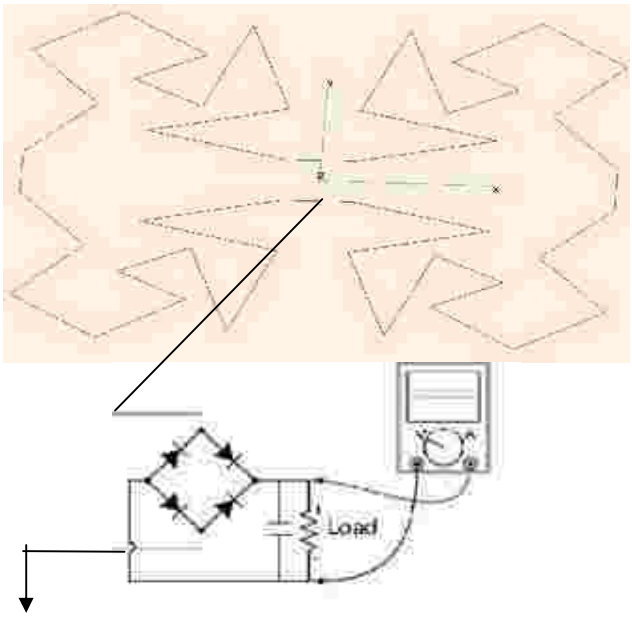


Fig.1 The complete rectenna

Several researchers reported the successful design and implementation of rectenna. J. Hagerty, ET. Al. have developed a new approach for construction of efficient rectenna arrays for arbitrarily polarized incident waves with broad spectral content. The approach has been validated experimentally on a dense grid array that rectifies two orthogonal linear polarizations, and on a self-similar spiral array with alternating right-hand and left-hand circular polarizations. The two arrays operate from 4.5to 8GHz and 8.5to 15GHz and have maximum open circuit voltages of 3.5 and 4.0V, respectively. Their efficiencies increase above 35% and 45%, respectively, for higher incident powers. The grid of rectifiers has excellent reliability and graceful degradation. The limiting factor on the size of the grid rectifier is the current rating on the diodes. Note that in the grid in Fig.2 the four corner diodes are the most critical ones, because one half of the current through the DC terminals passes through each of the diodes. If these 4 diodes are replaced by shorts, the current in the DC leads can be twice as large. The current intensity in the next diodes closest to the terminals is half of that through the four most critical diodes. Any overloaded diodes in the grid are automatically eliminated if they fail as shorts, and the rest of the grid continues to function. If a diode fails as an open, the current will find a path through the other diodes/shorts across the grid. [3]

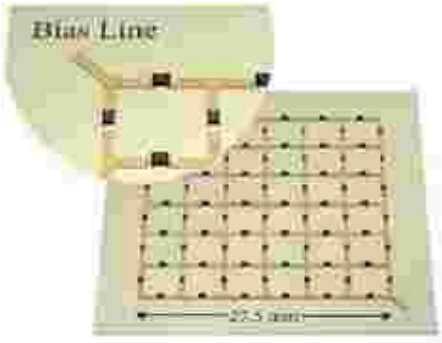

Fig.2 The grid array rectifier

Another researcher Y. Li has developed a 2.45 GHz low power rectenna design for wireless sensor and RFID applications. The system is monolithically integrated onto a single circuit board. A high gain patch antenna array is used to boost the power level at the input of the Rectenna for better power conversion efficiency. Moreover, a hybrid ring coupler is used to divide the power between Rectenna and detector. The system implements a key RF front end for GAP4S wireless sensor system [4].

III. FRACTAL ANTENNAS

Fractals are geometrical shapes, which are self-similar, repeating themselves at different scales. In this chapter we will shown two examples of fractal antenna (Sierpinski triangle antenna and kuch curve antenna), after that we will shown FRACTENT that will using in our FM rectenna.

The Sierpinski triangle, shown in Fig.3, is a common self-similar geometrical figure. It also has been used as a very effective antenna in the GHz frequency range.

The geometric construction of such a triangle is simple. One starts with the black equilateral shape and takes afterwards, in different steps, the middle of the sides and generates respectively 3, 9, 27, 81, triangles which are self similar and exactly scaled down versions of the initiating shape. The same procedure can be observed in Fig.4 where a Koch curve is iterated in 3 steps.

It is interesting to know something about the “Dimension” of such a fractured structure. The term “Dimension” in mathematics has different meanings. The common definition is the “Topologic Dimension” in which a point has the dimension 0, a line has the dimension 1, a surface has the dimension 2 and a cube has dimension 3.

Using Fractal geometry in antennas results in multi-frequency/broadband behavior. This behavior is best illustrated based on discussion of Sierpinski monopoles.

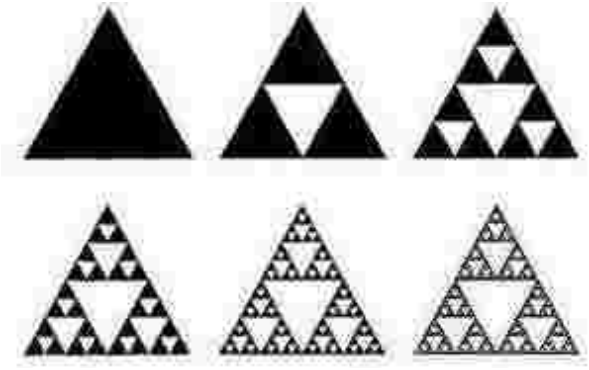

Fig.3 The Sierpinski triangle antenna

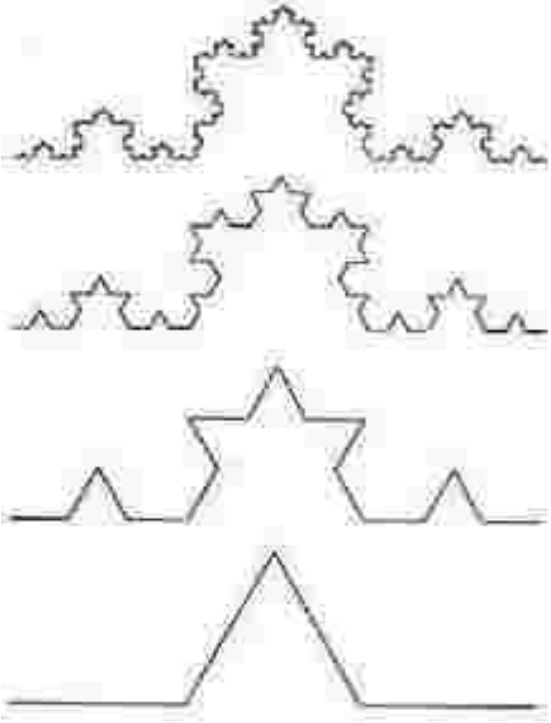

Fig.4 The Kuch curve antenna

The Sierpinski Monopole is shown in Fig.5. This is a monopole antenna resonant at frequencies of 0.44, 1.75, 3.51, 7.01 and 13.89GHz having an input resistance of 50Ω. One can easily see the 5 resonant frequencies of the structure by looking to the 5 circles marking the respective triangles.

The complete rectenna design (antenna+ rectifier and smoothing circuit) has been shown in Fig.1.

The multi broadband response of fractal antennas mentioned earlier make them suitable for use in rectenna applications since they can harvest more power than a single band antenna. The FRACTENT [5] is a particularly interesting antenna geometry as shown in Fig.6.

Since the Fractent operates at FM range, the author was able to construct it using the following simple procedure. First, the Fractent operating was drawn to scale. Second, a common 1-mm copper wire was shaped by hand to take the Fractent shape.

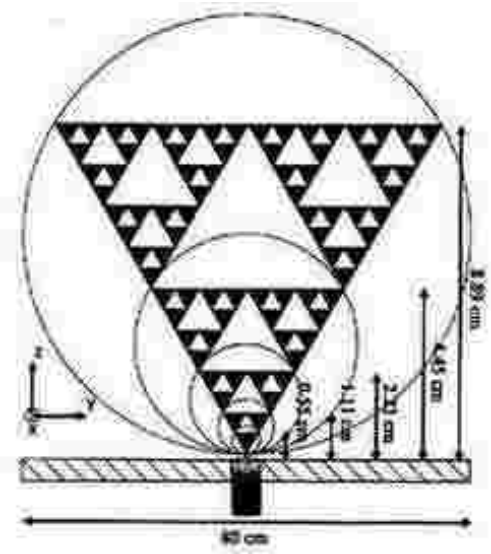

Fig.5 Sierpinski Monopole antenna resonant

Fig.6 Fractent antenna

The performance of FRACTENT has been studied through simulation using NEC2 software and has been validated practically by the author by putting it into operation as an FM antenna. The rectification circuit and smoothing circuit shown in Fig.1

The following design formula has been used Full-wave bridge rectifier with Schottky diode. Schottky diodes have been used duo to their low turn-on voltage and fast response which is necessary at high frequency.

It is important to note that the choice of FM range is important because it allows for easy and cheap rectifier/smoother circuit design and implementation while working in higher microwave frequency range requires more technologically complex methods.

IV. SIMULATION AND PRACTICAL RESULTS

The fractal antenna prototype constructed by the author is shown in Fig.7

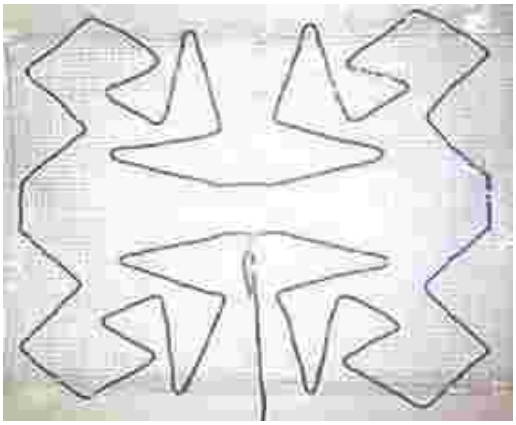

Fig.7 The cheap practical prototype made by the author

We use NEC2 software to simulate this antenna and results at 90 MHz are shown in Fig.8.The antenna radiation pattern is shown in Fig.9. Simple frequency scaling was used to change the dimensions of the antenna so as to transform its bandwidth to 90 MHz.

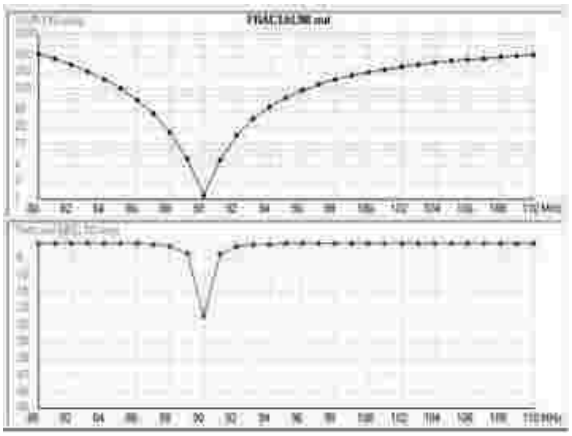

Fig.8 NEC2 simulation results for the practical prototype (VSWR and reflection coefficient in dB)

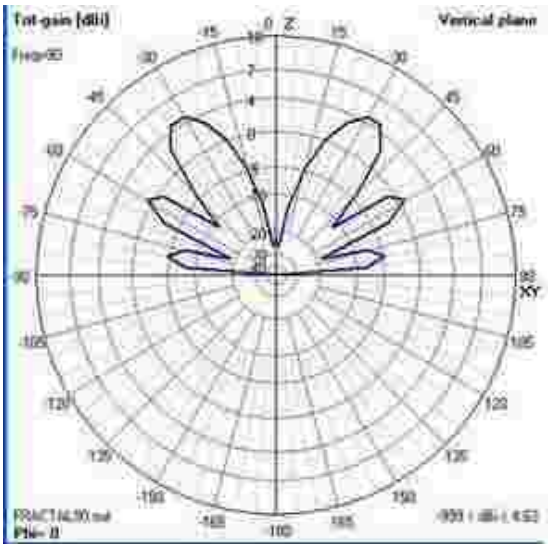

Fig.9 The Fractal antenna radiation pattern in the horizontal plane at 90 MHz

Rectifier circuit simulate on P-SPICE program. The results of P-SPICE program are shown in Fig.10.

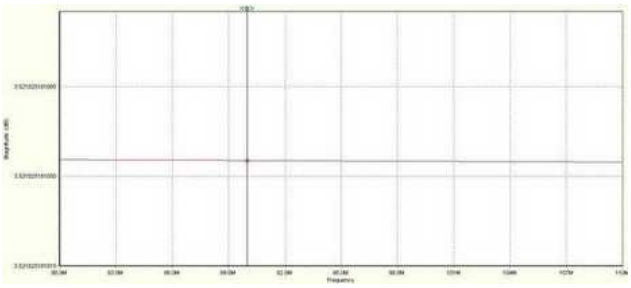

Fig.10 P-SPICE program results for usage rectifier circuit

V. CONCLUSIONS

In this paper, it was shown that energy can be harvested from some sources such as rectennas, human power, solar energy and offshore wind energy. The rectenna concept was the focus of the paper as efficient alternative to common GHz/THz rectennas. To get over the technological difficulties associated with developing rectennas at GHz/THz range, the author developed a new rectenna efficient design that uses fractal antennas operating at FM range. The rectenna operating an FM range is easily constructed using common copper wire, diodes and capacitors, which make them easy and cheap to develop even by inexperienced users without compromising rectenna efficiency. Thus, the developed rectenna is cheap, efficient, simple to implement and environmental friendly.

(Dated: April 20, 2014)

The Rectenna (RECTifying antENNA), which was first demonstrated by William C. Brown in 1964 as a receiver for microwave power transmission, is now increasingly researched as a means of harvesting solar radiation. Tapping into the growing photovoltaic market, the attraction of the rectenna concept is the potential for devices that, in theory, are not limited in efficiency by the Shockley-Queisser limit. In this review, the history and operation of this 40-year old device concept is explored in the context of power transmission and the ever increasing interest in its potential applications at THz frequencies, through the infra-red and visible spectra. Recent modelling approaches that have predicted controversially high efficiency values at these frequencies are critically examined. It is proposed that to unlock any of the promised potential in the solar rectenna concept, there is a need for each constituent part to be improved beyond the current best performance, with the existing nanometer scale antennas, the rectification and the impedance matching solutions all falling short of the necessary efficiencies at THz frequencies. Advances in the fabrication, characterisation and understanding of the antenna and the rectifier are reviewed, and common solar rectenna design approaches are summarised. Finally, the socio-economic impact of success in this field is discussed and future work is proposed.

I. INTRODUCTION

The ever increasing global demand for clean renewable energy is a crucial topic that has major economic and societal impact for our future on this planet. The sun is a constant source of energy, thus better harvesting its radiation would solve the energy challenge and help protect the environment. Conventional solar harvesting is via the increasingly popular photovoltaic (PV) p-n junction solar cells. Although this field has seen great improvement over the last few decades since the first silicon solar cell was developed in 1941 at Bell Laboratories, its fundamental limitations discussed by Shockley and Queisser[1] in 1961 puts an upper boundary on the efficiency at around 30% for single junction solar cells[1] and 55% for multi-junction solar cells[2]. Due to the efficiency limits of solar cells, other solar-energy converting technologies are becoming increasingly attractive. An alternative solar energy converter concept is the Rectenna (RECTifying antENNA) device, which has achieved very high efficiencies at microwave frequencies, while at THz frequencies, it has been speculated that efficiencies exceeding the Shockley-Queisser limit are achievable.

Fundamentally the Rectenna and the Solar Cell are similar as there is absorption of photons to generate a DC current. However, there is a substantial difference in their principles of operation. Solar cells are quantum devices, except for their anti-reflection coatings, and are only able to be understood and designed by the application of quantum physics[3], where light is perceived in its particle form, as photons. Hence, the efficiency is limited by the band gap energy of the active layers, where energy is lost due to low energy photons passing right through the material, and through heat loss from the high frequency photons. The rectenna device concept is different as it is based upon the wave nature of light, which is regarded as a propagating, oscillating electric and magnetic field[4]. Similar to a low pass filter in electronics, the efficient absorption of solar radiation is limited by the cut-off frequency of the device, i.e. any wavelength below this frequency can be harvested.

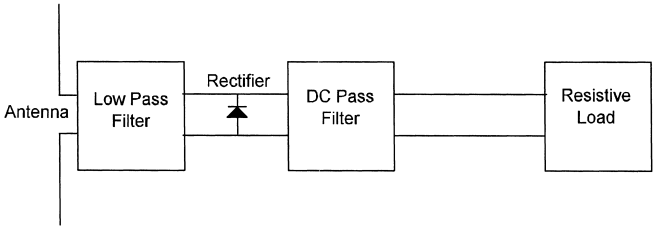

FIG. 1. Block diagram of microwave rectenna and load. (Reprinted from [3], ©2002 with permission from Elsevier)

The components of the rectenna device are shown in Figure 1. These components are commonly associated with a rectenna operating at microwave frequencies. The antenna is used to capture and convert the energy from an incoming microwave beam (or solar radiation in the case of solar rectenna) as it is an efficient transducer between free space and guided waves[5]. The electric field (**E**) from an incident electromagnetic wave induces an

alternating current (AC) in the conducting antenna. A low pass filter is used to form an impedance match between the antenna and the rectifier, and passes the signal at the tuned operating frequency whilst blocking reradiation of higher order harmonic energy produced by the rectifier[3,6–8]. The rectifier (a diode) converts the input AC signal to a usable direct current (DC) which is transferred to the load. A DC pass filter, consisting of an inductor in series, is used to smooth the rectified signal to DC whilst providing efficient transfer to the load.

The antenna dimensions are of the same length scale as the targeted frequency[5]. Therefore, for microwave frequencies, the antenna is relatively large (cm to mm scale) compared to that required for infrared (µm scale) and optical frequencies (nm scale). Due to its smaller size, it will be difficult to incorporate the aforementioned filters into the design of a rectenna for solar energy collection. Therefore the components of the solar rectenna are reduced to just the Antenna and Rectifier (Figure 2)[9]. The removal of the low-pass filter from this design enables broadband frequency harvesting up to the cut-off frequency of the device, although it introduces the difficulty of impedance matching the antenna and rectifier, resulting in a potential drop in efficiency. Losses in transferring the rectified DC signal to the load are dependent on the diode behaviour. However, appropriate design of a DC pass filter would make its use possible in this configuration[99,100].

There are two families of designs for rectenna solar energy collectors. Bailey[10] proposed that each antenna element is attached to its individual rectifier and the DC outputs are combined (see Figure 5). The immediate concern here is that the small voltage predicted from the antenna elements may be insufficient for rectification to occur in the attached diode element[3]. The only way to overcome this is to design a diode which turns on at a voltage as low as that arising from the single antenna element. The other design is by Kraus[11], who suggested that the electrical oscillations from many antenna elements be combined in a particular phase relationship, then delivered together to the rectifier. Limitations in this design arise from the need for spatial coherence across all the antenna elements feeding the signal to the diode[3]. This can be minimised by appropriate design and high quality fabrication of the antenna elements.

The aim of this article is to review key research in the development of the rectenna device as an alternative or in addition to conventional solar cell technology. We aim to expand upon a few short reviews, [3–5,9,100,105], that have been published, bringing the reader up to date with a more detailed overview of the device. This article will be the first to bring together all relevant research not only on the rectenna as a whole device, but also the research on its two main components – the antenna and the rectifier. The next section will briefly describe the history of the device and how the initial application of microwave power transmission (MPT) was later modified to a solar energy harvesting alternative. Section III will analyse and discuss the many publications on experimentally and theoretically derived device efficiencies. Breakthroughs in modelling and fabricating the antenna and rectifier will be reviewed in Section IV and V respectively. Section VI will bring together all components and look at different rectenna architectures, which show potential for efficient operation at solar frequencies. We will discuss the socio-economic impact of the research in this field and proposed future work in Section VII before completing the article with a short summary in Section VIII.

II. HISTORY OF THE RECTENNA DEVICE

The rectenna concept was initially proposed for wireless power transmission by William C. Brown of the Raytheon Company in the 1960's. At the time, Brown, a pioneer of microwave power transmission, was faced with a challenge of how to efficiently receive and convert to DC power an incoming microwave beam. Wireless power transmission was not a new concept as it had begun with the ideas and demonstrations by Tesla in 1899 using radio waves[12]. Tesla managed to demonstrate this concept although never found an applicable route into its commercialisation.

In 1959 the Raytheon Company proposed the Raytheon Airborne Microwave Platform (RAMP) concept to the US Department of Defence as a solution to communications and surveillance problems[13]. This proposed platform was to be flown at high altitude (50,000 ft) in the form of a helicopter, powered by microwave transmission. The US Department of Defence did not fund the project however the Raytheon Company pursued their interest by researching the required technological developments for its realization. One missing technology was a suitable microwave rectifier[14], capable of converting the microwave signal directly into the DC current necessary to power the platform's motors and stay airborne. Their initial design used a

horn-illuminated ellipsoidal reflector that focused the microwave beam into a trapezoidal horn at a 20 ft distance where the microwaves were converted to DC power by the rectifier[13]. Using this first design, Brown constructed and flew thirty feet above his lawn a small tethered helicopter that he had built with his son in his own workshop[13]. Although this concept worked, Brown was aware of the flaws in his system and continued to work on other possibilities.

In 1963, Brown met with his colleague and friend Roscoe George, a professor at Purdue University who had been working on a microwave point-contact semiconductor diode[15]. Following discussions regarding his challenge, a device which is now known as "Rectenna" was conceived. The proposed solution was patented in 1969 and consisted of taking individual full-wave rectifiers out of the waveguide, attaching them to half-wave dipoles, and placing a reflecting plate behind the structure[16]. The first microwave rectenna was built by R.H. George at Purdue University but conceived at Raytheon Company in 1963, shown in Figure 4. Later in 1964, Brown built a helicopter which had an array of 28 such Rectennas. The helicopter was demonstrated in flight 60 ft above a transmitting microwave beam on the CBS Walter Cronkite News in October 1964. Figure 3 shows some impressive images of this historic event. The interested reader is referred to Brown's recollection on "The History of Power Transmission by Radio Waves" in [13], where all the interesting details and facts about the invention of this device can be found.

Following this invention, microwave power transmission became very popular and many potential applications were researched. An interesting one is the solar

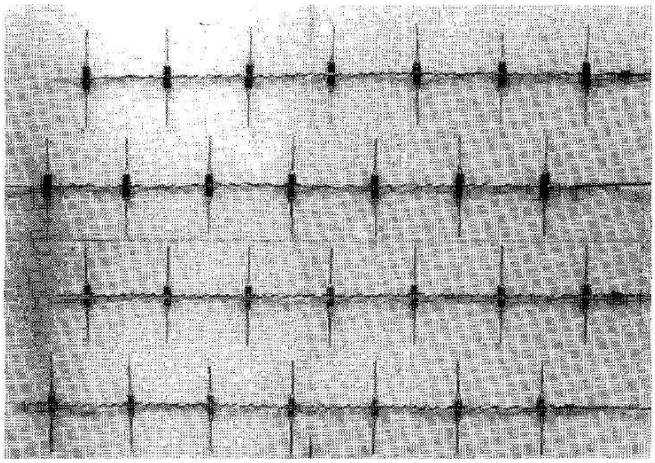

FIG. 4. The first rectenna. Conceived at Raytheon Company in 1963, built and tested by R.H. George at Purdue University. It was composed of 28 half–wave dipoles, each terminated in a bridge rectifier made from four 1N82G point–contact, semiconductor diodes for operation at 2.45 GHz. A power output of 7W was produced at 40% efficiency. (Reprinted from [13], ©1984 IEEE. Reprinted, with permission, from IEEE)

power satellite (SPS), proposed by P. E. Glaser[18] in 1968. The concept of the SPS represents a 5 GW power station on the geostationary orbit, which collects electrical power by means of solar cells and transmits microwaves of the 2.45 GHz band to a rectenna array site on the ground. The SPS project was researched by Brown and Glaser[19–22] which earned Glaser a patent in 1973[23] and

a collaborative three year project together with Brown in 1977 called the "DOE/NASA Satellite Power System Concept Development and Evaluation Program". The work ended in 1980 with much success in developing new ideas in the design of transmission technology and rectenna arrays however did not attract further funding. Although this was the end of the SPS initiative in the US, some experimental studies of the concept were seen in the 1990s in Yamasaki, Japan[24,25]. The interested reader is referred to Glaser's overview of SPS progress in [26].

The developments from the SPS project yielded other applications involving microwave transmission and rectenna, such as intersatellite power transmission[27], including utility power satellites[28], mechanical actuators for space-based telescopes[29], small dc motor driving[30], short range power transfer as for example between two parts of a satellite, RF identification tags (RFID) and biomedical implants[31]. These applications all include single band rectenna operation. Hagerty *et al*[31] have shown a broadband rectenna array for microwave operation to be used in low-power indoor sensor networks and RF energy recycling. Recent publications have shown a compact printed rectenna that can be used to supply DC power to electrical devices supporting data communication systems[32].

The idea of exploiting the wave nature of light, or solar radiation, and converting its energy into usable direct current by the use of antennas, originated as part of a NASA summer project in the late 1960s undertaken by J.C. Fletcher of NASA and R.L. Bailey of the University of Florida[4]. The first official report of this concept was published by Bailey in 1972[10]. In this paper, he named his device the "*Electromagnetic Wave Energy Converter (EWEC)*" and suggested an artificial pyramid or cone structure as antennas, analogous to those found in nature and similar to dielectric rod antennas. The paper described pairs of pyramids as modified dipole antennas, each pair electrically connected to a half-wave rectifying diode, filter and load. This invention is fundamentally very similar to the initial microwave rectenna proposed by Brown, but it is modified so that the antenna and rectifier operate at much high frequencies to harvest solar energy. The device called by Bailey EWEC is now referred to as a Solar Rectenna.

Bailey's first publication on the subject in 1972 served as a proof of concept as he showed the broadband characteristics of his pyramidal antennas by tests at 100-1000 MHz. Following this, in 1973, Fletcher and Bailey published a patent[33] on the EWEC concept. Later in 1975, in their final report, Bailey *et al*[34] presented their theoretical work highlighting the importance of future research into optimised antenna design and fabrication, while not forgetting that rectification of the signals was an equally critical issue and a significant challenge[4]. These two components of the rectenna solar energy harvester are now of equal research interest (see Sections IV & V).

Later, alternative rectenna structures were proposed

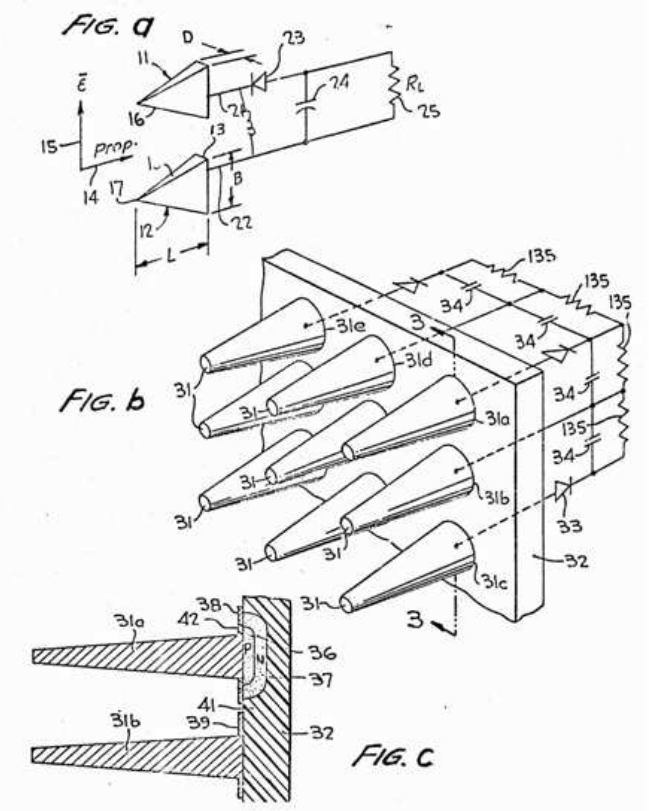

FIG. 5. The EWEC concept by Fletcher & Bailey. Each broadband conical antenna is connected to a rectifying diode, filters and load. (Reprinted from [33])

and patented by Marks[35–38], who was inspired by the earlier half-wave rectifier EWEC concept. His first patent in 1984 was a device with arrays of submicron crossed dipoles on an insulating sheet with fast full-wave rectifiers[35]. Later in 1988, Marks was first to patent antenna-like cylinders attached to asymmetrical metal-insulator-metal (MIM) diodes for rectification[37]. MIM diodes are one of the most promising rectifiers for use in Infrared and Optical Rectennas and will be later discussed (Section V.B).

The first reported experimental evidence of a fabricated resonant nanostructure absorbing and rectifying at visible light frequency was published by Lin *et al*[39] in 1996. They recorded a short circuit current using a parallel dipole sub-nanostructures connected to a p-n junction for the rectification of the absorbed signal. Credit must be given also to Gustafson & Billman[40] who first suggested harvesting visible radiation in 1974. Their work formed the basis of using optical diodes like the MIM diode.

Figure 6 outlines a brief timeline of the key events that have lead to the current research activity in solar rectenna. Further reading is suggested in [3,4] for a more detailed reference and explanation of the major historic breakthroughs in the field of solar harvesting by rectenna.

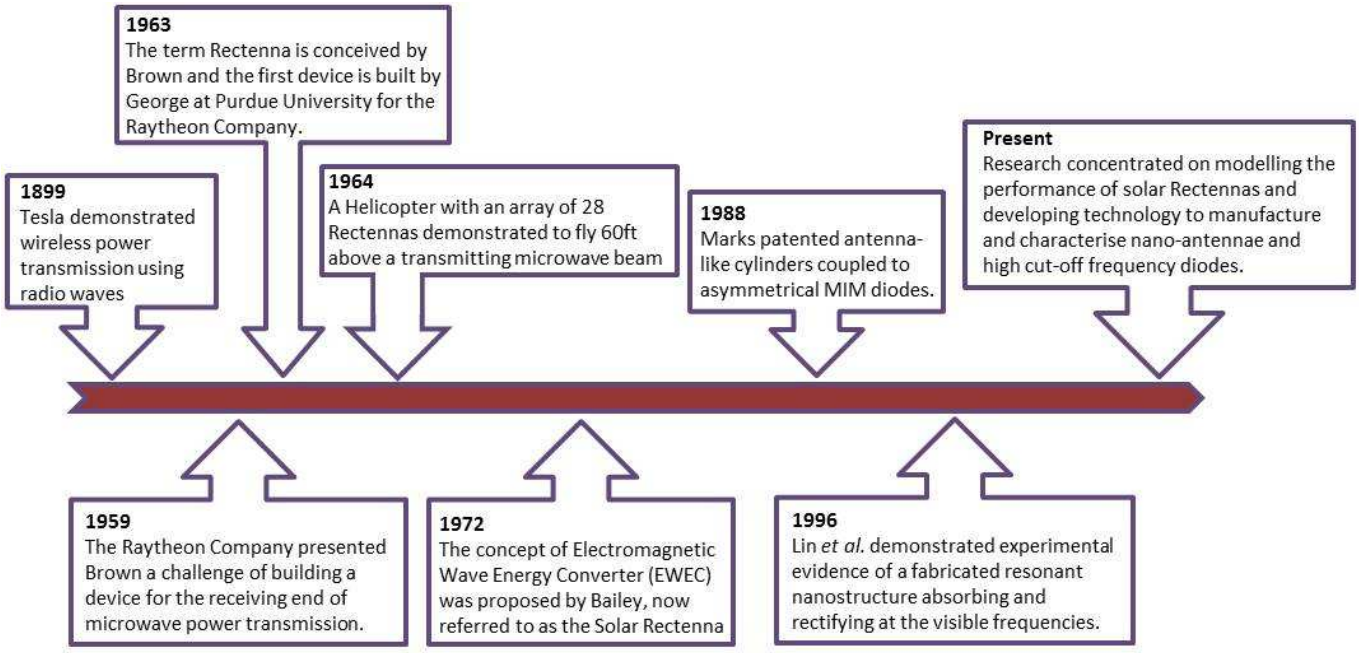

FIG. 6. Brief timeline of the rectenna device - from concept for microwave power transmission to research focused on solar harvesting

In the following sections, we mainly focus on the key research in harvesting optical and infrared frequencies using the rectenna concept.

III. EFFICIENCY LIMITS

The first rectenna device (Figure 4), which was built in 1963, provided a 7 W power output with 40% efficiency[13] designed to work at 2.45 GHz. This was the most commonly targeted transmitting frequency for MPT because of its low attenuation through the atmosphere even in severe weather and being at the centre of the industrial, scientific, and medical (ISM) band meant that it was the most advanced and efficient transmitting technology.

This rectenna used half-wave dipole antennas to receive the signal and point-contact semiconductor diodes for rectification. In later device attempts, the half-wave dipole antenna remained the preferred technology, but an increase in efficiency was mainly achieved by improving the rectifier performance, incorporating Schottky Barrier Diodes (SBD). From the early 1960's until the early 1980's there has been a steady increase in the experimentally demonstrated efficiency of the rectenna at 2.45 GHz (Figure 7a). Although Nahas[7] first developed a model (using a distributed transmission-line technique including skin-effect losses) to simulate the top performance of a rectenna utilising a dipole antenna and a conventional SBD, his prediction of an 80% upper boundary (most of the losses came from the diode rectifier) was later improved when Brown[82] experimentally demonstrated what is to date, the highest ever recorded efficiency at the 2.45 GHz band of 92%. This was made possible by using the then well established Pt/GaAs Schottky diode and supported Brown's predictions that 100% efficiency is possible for this device[44,82].

In another attempt to model the efficiency, Gutman & Borrego[51] predicted an upper boundary of 85% incorporating numerous rectifier outputs interconnected to a common DC load. They used a closed-form analytical circuit model and a computer-simulation model in an attempt to show that a higher output power can be achieved having an array of these components as opposed to a single rectenna element.

It is important to state that the conversion efficiencies (η) considered here are simply defined as the ratio of the output power (P_{out}) over the power incident on the antenna (P_{in}),

$$\eta(\%) = \frac{P_{out}}{P_{in}} \times 100 \tag{1}$$

One of the most successful demonstrations of MPT was in 1975 by Dickinson and Brown[42] who used an array of 5000 rectennas to receive a transmitted signal over a distance of one mile with 82% efficiency at 2.388 GHz[42,43]. The rectenna architecture again contained half-wave dipole antennas. In the last two decades many other antenna architectures have been proposed in search of enhanced performance and economical alternative. These include the microstrip patch[44,46], circular polarised[53,56–58], compact slot ring[55]

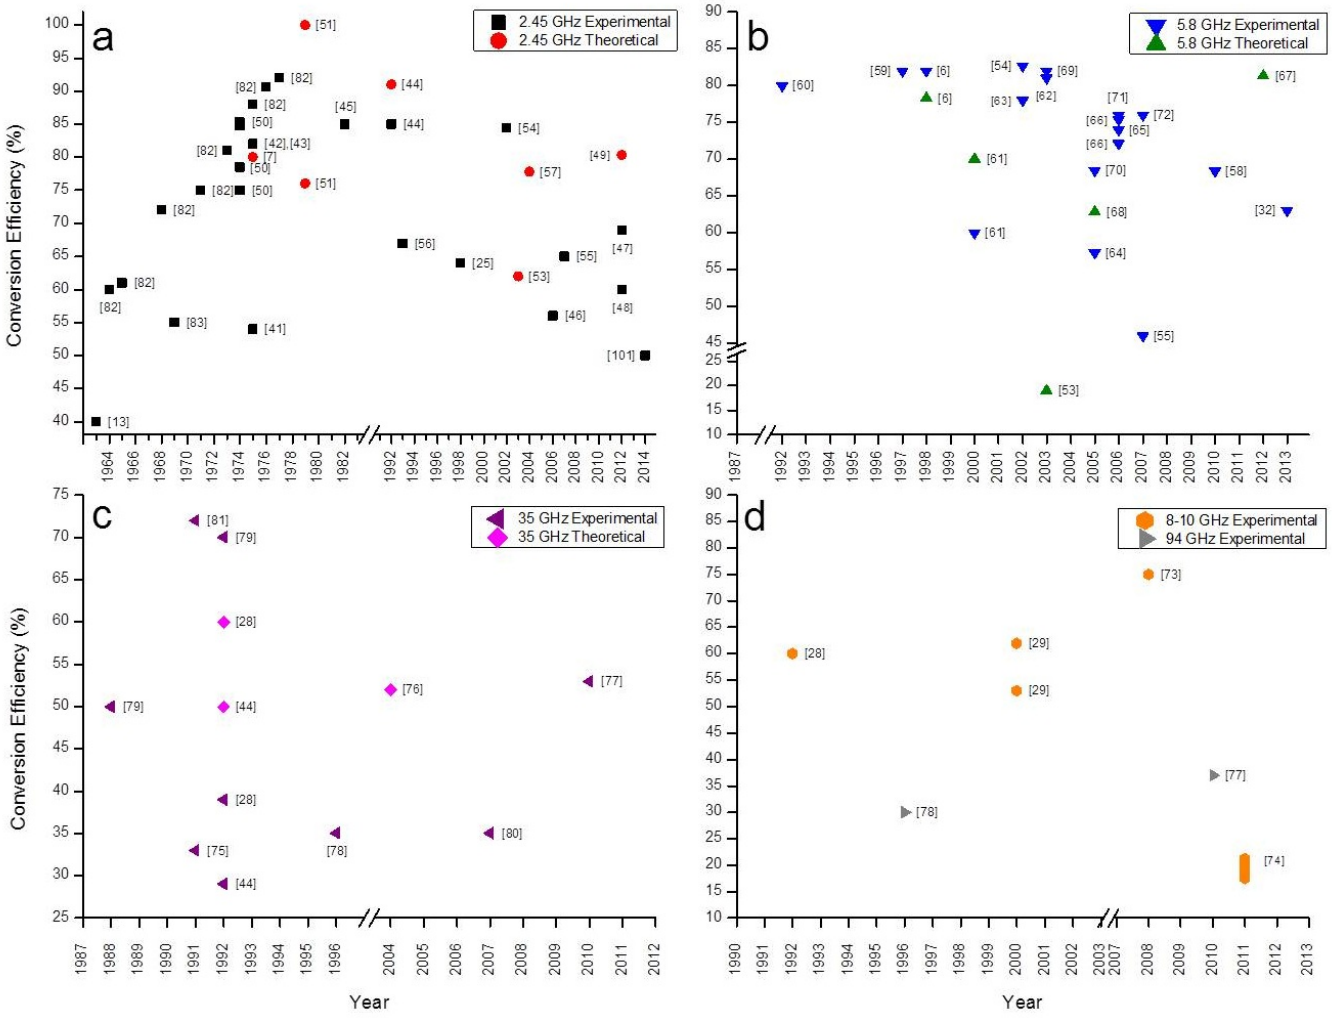

FIG. 7. Reported conversion efficiency (as defined by their authors) evolution over the years of a rectenna device for Microwave Power Transmission. Data points are split into Experimental and Theoretically derived values of efficiency. a) 2.45 GHz, b) 5.8 GHz, c) 35 GHz and d) 8-10 GHz and 94 GHz. [**] indicates the reference corresponding to the data point. Data collected from [3,5–7,10,11,13,25,28,29,32,41–51,53–82,101]

and shorted annular ring-slot[47,53] antennas with all attempts returning efficiencies between 55 and 85% (see Figure 7a). The higher efficiencies reported all used GaAs Schottky diodes as opposed to conventional Si Schottky diodes, showing the importance of diode behaviour on device performance.

In the 1990's a renewed interest in the solar power satellite (SPS) concept[18–26] started a new focus of research into high efficiency rectennas and rectenna arrays operating at higher frequency than the mid-ISM band (2.45 GHz)[41]. With higher operating frequency, the device dimensions can be reduced conveniently from the point of SPS construction feasibility[41]. Also small size design can be appropriately implemented in a range of other applications such as a supply source in RFID[31,55,58,64,68,77], wireless sensors[31,47,58,77] and data communication systems[32,61,64,65,67,77]. Rectennas operating in the C-band (≈ 5.8 GHz – Figure 7b), X-band (8-10 GHz Figure 7d), Kα-band (35 GHz Figure 7c) and W-band (94 GHz Figure 7d) have appeared after the 1990s, some even operating in two bands (2.45 & 5.8 GHz[53–55] and 35 & 94 GHz[77]). However, the efficiency is different in the two frequency bands with the higher frequency operation yielding lower efficiency due to losses in transferring the AC signal generated from the antenna to the rectifier circuit. The only dual frequency rectenna with high efficiency in both bands is reported by Suh & Chang[54] with an excess of 82% efficiency at both 2.45 and 5.8 GHz employing a CPS dipole antenna and GaAs SBD.

At 5.8 GHz, efficiency values in the range of 60-85% have been both predicted[6,61,67,68] and demonstrated[6,32,54,59–63,65,66,69–72] with different approaches returning equally successful devices through

the years (Figure 7b). The few experimentally reported rectennas at 8-10 GHz have seen slight improvement in efficiency when a circular or dual polarised printed patch antenna has been coupled to the GaAs[28,29] or Si[73] Schottky diode, however with a planar slot antenna[74] the efficiency is only 21.2% (Figure 7d). At 35 GHz (see Figure 7c) theoretical predictions are higher than their corresponding experimental results[28,44], although with a similar antenna and diode design, high experimental efficiency of 70% has been reported elsewhere [79,81]. Analysis of the different efficiencies achieved with similar rectenna technologies highlight the importance in the circuit and device design for rectennas used in microwave power transmission. Furthermore, load impedance and the power of the incoming beam also affect the overall efficiency of the device.

It can be noticed from Figure 7 that for a given frequency some models predict a lower efficiency than that which had already been experimentally achieved. The reason is that over the years, new antenna and rectifier technologies, and alternative, more compact circuit designs were emerging, which could not improve or even match the record efficiency achieved with the half-wave dipole antenna and Pt/GaAs SBD. Furthermore, scaling down the components and aiming towards higher frequency operation at lower cost, introduced difficulties for appropriate circuit design and the efficiency suffered a continuous drop. Overall, considering the evolution of reported efficiencies over the years (Figure 7) for MPT rectennas, it can be concluded that with appropriate antenna design, good matching to a suitable well-functioning diode rectifier connected to a DC load, experimental evidence of efficiencies over the 70% mark can be obtained for frequencies up to 35 GHz (see also Figure 8).

The high efficiencies achieved at the low GHz frequencies are due to the ease of fabricating the devices and designing appropriate filters (low pass and DC pass – see Figure 1). To be able to receive a signal, the antenna has to be of the same length scale as the wavelength of the incoming wave, which at the low GHz frequencies ranges from a few mm to 10's of cm. At infrared and optical frequencies, wavelengths are from μm to nm, which subsequently indicates the necessity of building the antenna and rectifier in this length scale range. At this scale, a direct impedance match of the antenna to rectifier has to be achieved (Figure 2) instead of using a low-pass filter, which cannot be designed at such small dimensions. This is what Bailey's proposed electromagnetic wave energy converter[10] implies – a scaled down version of Brown's rectenna consisting of a μm length antenna connected directly to the diode rectifier transferring the output to the load through a DC pass filter of some sort. Bailey predicted an efficiency in excess of 50% for his EWEC device at microwave frequencies, although not backed by any modelling or experimental evidence of a whole device. The only evidence he gives is the ability of an EWEC prototype to absorb electromagnetic plane polarized waves at 475 MHz. His vision was to study the concept at microwaves and later scaling it to light frequencies where he speculates potential for unity efficiency. A MPT rectenna device without a low-pass filter is possible and was demonstrated in 2012 at 2.45 GHz[47]. The proposed printed shorted annular ring-slot rectenna is designed to match the impedance of the SBD rectifier at 2.45 GHz. The diode however will produce second and third order harmonics which will re-radiate at 4.9 and 7.35 GHz but these will be blocked because the antenna is designed to mismatch its impedance at the higher order harmonics thus preventing re-radiation[47]. This device architecture removes the need for a low-pass filter design and achieves 69% efficiency.

Apart from Brown[45,82] (for microwave) and Bailey[10] (for solar) several other authors (Kraus[11], Balanis[86], and Andersen & Frandsen[107]) have speculated about the possibility of 100% conversion efficiency coming from highly absorptive no-loss antennas and ideal matching, transferring and rectification of the absorbed input signal to the load. This antenna efficiency is assuming uniform distribution of energy across the antenna, a single frequency and a coherent source. The high efficiency values for MPT are achieved not only with appropriate antenna design, matching circuit and rectifier performance, but also with efficient delivery of a good signal, because the artificially created microwave signal is single band, polarised and coherent. This makes the antenna engineering easier. Simply reducing the size of the components to operate at solar frequencies does not necessary mean that the efficiency will remain as high as that observed for MPT Rectennas. Unlike monochromatic microwave radiation, sunlight is unpolarised, incoherent and distributed over a wide band of wavelengths[96]. This creates further challenges in antenna engineering and lead to disputes on how to model the device performance. Furthermore, the diode has to be optimised to rectify the signal at the higher frequencies and both antenna and diode have to be well matched to maximise power transfer.

Provisional tests at 10 GHz with a dipole antenna and a Schottky diode were demonstrated by ITN[5] estimating efficiencies of over 50% however this frequency is too low for solar energy harvesting. ITN state that the lower frequency rectenna is scalable to the higher THz frequencies required for solar harvesting with their models predicting up to 85%[5] efficiency. According to microwave antenna theory, the antenna length scales linearly with the incident frequency which means that in theory the antenna can be scaled to resonate at IR and optical frequencies[5]. This is not entirely the case because at IR and optical frequencies the conduction is not Ohmic and the scaling laws are rather an estimation than an accurate representation of the real-life situation as the majority of the energy in the surface modes is carried in the dielectric above the antenna. This symbolises the importance of impedance losses. The antenna has to be designed to resonate against a complex waveform

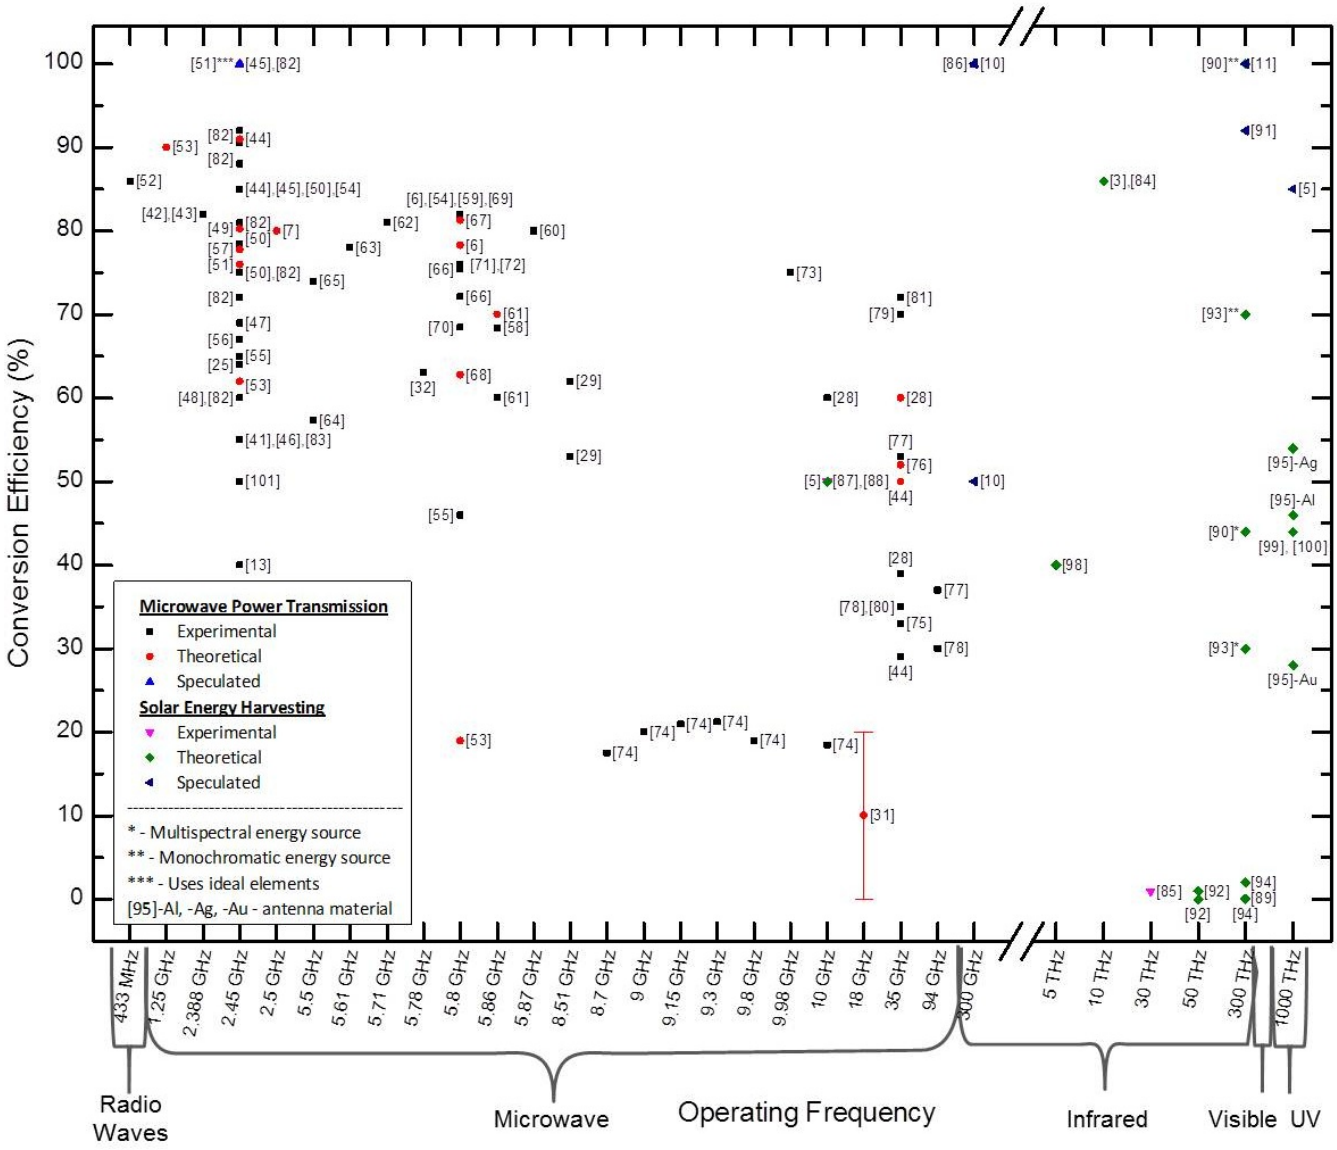

FIG. 8. Reported conversion efficiencies (as defined by their authors) at their maximum operating frequency of a rectenna device. Data points are grouped by the two applications of the rectenna - either Microwave Power Transmission or Solar Energy Harvesting, each displaying experimental, theoretical or speculated efficiency values. [**] indicates the reference corresponding to the data point. Data collected from [3,5–8,10,11,13,25,28,29,31,32,41–101]

and absorb broadband solar radiation which ranges from about 150 to 1000 THz, 85% of which corresponds to a wavelength of between 0.4μm to 1.6μm[5]. To reach the targeted frequencies in the high THz region, SBD rectifiers would not meet the criteria as the best cut-off frequencies are only up to a few terahertz[103]. MIM diodes are used for their potential to work in the higher THz region. The first practical demonstration was done by NIST[85] who used atomic layer deposition grown $Cr/CrO_x/Au$ diodes coupled to a dipole antenna and measured its efficiency at 30 THz (achieved using a CO_2 laser) to be below 1%. This attempt was carried out on an un-optimised antenna structure with a poor MIM diode. Following this, numerous theoretical models have been proposed, predicting the overall conversion efficiency of the solar rectenna (see Figure 8). For MPT rectennas, most theoretical and experimental efficiency results tend to be of the same order, whereas it can be seen that for Solar rectennas different attempts on modelling the performance predict a spread of efficiencies. Some approaches are close to the Landsberg limit of 93.3%[102] whilst others predict discouraging figures below 1% (Figure 8).

Conversion efficiencies from 0.001% to 2% have been

theoretically derived[89,92,94] employing various assumptions and a variation of modelling approaches (Figure 8). Mashaal & Gordon[89] analysed the efficiency in terms of losses by the state-of-art rectenna designs which adopt single polarization antennas able to convert only half of the random-polarization input power from solar radiation and a half-wave rectifier blocking the negative voltages of the input signal. Their assumptions were based on ideal matching between antenna and rectifier, zero turn-on voltage, limitless switching speeds and non-filtered signal output from the antenna prior to entering the rectifier which yielded an overall conversion efficiency of 0.0795% and four times as high if a full-wave rectifier is employed. It is a common misperception that with rectennas, the diode forms a half-wave rectifier, which would hold true for a single diode in a series configuration. However, common rectenna design incorporates a diode connected in parallel, which forms a clamp circuit capable of rectifying the full wave[99,100]. Therefore, estimating rectenna conversion efficiency should not be discouraged by assuming a half-wave rectification mechanism. Instead, efforts should be concentrated in understanding the effect of impedance mismatch. Briones *et al.*[92] based their model on the assumption that the collection of EM radiation by the antenna is done efficiently, which resulted in 0.001% efficiency of the system due to impedance mismatch losses between antenna and rectifier and inefficient rectification of the signal. By assuming efficient rectifier performance, the potential efficiency rises to approximately 1%.

An equally important criterion for efficient device operation is antenna material selection. Vandenbosch & Ma divided the analysis on the efficiency of nano-rectennas into two parts – 1) the efficiency by which the light is captured by the antenna and brought to its terminals[97] and 2) the efficiency by which the captured light is transformed to low frequency power by the diode[95,96]. Considering first the antenna efficiency, they studied various antenna materials in the form of 250 nm dipoles placed on a substrate[97]. Their calculations predicted antenna efficiency of 61.6% for Ag, 50.3% for Al, 34.3% for Au, 29.5% for Cu and 9.4% for Cr. In a later paper, [95], they looked at the diode efficiency and more specifically, investigated the power loss due to impedance matching whilst assuming efficient signal rectification. This analysis was only done on the highest performing materials – Ag, Al and Au. Their work was a continuation of a previous work by Sarehraz *et al.*[96], however their analysis covered 75% of the power radiated by the sun (up to 1000 THz) whereas Sarehraz *et al.* only based their analysis on 15% of the spectrum. Although Al gave the best matching efficiency of 97%, the best overall conversion efficiency of the rectenna considering both constituent parts is with Ag which gives 54% whereas Al would have 46% and Au just 28%[95](Figure 8). So far the analysed publications all share a united opinion that a suitable rectifier is needed in order for the above mentioned efficiency estimates to be achieved or improved. For impedence matching, Ma & Vandenbosch[95] suggest that the impedance of the rectifier must be of the order of 100Ω both for the real and imaginary part and favour aluminium as being a suitable material for this application.

A governing factor in rectifier performance is its RC time constant which defines the cut-off frequency, f_c. This is the upper limit at which the rectification process is efficient. Above the cut-off frequency, rectification is still possible however the strength of the rectified signal at the output of the MIM will drop by a factor of approximately $(f_c)^2$, thus the higher the frequency above f_c the lower the rectification efficiency[96]. The cut-off frequency is estimated by the following expression proposed by Sanchez *et al.*[104],

$$f_c = \frac{1}{2\pi RC} \tag{2}$$

where R is the series resistance and C is the capacitance. The cut-off frequency of the whole rectenna device can be evaluated by the following relation, which considers the antenna impedance (R_A) and diode resistance (R_D)[92],

$$f_c = \frac{R_A + R_D}{2\pi R_A R_D C_D} \tag{3}$$

To achieve a high cut-off frequency, the RC constant must be small, which can be obtained with a small junction area[104], and appropriate material selection and fabrication. MIM rectifiers, although the most promising rectifier technology, have not been demonstrated at high THz frequencies with the best MIM diodes operating only up to 150 THz ($\lambda = 2$ μm)[5] (more detail in Section V). Improving MIM fabrication technology and material system design would potentially yield the solution to the rectenna efficiency.

So far, the reviewed efficiencies were all based on classical approaches, not concerning thermodynamic limits to solar energy conversion. In terms of equilibrium, an antenna receiving power from any source and transferring it to the load must transmit the same amount of power back to the source[3]. If the power is extracted from the load, the reduction in its temperature will introduce a different approach to analysing the energy balance between the incoming, extracted and reradiated powers. In this case, Corkish *et al.*[3] state that the system would have the same conversion efficiency limit as the one expected for a solar thermal collector. Assuming the Sun to be a 6000 K black body and the surroundings to be at 300 K, this limit is 85.4% for mono-spectral energy conversion and 86.8% for multi-spectral. Further analysis suggests that the Landsberg[102] limit of 93.3% can be reached due to certain benefits that the rectifying diodes have in rectennas (see [3] for more details), however this is hard to justify due to the generation of thermal noise by the rectifiers. Diodes cannot rectify their own thermal noise as it violates the second law of thermodynamics (known as Brillouin's paradox[106]).

Lerner *et al.*[93] developed a thermodynamic expression

for the open circuit voltage and conversion efficiency of a rectenna with the rectification process based on the geometric property of the antenna tip which provides a connection to the circuit and creates a tunnel junction. They envisioned the possibility of using advanced nanofabrication techniques and a selective atomic layer deposition process to manufacture nanometer junctions which would potentially allow for rectification of blue light frequencies[93]. In modelling the circuit of the rectenna, it can either be considered as a constant voltage source with an emf independent of the load resistance or as a constant current source whose emf depends on the load resistance. As suggested by Lerner *et al.*[93], the rectenna device is more appropriately modelled as a constant current source in which case efficiencies are predicted in excess of 70% for a monochromatic light source and an optimised device. Should the device be tuned for multiphoton absorption, the efficiencies are expected to be further enhanced[93]. The question remains as to whether a suitable technology is yet available to make such structures.

Another analysis on the broadband blackbody radiation response of optical rectennas was done by Joshi & Moddel[90] by using the theory of photon assisted tunnelling. By assuming negligible reverse current of the diode, zero dark current turn-on voltage and perfect matching to the antenna, the device power conversion efficiency at monochromatic light can approach 100%, whereas for multispectral light the value is approaching a maximum at 44% at an operating voltage of 1.1 V. It should be noted that these authors also suggest that spectral splitting is likely to improve the efficiency. This can be achieved by setting the operating voltage for each rectenna to rectify the desired spectral range, thus implying that the operating voltage for the diodes in rectennas has a similar role to the band-gap as a limiting factor in photovoltaic devices[90].

With its proven success to receive and rectify monochromatic microwave beams with high efficiency, there is a growing interest in establishing the true potential of the rectennas' ability to convert solar radiation. As seen in Figure 8, there are many theoretical approaches predicting this, however there is no one universal theory that clearly states whether the solar rectenna can compete with, let alone surpass common photovoltaic cells. There is however, the common opinion between scientists worldwide that the technology is not mature enough to fabricate a device of comparable efficiency. Advances in antenna engineering suggest that it is now possible to manufacture nano sized antennas which can absorb solar radiation from the infrared to the visible frequencies (Section IV). Work on the rectifier component has seen great progress over the years with many attempts showing great potential for use in rectenna devices (Section V).

IV. ANTENNA

Antennas are used either as transmitters, to create electromagnetic (EM) waves that have a well-defined radiation pattern, or as receivers of EM waves from a remote source[86]. The purpose is usually to send or extract information that is encoded into the EM wave. Antennas are now essential in many aspects of modern day living, the mobile phone being the most common example. They normally operate at a resonance. Typically this is a half wavelength dipole antenna. The resonant wavelength of the antenna will be at the wavelength of the incoming propagating signal and energy is then transferred between them. For this reason, the antennas are usually fabricated in the dimensions of the wavelength of the incident wave. A higher frequency thus requires a smaller antenna. However, an antenna designed to be resonant at a very specific frequency by only considering a linear dimension does not guarantee efficient energy absorption. Other factors such as impedance mismatch in the circuits, bandwidth, direction and polarisation of incidence radiation needs to be considered. The aim of this section is to introduce some different designs of antennas for microwave and optical frequencies.

Most antennas at microwave frequencies are designed to work within a specific frequency band reserved for industrial, scientific and medical (ISM) frequency use. For example, one of the most popular frequency bands is 2.4 – 2.5 GHz, which devices such as wireless networks, near-field communications, and Bluetooth use. Therefore these antennas only require millimeter dimension. A dipole antenna is one of the simplest designs. It consists of two identical metal elements in mirror symmetry. The most common form is two metal rods aligned on the same axis. The length of the metal rods is half the size of the resonance wavelength. Higher-order resonance modes also occur in the same antenna but at reduced efficiency due to attenuation of the induced current in the antenna. Nevertheless, the accepted frequency bandwidth is very narrow. A slight variation of the incoming frequency gives rise to parasitic capacitance and inductance resulting in inefficient energy absorption. Therefore, a precise fabrication of the antenna is necessary. This increases the difficulty in manufacturing good devices, especially when the frequency of interest is higher.

One method to circumvent the narrowband absorption problem, which dipole antennas encounter is to extend the arms width above the standard limit (i.e. 5% longer than the wavelength)[108], allowing a bigger window of frequency acceptance. This type of antenna is referred to as the bow-tie antenna (Figure 9). The length of each arm is half the size of the radiation of interest. However, the correct length of the antenna alone does not guarantee high efficiency absorption since the incoming wave has various angles of incidence and polarisation[109]. To overcome this problem, a variety of designs have been investigated, such as spiral[108,110](Figure 9), log-periodic[108,110], microstrip slot[111], and retrodirective rectenna array[112].

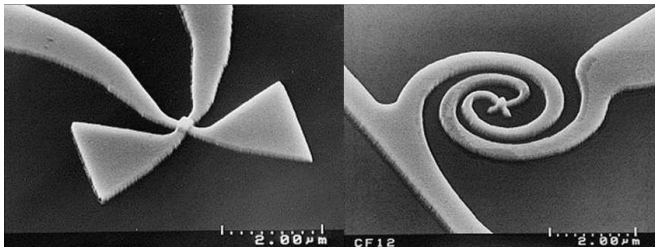

FIG. 9. SEM images of (left) bow-tie antenna with integrated Ni-NiO-Ni diode and (right) spiral antenna. (Reprinted from [108], ©1998 with permission from Elsevier)

As previously discussed in Section III, at microwave frequencies, antennas can be designed to be very efficient. Achieving such high efficiencies at the higher frequencies is more challenging with scaling down antennas. The solar spectrum emits energy across a broad band, which implies that the antenna must absorb a large bandwidth of solar frequency, otherwise most energy will be lost. For an antenna to operate efficiently at optical frequencies it is necessary to adjust both the inductance (L) and capacitance (C) to bring the device resonance to the required short wavelength. This would require both L and C to be very small[113]. To achieve this, the dimensions of the antenna must be reduced to the scale of the optical wavelength, i.e. nanometer. Scaling down the conventional antenna design to nanometer is of interest, as it can be determined whether classical antenna theory remains valid. For example, electron beam lithography has been used to fabricate a dipole antenna with a 3.5 nm NiO layer, sputtered between the two Ni antenna arms[109]. The dipole antenna had a total length of 6.7 μm and was designed for 10 μm wavelength (30 THz). Another example is of a gold dipole antenna fabricated by using focus ion beam (FIB) milling[114].

These attempts have proven it impossible to scale classical antenna designs to the optical frequency regime. At radio frequency the metals used for the construction of antennas can be considered almost lossless. This allows a large variation of radio frequency antennas to be designed by considering the metal to be a perfect conductor. However, the losses become increasingly significant as the frequency rises. This is due to the finite effective mass of electrons causing the electrons to react with increasing phase lag to an oscillating EM field[115]. As soon as the phase lag approaches 90^o the amplitude of the charge oscillation goes through a maximum and is only limited by the Ohmic and radiation damping of the system[116]. In metallic nanoparticles this resonance corresponds to the localized surface plasmon resonance (LSPR). For gold, silver, aluminium and copper the LSPR is in, or very close to the visible light part of the spectrum. The LSPR can be exploited to overcome some of the drawbacks of antennas at optical frequency, in particular the high Ohmic losses compared to microwave frequencies.

A. Properties of Metals at Optical Frequencies

The optical response of metals can be described by a complex frequency-dependent dielectric function,

$$\epsilon(\omega) = \epsilon_1(\omega) + i\epsilon_2(\omega) \tag{4}$$

The electric field is related to the induced polarization density as[117],

$$P(\omega) = \epsilon_0[\epsilon(\omega) - 1]E(\omega) \tag{5}$$

For optical antennas, Ohmic losses in the metal should be minimized. The Ohmic absorption is proportional to the conductivity of the material, $\sigma(\omega)$, which is related to the dielectric function by.

$$\epsilon_2 = \sigma(\omega)/\epsilon_0\omega \tag{6}$$

Ohmic losses take place in close proximity to the surface of the metal, within the so-called penetration depth[118], which for metals at visible wavelengths are of the order of several nanometers (approximately 13 nm and 31 nm for aluminium and gold at 620 nm wavelength, respectively)[119]. The dielectric properties of a metal can cause a LSPR in the visible spectrum, which is connected to large local fields, and enhanced scattering and absorption.

At optical frequencies the metal conduction electrons may be treated as an ideal electron gas. The collective behaviour of this free electron gas can be expressed using the Drude-Sommerfield model[118],

$$\epsilon(\omega) = \epsilon_\infty - \frac{\omega_p^2}{\omega^2 + i\gamma\omega} \tag{7}$$

where ω_p is the volume plasma frequency and γ is a damping constant[118]. (For Au at optical frequencies $\omega_p = 13.8 \times 10^{15} s^{-1}$ and $\gamma = 1.07 \times 10^{14} s^{-1}$)[116]

The DrudeSommerfield model does not account for interband transitions due to photons with high-enough energy promoting electrons from lower lying valence bands to higher energy conduction bands[120]. This can be described using a Lorentz model of the dielectric function, which is described by a collection of damped harmonic oscillators with well-defined resonance frequencies, ω_0,

$$\epsilon(\omega) = \epsilon_\infty + \sum_{i=1}^{n} \frac{\alpha_i \omega_p^2}{\omega_{0i}^2 - \omega^2 - i\gamma_i\omega} \tag{8}$$

where ω_p depends on the density of bound electrons involved in the absorption process and γ is a damping constant for the bound electrons. This Lorentz model shows strong deviation from the free electron gas model near ω_0, leading to a maximum in the imaginary part of $\epsilon(\omega)$ and strongly increased damping.

Au, Ag, Al and Cu are used as materials for metallic optical antennas. The dielectric constants of Au and

Cu are very similar, with a Drude-like response for wavelength above 600 nm and an onset of interband transitions occurring around 530–550 nm, making them excellent for antennas in the red and near-IR spectral region. For Ag the first interband transition is for a short wavelength, less than 400 nm, making it superior to Au for wavelengths around 500 nm. Al has a larger negative real part of dielectric function, and so among the four metals is the one that best approximates an ideal metal, especially in the 400–600 nm spectral region[116]. Unfortunately there is an interband absorption peak located at 800 nm wavelength, making Al unsuitable for use in the near-IR region, although, as previously discussed, it makes a good candidate for solar rectenna due to its high predicted matching efficiency[95]. As well as the spectral properties of the metals, the chemical stability also needs to be carefully considered. Ag and Cu are known to rapidly oxidise under ambient conditions and Al forms thin passivation layers of Al_2O_3. Due to its dielectric functions in the red and near IR parts of the spectrum and its excellent chemical stability, Au is the material most often used as a nanoantenna.

B. Scattering and Absorption Properties of Optical Antennas

Radio frequency and microwave antennas will normally always be considered as circuit elements connected to a feeding circuit. At optical frequencies the circuit element models are not valid and so optical antennas often appear as isolated or electromagnetically coupled structures, whose resonant properties have to be considered. Here, the LSPR of single and coupled metal nanoparticles, specifically the absorption and scattering properties, are considered. Consider a monochromatic plane wave of irradiance I_i incident on a sphere of radius a. If the irradiance is multiplied by a cross-section then the power absorbed or scattered by the particle can be calculated,

$$P_{abs} = I_i.C_{abs} \tag{9}$$

$$P_{sca} = I_i.C_{sca} \tag{10}$$

where C_{abs} and C_{sca} are the absorption and scattering cross-sections, respectively. The cross-sectional areas can be normalized to the cross-section of the sphere to give the scattering and absorption efficiencies:

$$Q_{abs} = \frac{C_{abs}}{\pi a^2} \tag{11}$$

$$Q_{sca} = \frac{C_{sca}}{\pi a^2} \tag{12}$$

where a is the radius of the sphere. Equations 11 and 12 define the two loss mechanisms, Q_{sca} which is radiative and Q_{abs}, which is non-radiative, the extinction efficiency being the sum of both these terms.

Smaller sized particles restrict electron motion and cause electrons to collide with the inner surface of the particle, resulting in loss of energy and increased absorption. Absorption is therefore the greater loss mechanism in smaller particles. The radiation damping rate is proportional to the number of electrons. This means that the larger the particle, the more significant this factor and the broader the plasmon resonance becomes. A larger particle volume results in a decrease in the amount of incident radiation absorbed but an increase in the scattering. Scattering and absorption due to small spheres can be described using the well-known Mie theory[121], where

$$C_{abs} = \frac{2\pi n_1}{\lambda_o} Im(\alpha) \tag{13}$$

$$C_{sca} = \frac{\left(\frac{2\pi n_1}{\lambda_o}\right)^4 |\alpha|^2}{6\pi} \tag{14}$$

The polarization, α, is given by:

$$\alpha = r^3 \frac{(\epsilon_2 - \epsilon_1)}{(\epsilon_2 + 2\epsilon_1)} \tag{15}$$

where r is the radius of the sphere, ϵ_2 the complex permittivity of the sphere and ϵ_1 the complex permittivity of the surrounding medium. Examples of Mie theory calculations of extinction, scattering and absorption for gold and silver spheres of various radii are shown in Figure 10.

Interesting observations that arise from the Mie theory calculations are that a number of peaks can be observed for larger diameter spheres, the longest wavelength peak being a dipole mode. As expected the LSPR broadens as the particle size increases but absorption and scattering maximums are not always at the same wavelength. The absorption and scattering properties can be tuned using different shaped particles. In this case more complex calculation methods are required, for example the Discrete Dipole Approximation (DDA)[123], Finite Element Method (FEM)[124] or Finite Different Time Domain (FDTD)[125]. FDTD is a popular method since it is possible to consider the scattering and absorption from any shaped particle in any dielectric environment and since the calculation is in the time domain a single calculation will yield the spectral response over a wide bandwidth, using a Fourier Transform[126].

If a surface that fully encloses the scattering object is now defined, then by considering the total field flowing through it, one can calculate the normalized absorption cross-section Q_{abs} from[127],

$$Q_{abs} = \frac{\int\limits_s Re(0.5\mathbf{E} \times \mathbf{H}^*) d\mathbf{a}}{|S_i|} \tag{16}$$

and by considering the scattered field the normalised scattering cross-section, Q_{sca}, is found from[127],

$$Q_{sca} = \frac{-\int\limits_s Re(0.5\mathbf{E}_s \times \mathbf{H}_s^*) d\mathbf{a}}{|S_i|} \tag{17}$$

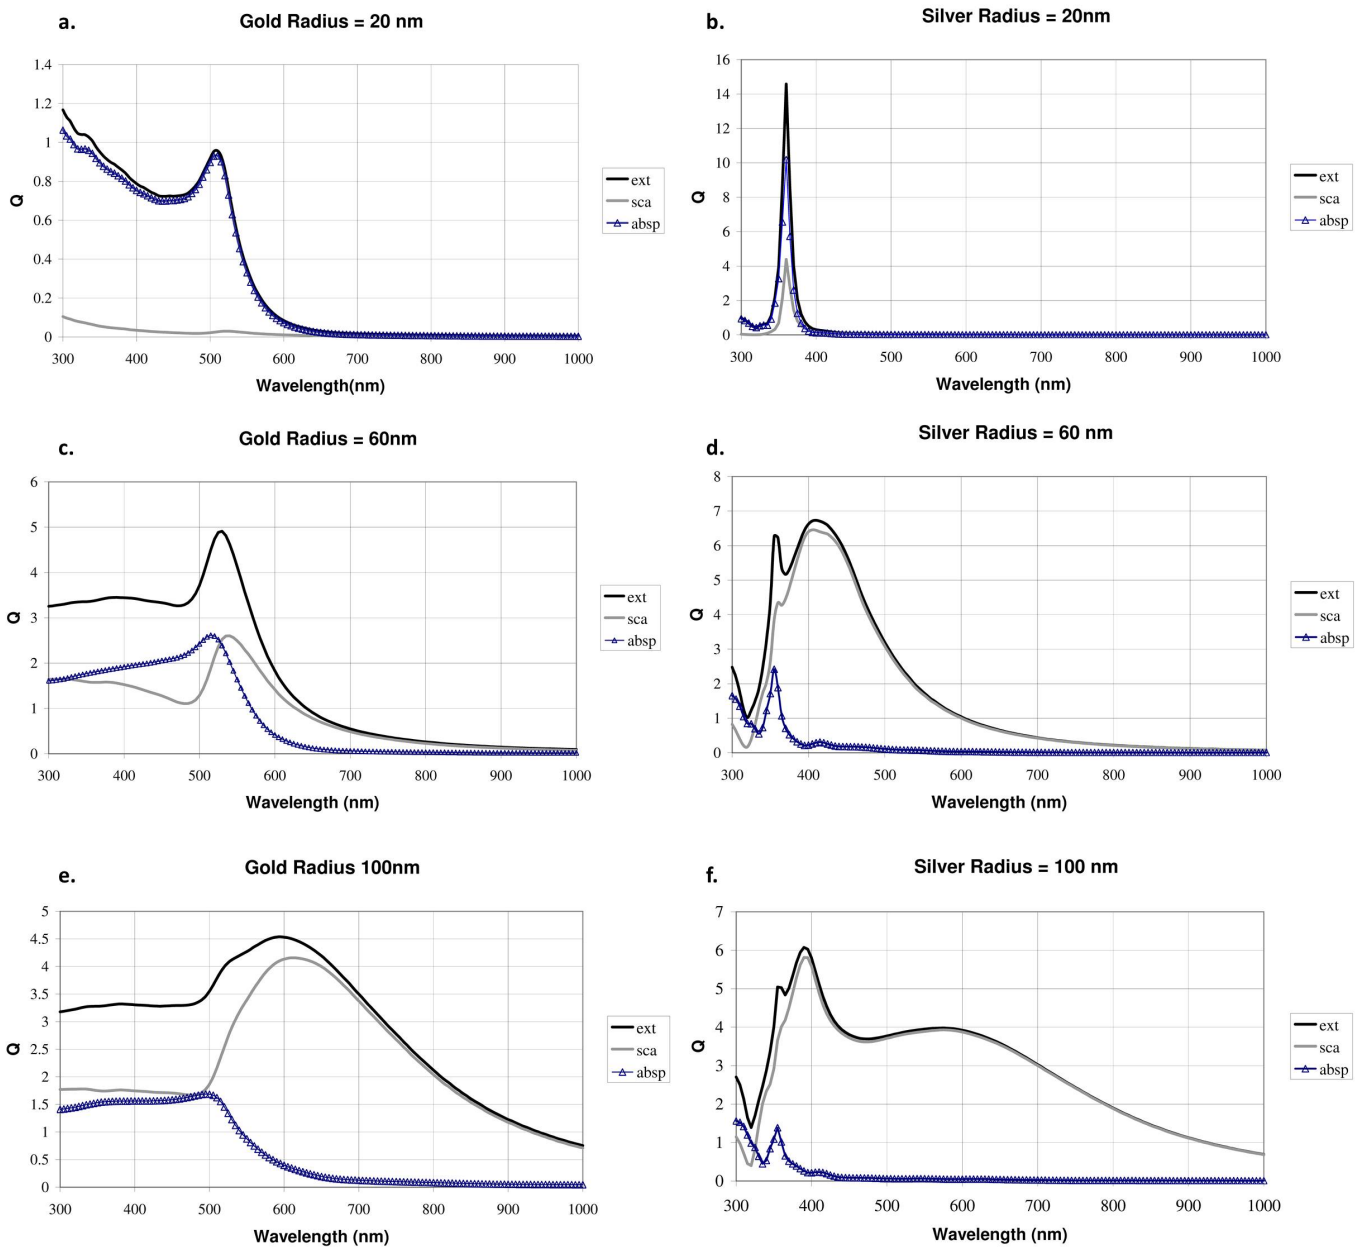

FIG. 10. Mie calculations of extinction, scattering and absorption efficiencies for silver and gold nanospheres (a) Au sphere of 20 nm radius (b) Ag sphere of 20 nm radius (c) Au sphere of 60 nm radius (d) Ag sphere of 60 nm radius (e) Au sphere of 100 nm radius (f) Ag sphere of 100 nm radius.

where $|S_i|$ is the power incident on the cross-sectional area of the nanoantenna. Using computational electromagnetics to calculate the electric (**E**) and magnetic (**H**) fields at the enclosing surface, Equations 16 and 17 can be solved. Figure 11 shows the Q_{sca} calculated using FDTD for (a) two closely spaced and (b) two overlapping spheres, where the spheres are silver and of 50 nm diameter[122].

Furthermore, the surrounding dielectric environment and orientation of the nanoparticle can significantly modify the absorption and scattering properties[127]. As an example, consider the two configurations of 30 nm radius hemispherical Au nanoparticles, depicted in Figure 12. In both configurations the metal nanoparticle is at the interface between the air and silicon on the lower surface of the semiconductor. In the first case the nanoparticle extends into air whilst for the second case it extends back into the silicon. In each case the scattering properties of the metal nanoparticle are calculated when there is a normally incident field from within the silicon[127]. The results are shown in Figure 13. It can be seen that in case (b) the scattering efficiency is dominant whereas in

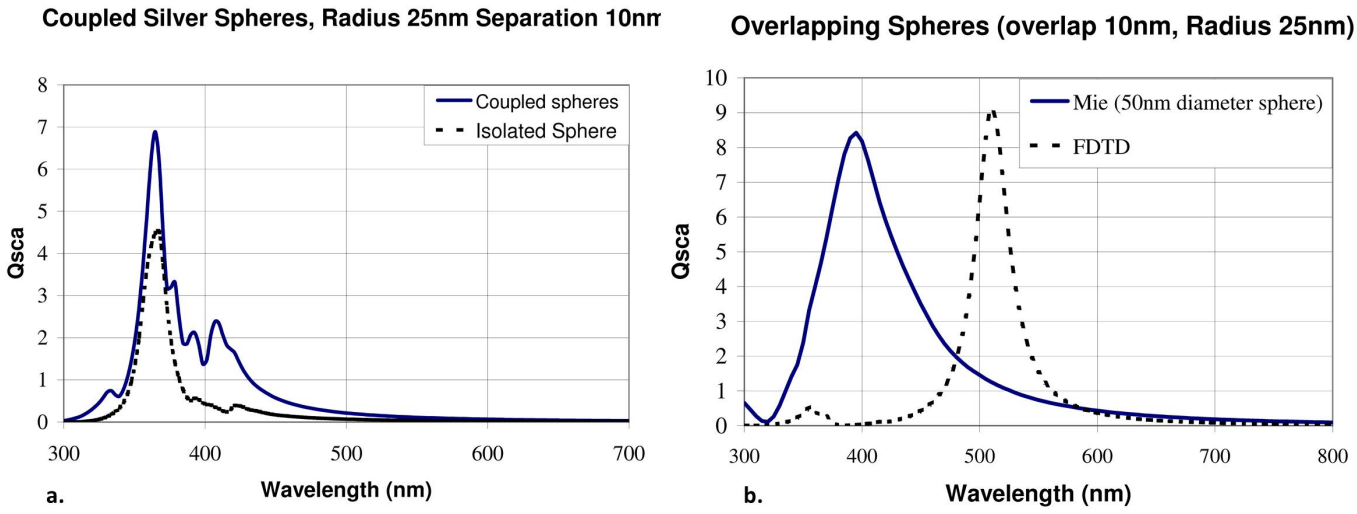

FIG. 11. FDTD calculations of Q_{sca} for (a) two closely coupled Ag spheres and (b) two overlapping Ag spheres.

case (a) it is the absorption that is the largest extinction component.

We have discussed the LSPR of isolated and coupled nanoparticles in terms of their absorption and scattering efficiencies. The subsequent coupling between the nanoantenna and rectifying diode will need to be optimised. Absorption is caused by the generation and recombination of electron hole pairs (EHP). EHP formation occurs when the plasmon quantum excites an electron from the Fermi level to an occupied state below the vacuum level. It has been shown that the concentrated electric fields around a nanoantenna, due to the LSPR, can cause hot electron carriers[128–130]. Because of their higher energy, hot electrons will extend further away from the nanoparticle than an equilibrium electron distribution, which is above the vacuum level. If a nearby electron acceptor is present, hot electrons can transfer into its electronic states. This hot electron carrier generation and injection into an acceptor due to the high fields is a topic of much current research in photovoltaic devices[128–131], in particular optimizing the efficiency of this process.

For an optical rectenna it is desirable to enhance and localize (i.e. concentrate) the propagating fields to enable coupling into external circuit elements. The concentrated fields tend to be higher for particles with a higher scattering efficiency and between the small gaps of coupled nanoparticles. This is opposite to hot electron devices which seek to maximise the absorption of photons in the nanoparticle. Figure 14 shows the values of electric field, normalized to the incident field, around Ag nanoparticles, formed by colloidal lithography using 500 nm polystyrene spheres as a template on a glass substrate[132] (this makes the triangular sides around 120 nm in this case). The scale is logarithmic and it can be seen that there are up to two orders of magnitude electric field enhancement in the gaps between the particles.

C. Alternative structures

Progressing toward a more efficient energy harvesting technology, some creative and novel designs have been explored. Other than the hot electron assisted mechanism, the idea of optomechanical nanoantenna has also been explored. In this design, the plasmonic bowtie antenna when coupling with the incident radiation, generates a strong electric field in the gap regions of the antenna arms and bend the arms toward each other[133] (Figure 15). As the arm bends toward each other, a redshift in transmission and reflection power occurs, allowing the device to have a larger operation bandwidth. With the inclusion of surface plasmon polariton property, it is calculated that

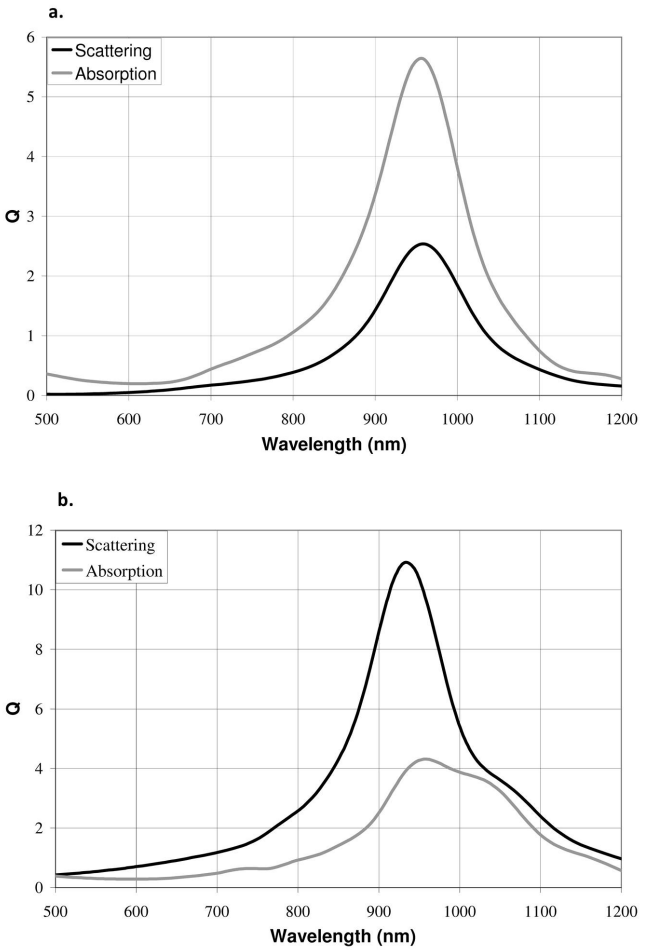

FIG. 13. Q_{sca} and Q_{abs} FDTD calculations for (a) nanoparticle extending into air (b) nanoparticle extending into silicon. (Reprinted from [127])

the antenna length can be greatly reduced while provide a mechanical bandwidth of 4.4 GHz.

The propagation wavelength for the waveguide in the material is very small. This suggests that if the antenna is very close to the diode, it can reduce losses[116]. In Travelling Wave (TW) MIM rectenna design, a MIM junction is created between the top and bottom bow-tie antenna[134,178] (Figure 16a). This allows the diode to rectify the absorbed radiation at this MIM junction. This design is similar to a bow-tie antenna, except that the left bow and the right bow are separated by a very thin layer of insulator, forming an extended MIM tunnelling diode. The absorbed radiation excites surface plasmon and propagates along this axis (Figure 16c). The current induced between the top metal and bottom metal cause tunneling of electrons to occur. A final rectified current is produced due to the asymmetry in the IV characteristic at the bias point (further information in Section V). One of the advantage in this design is that it is not limited by the RC bandwidth.

Another example of integrated rectenna design is the slot-antenna-based frequency selective surface (FSS) with integrated MOM diode[135]. The materials consists of Al, Al_2O_3 and Pt on benzocyclobutene (BCB) standoff, designed for absorbing radiation at 28.3 THz (10.6 m). Numerical simulations showed that when the incoming radi-

ation is parallel to the diode junction, the electric field is concentrated 2000 times across the diode with a decrease of reflectance around the desired wavelength, which can be used as an indication of absorption. A working device was fabricated with e-beam lithography (Figure 17) and similar optical response in reflectance was measured.

The recent development of graphene technology also prompts the incorporation of graphene into nanoantenna design. Ag is known to suffer from sulfidation under ambient environment, resulting in degradation of the plasmonic property[136]. Graphene was shown to be able to passivate the Ag and prevent sulfidation without affecting the plasmonic property of the Ag nanoantenna[136]. Additionally, radical changes in the plasmon energy and strength were also observed by electrically doping patterned graphene arrays with a gate voltage[137]. The development of new materials such as graphene open up new possibility to design a better optical antenna.

D. Impedance matching

As previously introduced, the efficient energy transfer from antenna to diode requires an impedance match between both components. A theoretical analysis on an optical dipole nanoantenna showed that the nanoantenna appears to be an effective RLC parallel circuit[138] (Figure 18). The two parallel resistances are due to radiative decay and non-radiative decay rates. The electrical properties of a nanoantenna are intrinsically influenced by the material used, dimensions and geometric shape[95]. Dipole antennas of length between 100 and 350 nm for Ag, Al, and Au on glass have been studied through simulation[95], as previously introduced. At a single frequency and assuming no loss of power in impedance mismatch, a silver dipole shows the highest efficiency. However, the upper bound efficiency drops when the solar irradiance spectrum is taken into account. Further investigation by inclusion of losses due to impedance mismatching showed even further decrease in conversion efficiency (see Section III).

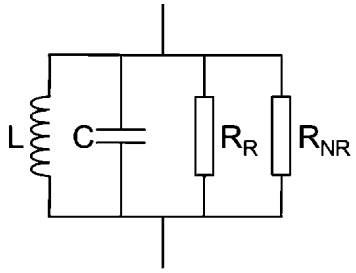

FIG. 18. Equivalent circuit of a metallic nanoantenna. (Reprinted (Fig. 1) with permission from [138], ©2010 by the American Physical Society)

Liu *et al.*[139] considered the nanoantenna as lumped elements in three-dimensional nanocircuits and demonstrated that impedance of the antenna can be tuned by loading a dielectric or a metal in the gap between a dimer. A SiO_2 load was used as the dielectric material. In the circuits it represents an additional capacitor for the dimer system. When gold is loaded between the gold dimers, the nanocircuit becomes an LC circuit. The gold load acts as an optical frequency inductor and the two gaps between the gold load and gold antenna behave as two

capacitors. To develop the idea further, a combined gold-SiO_2 load was also fabricated. The circuit now corresponds to an LC parallel circuit in series. In all cases, the impedance was tunable by changing the dimensions and the materials of the load, with the gold-SiO_2 showing largest tunability.

E. Nanofabrication

For microwave energy extraction device dimensions are in the micrometre range, achievable using well established photolithography techniques. At infrared and optical frequencies nanometre dimensions are required. Unfortunately the resolution of photolithography is limited by the diffraction wavelength of light and so different fabrication techniques are required. Fabrication techniques that have been demonstrated to be effective at obtaining nanometre resolution are electron beam lithography, nano-imprint lithography and colloidal lithography.

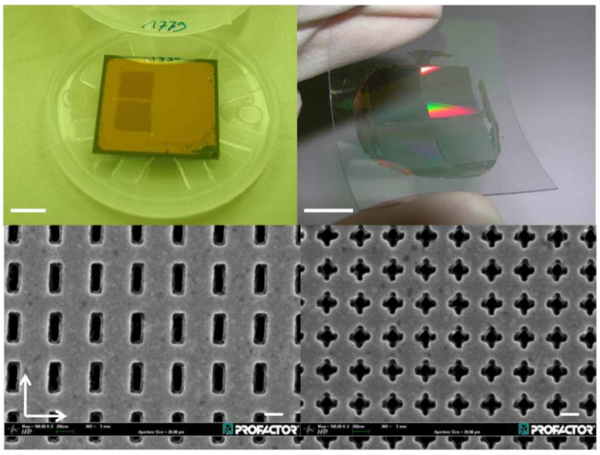

FIG. 19. (a) Photograph of a single layer negative index material (NIM) sample and (b) transfer printed gold grating on a flexible foil. Reproduced by permission of IOP Publishing. All rights reserved.)

Electron beam lithography is similar to photolithography but uses an electron beam instead of light. The wavelength of the electron beam is much smaller than light, allowing sub-10 nm resolution in patterning and creation of well-defined structure such as the nanogap in antenna-coupled diode in Figure 18. However it is costly and cannot be effectively up scaled for a large area. Nanoimprint lithography uses a pre-made mask to create a pattern on a substrate[140]. This mask can be used numerous times and allows large area fabrication. Compared to e-beam lithography, nanoimprint lithography enables large area patterning but each mask is specially designed for a specific nanostructure. Figure 19 illustrates an example of a large area of nanostructures fabricated using nanoimprint technology. A new mask will have to be made if the nanostructure required is different and the cost of the mask is high. Nanosphere lithography is a more versatile lithography technique, based on self-assembly of nanospheres. It allows fabrication of large area devices at relatively low cost. Although it does not allow huge degree of manipulation in the shape of nanostructure compared to e-beam lithography, a variety of shapes in large ordered array has been fabricated successfully (Figure 20), such as nanotriangles[132,142,143], crescent moon[144], nanorings[144], nanocones[145], and three-dimensional structures[146].

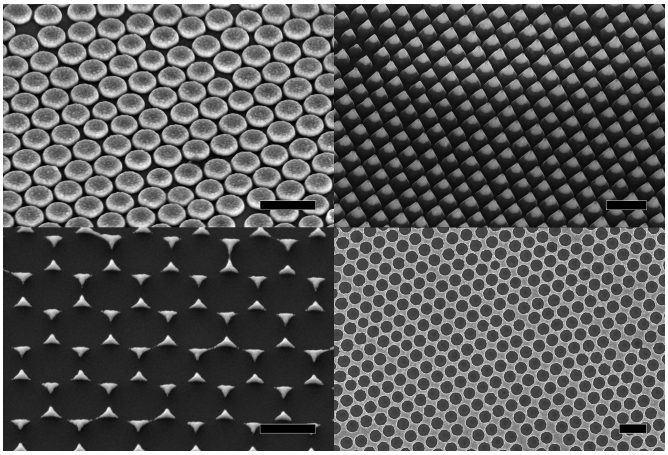

FIG. 20. SEM images of variety of gold nanostructures based on nanosphere lithography technique (a) nanotriangles, (b) slanted nanocones, (c) nanodisc array, (d) nanoholes. (*Note: 500 nm scale bar in all images*)

Advances in nanofabrication techniques are crucial in developing a better nanoantenna. Further details on nanoantenna theory and application can be found in some recent reviews [116,147].

V. RECTIFIER

A rectifier, a non-linear device such as a diode, is an integral part of the rectenna device, used to convert an AC input voltage from the antenna into a usable DC voltage. As discussed in Section III, the rectenna is fundamentally limited by the cut-off frequency (f_c) of the diode, above which the rectification process will become increasingly inefficient. f_c changes with the type of rectifier used due to the physical nature of the diode's operation dictated by its potential of achieving a low RC time constant. Schottky barrier diodes have been demonstrated and are theoretically limited to frequencies of a few THz, whereas MIM/MIIM diodes are shown to be operational at 150 THz[5,148] and are predicted to potentially exceed this and reach the visible regime. Three

parameters have been defined[5,149,185,188], which, if satisfied, result in characterising a device as a diode rectifier:

$$f_{asym}(V) = \left|\frac{I_F(V)}{I_R(V)}\right|; \textbf{ Asymmetry>1} \quad (18)$$

$$f_{NL}(V) = \frac{dI}{dV}(V)/\frac{I(V)}{V}; \textbf{ Nonlinearity>3} \quad (19)$$

$$f_{RES}(V) = \frac{d^2I}{d^2V}(V)/\frac{dI}{dV}(V); \textbf{Responsivity>7}V^{-1} \quad (20)$$

These three Figures of Merit (FOM) are commonly used to characterise the performance of MIM devices however can be equally applied to other diodes. The asymmetry FOM, defined in Equation 18, is the absolute ratio of forward to reverse current at a bias, a value of 1 indicating full symmetry and hence no rectification. The non-linearity FOM, as defined by Equation 19, is the ratio of the differential conductance to the conductance and is a measure of the deviation from a linear resistor. Finally the responsivity FOM defined in Equation 20 is the ratio of the second derivative of the I-V curve and the differential conductance and is a measure of the rectified signal as a function of input power. It is essential that the diode in a rectenna exceeds all of these criteria as the higher the FOMs for the diode, the more efficient the rectification process.

note: There was some disagreement argued by Tucker & Feldman[150] that responsivity should be described using second-difference equations and not derivatives in order to understand high frequency rectification. However, proving which is the correct approach is beyond the scope of this review as the authors aimed to only bring this theory to the attention of readers. The authors support the use of derivatives of the I-V curve in analysis of these FOMs.

The fundamental operational theory and recent experimental and theoretical developments of Schottky barrier diodes (used in the microwave power transmission rectenna), metal-insulator-metal and metal-insulator-insulator-metal diodes (proposed for solar rectenna), and geometric diodes (proposed for solar rectenna) will be reviewed in this chapter.

A. Schottky Barrier Diodes

Schottky barriers have been used as rectifying devices since the first cat's whisker detectors in the first decade of the 20$^{\text{th}}$ century. The 'barrier' itself is formed within the semiconductor side of a metal-semiconductor (MS) interface, the result of its conduction and valence bands bending to align the Fermi levels of each material. Figure 21 shows an ideal MS interface with the Schottky barrier, $\Phi^0_{B,n}$, marked.

In Figure 21, note that within the semiconductor, a depletion region, or space charge region, forms. This is a region of the semiconductor that is devoid of mobile charge carriers when the device is unbiased, and as such it can be considered as the dielectric between two plates of a capacitor, so having a direct influence on the *RC* time constant. Minimising the capacitance of a Schottky diode can be achieved through scaling (though this has the equal and opposite effect on the diode's resistance), or by increasing the depletion region width by using low semiconductor doping.

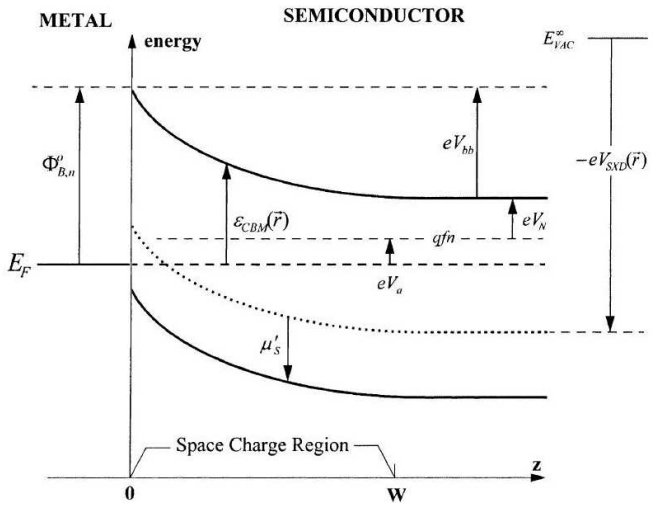

FIG. 21. Band diagram of an ideal Schottky Barrier, $\Phi^0_{B,n}$, contact formed with n-type semiconductor with an applied bias, V_a. (Reprinted from [151], ©2001 with permission from Elsevier)

The full operation of a diode has been well studied and understood over the past century, and readers are referred to [152,154], for a basic understanding of Schottky diode formation, operation and physics under different biasing conditions. Both the forward and reverse current-voltage (I-V) relationship is in most cases, where semiconductor doping is low enough, dictated by thermionic emission, rather than recombination or tunneling. The equation for thermionic emission, where the carrier in the semiconductor must pass up and over the potential barrier into the metal, is classically expressed as[152–154],

$$I = AA^*T^2 \exp\left(-\beta\Phi^0_{B,n}\right)\left[\exp\left(\beta V_A/\eta\right) - 1\right] \quad (21)$$

where A represents the contact area, A^* is the Richardson constant, T is the temperature, V_A is the applied voltage, η the ideality factor and $\beta = q/k_bT$, with q the electron charge, and k_b the Boltzmann constant. However, built into Equation 21 is the presumption that a perfect, homogeneous interface exists, with just one uniform value of $\Phi^0_{B,n}$. Instead, a more realistic scenario should be considered where multiple current paths exist flowing over barriers of different barrier height, so modifying this equation that has been the standard for a century or more. The papers by Tung[151,160] and others[155–159] pro-

vide a much more rigorous understanding of the Schottky diode and its operation under this inhomogeneous regime. Given the small potential size of a Schottky rectenna, the impact of such interface inhomogeneity will be the source of significant device-device variation, and an unpredictability of cut-off frequencies.

Typical Schottky diodes can have good diode characteristics in terms of the FOMs mentioned in Equations 18, 19 and 20, as demonstrated by the simple example of a Cr/Si Schottky diode made in-house for [155]. The characteristics of this diode are close to ideal (i.e. $\eta < 1.1$), and its FOM values are strong, with a diode asymmetry of 1669, nonlinearity of approximately 0.2 and responsivity above 10 V^{-1}. However, high series resistance and depletion region capacitance result in a cut-off frequency of just 40 GHz. Therefore, this is a device which could be suitable in a microwave power transmission rectenna, but it would be entirely ineffectual at solar frequencies.

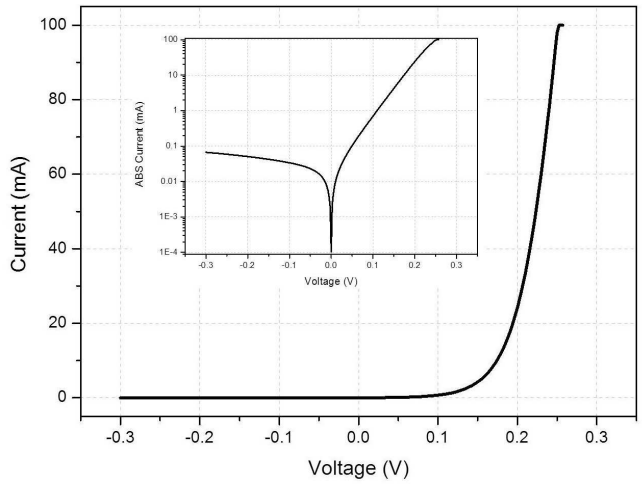

FIG. 22. Room temperature Current-Voltage characteristics of a simple Cr/n-Si lateral type Schottky barier diode of area $0.448mm^3$. SBH calculated at $0.51eV$, ideality factor of 1.06, diode asymmetry at ± 0.25 V of 1669, nonlinearity estimated at 0.2 and responsivity above 10 V^{-1}. The cut-off frequency has been estimated at 40 GHz.

With appropriate device design in terms of size and interface homogeneity, parasitic capacitances and resistances, arising from skin effects and residual native oxide scales at the MS interface, can be minimised to have a significant effect on the RC time constant. In silicon the cut-off frequency has been seen to reach 1 THz obtained by a layer of Ti-Pt-Au on a thin layer of n-Si[161], whereas 400 GHz has been seen from a simple Ti/n-Si structure[162]. On GaAs, frequencies of up to 5 THz have been achieved, as reviewed by Sizov & Rogalski[163]. This is obtained using highly doped GaAs substrate with an Ohmic contact on the back side upon which a thin (0.3-1 μm) epitaxial GaAs layer is grown, with Pt forming the Schottky contact. A honeycomb diode chip design enables thousands of diodes (diameters of 0.25-1 μm) on a single chip whilst minimising parasitic losses.

As rectifiers in the wireless power transmission rectenna application, SBDs are more than suitable candidates and as seen in Section III can operate efficiently. With cut-off frequencies in the low THz, Schottky diodes may potentially find usage as infrared rectennas although they will be limited to only function at a fraction of the far-infrared range, where the incident solar radiation is only up to 0.3 $W/m^2/nm$. The aim is to have solar rectennas operating at the high THz region where solar radiation is up to 1.7 $W/m^2/nm$, however Schottky diodes will not be able to efficiently rectify such high signals. Therefore, other approaches such as the MIM/MIIM and geometric diodes are being considered for the solar rectenna.

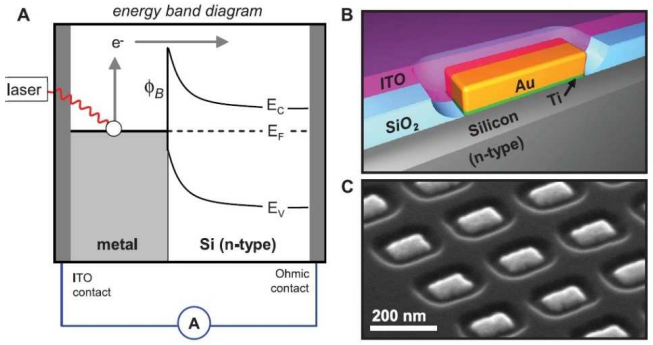

FIG. 23. Schottky diode as the active component for the solar rectenna device - concept inspired by Knight *et al.* **A** showing a band diagram of the proposed photocurrent mechanism, **B** showing the device layout and structure and **C** showing an SEM image of the array of devices. (Reprinted from [94], ©2011 with permission from The American Association for the Advancement of Science)

An alternative approach, which was first proposed by Knight *et al.*[94], is to use the diode as the active component in a hot-electron device. In this case, the array of nano-metre scale anodes double as the antennas, in which the incident light causes a localised surface plasmon resonance. Plasmon decay produces electron-hole pairs and as represented in Figure 23A, hot electrons are injected into the semiconductor after overcoming the Schottky barrier energy. The reported[94] quantum efficiency of this structure is estimated at being just 0.01%, though improvements are suggested to reach efficiencies of 2%. Recent publication suggests 30% efficiency of converting "hot electrons" in the metal to electrons in the semiconductor[164], though full conversion efficiency has not been estimated. In this case, although the device is based on an antenna coupled to a rectifier (similar components to a rectenna), the device is not proposed for light harvesting purposes due to its low efficiency and is instead demonstrated as a photodetector. Development of this concept into an energy harvesting applications

would require the conversion efficiency to be increased, though with the current state-of-art, this seems improbable.

B. Metal-Insulator-Metal Diodes

Current transport in Metal-Insulator-Metal (MIM) diodes is due to quantum electron tunnelling through an ultra-thin insulator layer (typically < 10 nm[165]). Rectification in these devices is due to variation in tunnelling rates caused by barrier asymmetry due to material selection, device geometry, thermal asymmetry, and photon induced deviation in electron flux distribution across occupied and unoccupied states[105], all contributing towards a nonlinear asymmetric I-V response. In the current review, we will qualitatively explain the nature of the I-V asymmetry taking into account the material selection for planar MIM devices under no illumination and thermal equilibrium. Under illumination, electron tunnelling is stimulated by different processes depending whether an antenna is or is not coupled to the diode. Further reading is suggested in [105,165,166,169]. Thermionic emission also contributes to tunnel diodes' I-V curves[165,188,189], especially to devices with thick insulating layers[188].

1. *Theory of operation*

Consider a Metal-Insulator-Metal junction as shown in Figure 24**a**. Metal 1 has a workfunction, Φ_1, lower than that of Metal 2, Φ_2, and χ is the electron affinity of the Insulator. The barrier height at the metal-insulator interface is determined from the difference between the workfunction and electron affinity respectively. At zero bias the band structure is shown in Figure 24**a**. By applying a negative bias (Reverse bias) to Metal 1, the band diagram shifts as in Figure 24**b**. In this case direct tunnelling is observed as a result of the *effective* tunnelling distance, d_t, being the same length as the insulator thickness. Further increasing the applied voltage, V_A, decreases the *effective* d_t, and it becomes shorter than the length of the insulator (as seen in Figure 24**c**). In this case, Fowler-Nordheim tunnelling[167] starts to occur. When a bias of the same magnitude is applied to Metal 2 (Forward biasing), the bands shift as in Figure 24**d**. Fowler-Nordheim tunnelling is observed in this case and occurs at a lower voltage, the higher the barrier asymmetry at both metal-insulator interfaces (arising from the difference in metal workfunctions). Further increasing the reverse bias (as in Figure 24**e**) will further decrease the *effective* tunnelling distance, d_t, which further increases the tunnelling probability in forward bias. Therefore, rectificaton occurs because for the same voltage magnitude in forward bias, d_t will be shorter and more current will be flowing than in the equivalent case in reverse bias. By changing the applied voltage, the tunnel distance changes linearly and the tunnel current is ex-

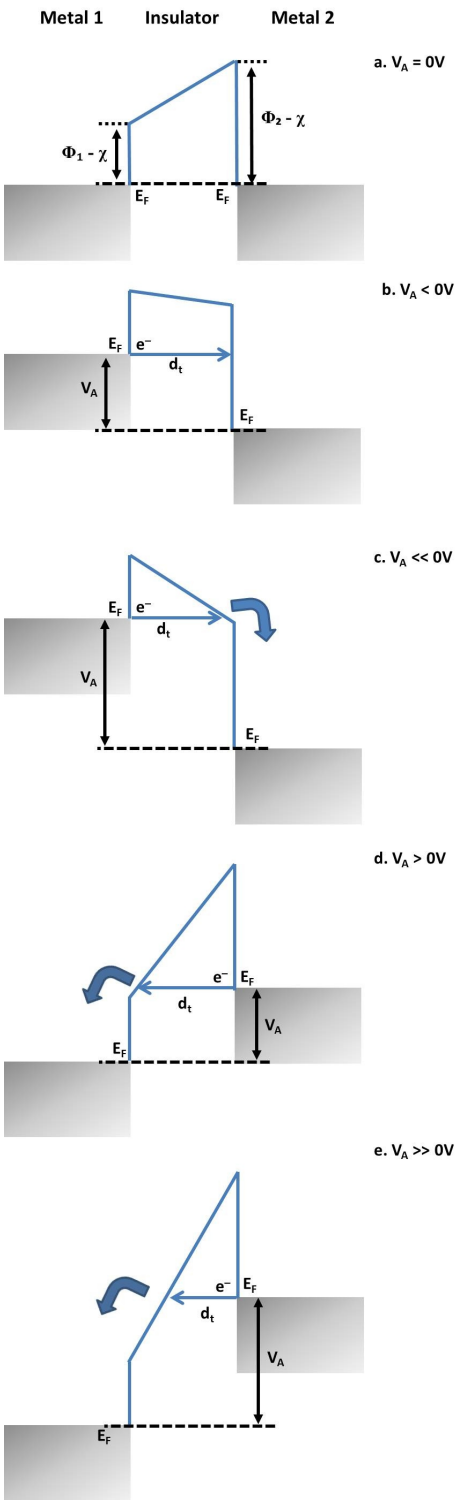

FIG. 24. Ideal band diagram for a MIM diode with dissimilar workfunctions for Metal 1, Φ_1, and Metal 2, Φ_2, χ the Insulator's electron affinity, E_F the Fermi level, d_t the tunnel distance and V_A the applied voltage. **a.** No bias situation ($V_A = 0V$); **b.** & **c.** Negative bias at Metal 1 (Reverse bias); **d.** & **e.** Positive bias at Metal 1 (Forward bias).

ponentially dependant on this distance[168]. This leads to an asymmetric, nonlinear current-voltage response and is the origin of the rectification mechanism in MIM diodes.

2. *Experimental devices*

Various metal-insulator systems have been used to investigate the rectification behaviour of MIM diodes. Research attempts are concentrated either towards modelling the behaviour and rectification properties or improving the figure of merits by optimising the material selection and fabrication techniques of these structures. As theory suggests, using similar metals in the MIM configuration should yield symmetric I-V curves, however asymmetric I-V curves have been reported for $Al/Al_2O_3/Al$[170] with structures and experiments conducted by the authors on $Ti/TiO_2/Ti$ and $Nb/Nb_2O_5/Nb$ devices having also displayed asymmetric I-V curves for these structures. The origin of this asymmetry is suspected to come from the formation of two different metal-insulator interfaces arising from dissimilar deposition processes, thus creating regions of enhanced leakage currents through the barrier. Other reported structures with optimised oxide layers such as Ni/NiO/Ni[108,174,176–178,180], $Al/Al_2O_3/Al$[171] and $Nb/Nb_2O_5/Nb$[149,185,187] show symmetry in the I-V curves, which is compliant with theoretical predictions. Although not displaying rectification properties, the Ni/NiO/Ni system is widely used for detection and mixing up to 30 THz infrared radiation due its significantly low resistance-area product of 1 $\Omega(\mu m^2)$[108,176–178], which indicates the potential for a low RC constant. However due to a lack of asymmetry, the second Ni electrode must be replaced with a metal of different workfunction in order to achieve rectification. This has been investigated by Hoofring *et al.*[175], Krishnan *et al.*[111,179] and Esfandiari *et al.*[181] with Au, Cr and Pt contacts respectively, all displaying good asymmetrical I-V response. Other structures of dissimilar materials which have shown promising results are $Al/Al_2O_3/Ni$[172], $Nb/Nb_2O_5/Pt$[149,184,185], $ZrCuAlNi/Al_2O_3/Al$[182] and also $Nb/Nb_2O_5/Ag$ (tested in-house and by [190]). More tested metal-insulator combinations are listed in [149].

ZrCuAlNi was suggested as an electrode due to its low roughness after growth, making it suitable for MIM devices[182,183]. However, it is not ideal due to formation of an interfacial compound at the interface with the insulator. This was highlighted by Grover & Moddel[168], who anticipated the importance of material selection for a good MIM and that arbitrary combinations of metals and oxides are not always feasible, as for example $Al/Al_2O_3/Pt$[173] displays a linear I-V and yet has been successfully shown to work in an antenna-coupled infrared detector. A study by Heiblum *et al.*[174] tested $Al/Al_2O_3/Al$, $Cr/Cr_2O_3/Au$, $Al/Al_2O_3/Ag$ and $Nb/Nb_2O_5/Au$ MIMs by exposing them to an IR laser and concluded their poor rectification properties due to the production of large thermal contributions when exposed to laser radiation. This is a very useful approach, which must be applied to other MIM candidates for solar applications. An alternative concept was previously described (Figure 16), consisting of a MIM diode based on a travelling-wave structure, which although having a symmetrical configuration ($Nb/Nb_2O_5/Nb$), outperforms planar type MIM diodes by three orders of magnitude at μm wavelength[134].

One of the most important findings in this field is a method for characterising the electrical properties of MIM devices by nanoindentation and later a bent wire technique suggested by Periasamy *et al.*[149,184–187]. The concept is based on a metal being deposited on a silicon substrate, after which a continuous oxide is grown and the second electrode is a bent wire of a desired material. This ensures a small contact area and the ability to characterise a point-contact type MIM junction. This work is very useful as it gives the chance to study various metal-insulator combinations before attempting to optimise planar thin-film diode devices. This technique was used to systematically study the influence the metal workfunction difference has on the electrical properties of MIM diodes (reference [149]). The structures analysed have a Nb bottom electrode, Nb_2O_5 insulator grown by anodic oxidation, and eight different metal 2 selections (Hf, Zr, Nb, Ti, Cu, Ag, Au, and Pt). The result was that the workfunction difference has a direct influence on rectification properties, with the asymmetry increasing sharply for $\Delta\Phi > k_BT$. This agrees with theoretical predictions and with the models by Simmons[191]. Conversely, nonlinearity FOM displayed no direct correlation with $\Delta\Phi$. The highest FOMs were observed for $Nb/Nb_2O_5/Pt$, which displayed 1500 asymmetry, 4 nonlinearity and 20 V^{-1} responsivity meeting the criteria outlined in Equations 18, 19 and 20. Recently, this work was continued through (reference [188]) the fabrication of 6400μm^2 planar devices with the same Nb/Nb_2O_5 base and six metal top contacts (Ag, Cu, Nb, Ni, Au and Pt). The work confirmed a direct linear relation between increasing asymmetry and increasing $\Delta\Phi$ with $Nb/Nb_2O_5/Pt$ showing optimal results with figure of merits of 7742 asymmetry, 4.7 nonlineary and 52.2 V^{-1} responsivity. These are to our knowledge the largest FOM values recorded and hence the most promising structure to be successfully integrated into a solar rectenna.

Periasamy *et al.*[185] also characterise other oxides with a Nb metal base and Pt bent wire and prove a hypothesis whereby the best rectification properties are expected from using dissimilar metals and low barrier heights at each metal-insulator interface in order to sooner promote the faster Fowler-Nordheim tunnelling in the forward direction. To achieve smaller barriers, high electron affinity insulators must be selected. Due to this reason, Nb_2O_5 and TiO_2 outperform Al_2O_3 and MgO. Another requirement for the insulator is a large dielectric constant since for small area devices the capacitance is reduced, however due to the requirements for tunneling the ultra-thin

thicknesses in turn increases capacitance, which has to be kept to a minimum as per Equation 2.

3. *Modelling approaches*

Modelling MIM devices is a significant challenge due to the many practical aspects of such ultra-thin layers. Interface roughness, pinholes and fabrication anomalies may all adversely influence device performance, and are difficult to account for reliably in the models. Nevertheless, modelling MIM performance is essential in order to confirm established experimental results and fully understand device operation as there is always room for improvement. Simmons[191] first proposed a model incorporating the WentzelKramersBrillouin (WKB) approximation, which is frequently used to reproduce MIM I-V curves. This model is very good at predicting forward characteristics, however it overestimates currents passing in reverse bias, leading to close to symmetric simulated I-V curves for dissimilar metal electrodes. Eliasson[165] developed a comprehensive model to predict rectification efficiency, tunneling transmission probability and estimation of device resistance in thin MIM diodes, with the exception of image forces and effective mass. Recently Hashem *et al.*[192] developed more accurate models to simulate the I-V curves and figures of merit of MIM devices. The model can be used for multiple insulator layers, whereas Simmons model is only limited to single insulator predictions. These models were shown to accurately trace experimental results reported by Choi *et al.*[193](on a polysilicon/SiO_2/polysilicon tunnel diode) whilst Simmons simulations predicted almost linear behaviour. With double insulator devices, the models are accurate in forward characteristics, however slightly underestimate the leakage currents in reverse bias. Recent work by Cowell III *et al.*[194] has developed a model to estimate the barrier height formation and tunneling effective mass of a MIM diode exhibiting Fowler-Nordheim tunneling, which can be used to help assess the impact of different processing conditions on the performance of the device.

4. *Fabrication and Characterisation*

Apart from material selection, the fabrication techniques used to manufacture MIM devices are also important for good device performance. Metal deposition is commonly deposited by sputtering or evaporation, techniques which are well understood, give high quality thin films and are industrially scalable. Controlled deposition of the ultra-thin insulator required for tunneling is a challenge. Anodic oxidation[149,185,188] of the first metal electrode is a good way of controlling growth of a high quality oxide, however, it is limited to only being able to grow the derivative oxide of the underlying metal. For research purposes, pulsed-laser deposition (PLD) supplemented by reflection high energy electron diffraction (RHHED)[195,196] can be used for monolayer controlled growth of oxide layers. This technique achieves ultra-thin continuous stoichiometric films of extremely high qualities, however PLD is not industrially scalable. Alternatively, reactive magnetron sputtering may be used, but there is some uncertainty over the stoichiometry and thickness control when depositing insulators. One of the most promising growth techniques is atomic layer deposition (ALD), which is a self-limiting deposition process allowing accurate thickness and stoichiometry control similar to RHEED PLD whilst maintaining a comparably high throughput and possibility of industrial scale processing.

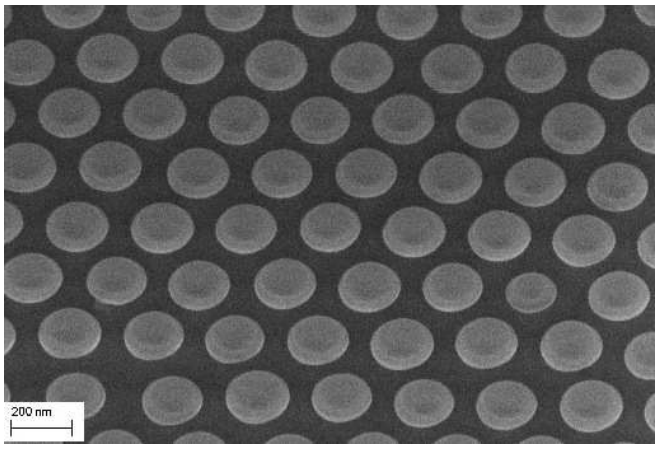

FIG. 25. SEM image showing an array of nanodiodes produced by growing an MIM multilayer, followed by colloidal lithography and Ar ion milling.

MIM device arrays of nanometer gap junctions over cm^2 areas[105], to create metal-vacuum-metal tunnel junctions which have similar properties to MIM diodes, also present a fabrication challenge. Common lithographic techniques have been used, but the economically viable techniques are limited to micron scale devices. However when the common lithographic techniques are supplemented by a recently optimised selective area atomic layer deposition technology[197], tunnel junctions of approximately 1 nm can be produced. This enables designs of antenna-rectifier coupled devices other than the more common planar types, which have great potential for success (see Miskovsky *et al.*[105]). Another challenge is fabricating arrays of nano-scaled lateral diodes to be of the same size scale as required for high frequency antennas. Bareib *et al.* have developed a highly efficient method for producing an array of several million nanodiodes by temperature-enhanced transfer priniting[198]. These devices were characterised with a conductive atomic force microscope setup (C-AFM), which showed good asymmetry in the I-V response of the nanodiodes. An alternative technique was developed by the authors, which involves the deposition in a vacuum of the full MIM layers, fol-

lowed by colloidal lithography and Ar ion milling to give an array of nanodiodes (Figure 25), and preliminary C-AFM confirms assymetry.

Current MIM tunnel diodes remain limited to rectify the infrared part of the solar spectrum due to their *RC* time constant. In a study to confirm the applicability of MIM diodes to solar rectennas, Grover & Moddel[168] conclude that efficient coupling between antenna and rectifier must be achieved, which implies that the rectifier impedance must be around 100 Ω as identified by Ma & Vandenbosch[95]. Results by Chin *et al.*[188] show promising improvement in MIM performance, although the structure has a limited current density passing through it due to the relatively *thick* oxide used (15nm). MIM diodes appear to be a good candidate for the rectifiers in a solar rectenna and the ever increasing success in modelling, characterisation and fabrication of these multi-layered devices have shown their potential.

C. Metal-Insulator-Insulator-Metal Diodes

The addition of another Insulating layer was proposed as it would benefit the rectification properties of the tunnel diode. Using Metal-Insulator-Insulator-Metal (MIIM) devices, the diode figure of merits are improved over the single insulator case. Asymmetry here can be achieved even with similar metal electrodes, as long as the electron affinity of both insulators is different. For the purpose of understanding the concept, we will qualitatively explain the simple case of Metal 1 and 2 being the same and Insulator 1 having a higher electron affinity than Insulator 2. At zero bias the band structure is the one depicted in Figure 26**a**. When a negative bias is applied to Metal 1 the bands shift as in Figure 26**b**, where the *effective* tunneling distance, d_t, is of the length of both insulator thicknesses and direct tunneling through both insulators is observed. Increasing the bias will eventually shift the bands to the situation in Figure 26**c** and the d_t is now shorter, however the electrons will fall into the Quantum Well (QW), from where the tunneling probability is reduced. By reversing the bias, initially tunneling will be direct through both insulators as in Figure 26**d**. Further increasing the bias will shorten the *effective* d_t and the tunneling is again direct but through only one of the insulators (Figure 26**e**). Further increasing the bias will further decrease d_t by promoting Fowler-Nordheim tunneling, whilst in the reverse case electrons will continue to tunnel into the QW. The origin of the asymmetry in the I-V curves of MIIM diodes with similar metal electrodes is due to the shift in dominant tunneling mechanism during forward and reverse bias and the formation of the Quantum Well due to using insulators of dissimilar electron affinity. By employing different metal electrons, the rectification properties of MIIM diodes can be further improved.

If the thickness of the lower electron affinity insulator is increased relative to the other insulator then the

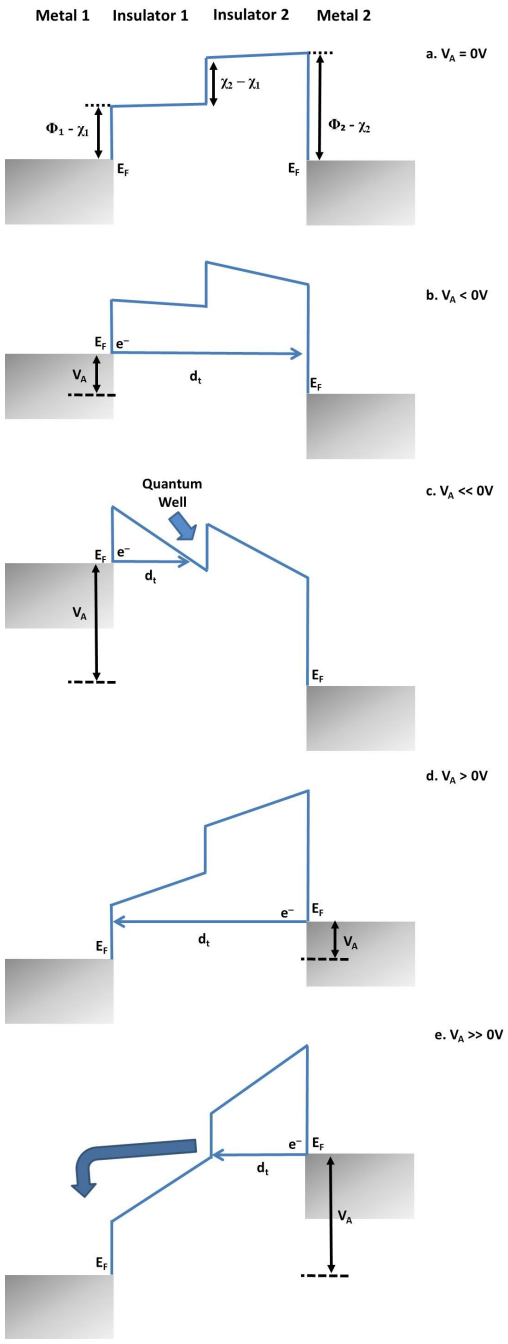

FIG. 26. Ideal band diagram for a MIIM diode with the same metal electrodes ($\Phi_1 = \Phi_2$) and two Insulators of equal thickness ($\chi_1 > \chi_2$). **a.** No bias situation ($V_A = 0V$); **b.** & **c.** Negative bias at Metal 1 (Reverse bias); **d.** & **e.** Positive bias at Metal 1 (Forward bias).

Quantum Well will be wide enough to form resonant energy levels[199,200]. These quantised resonant tunneling energy levels have electron transmission probabilities higher than that for adjacent energy levels. Therefore, they introduce significant asymmetry into the I-V curve[165] in the opposite direction to the one which would be observed

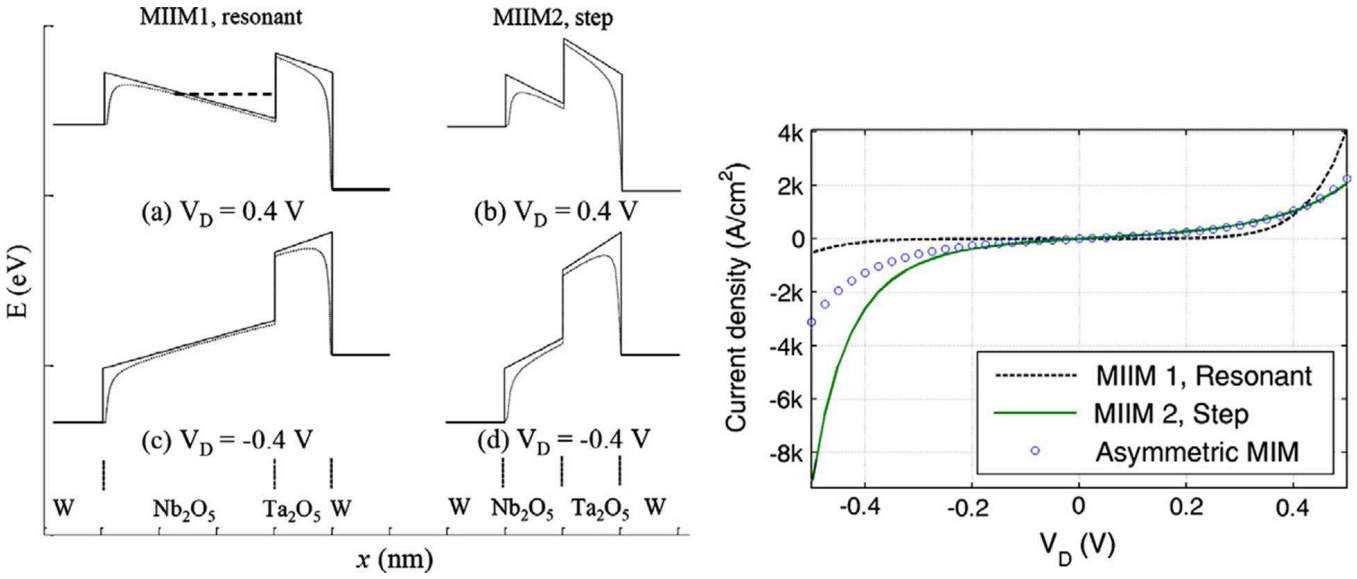

FIG. 27. Energy-band profiles for the W/Nb_2O_5/Ta_2O_5/W MIIM diodes discused by Grover & Moddel (left) under forward and reverse bias for the resonant (a and c) and step (b and d) diodes, and their corresponding I-V curves also compared to an Asymmetric MIM diode (right). Notice how current enhancement for the resonant diode is in forward bias, whilst that for the step diode is in reverse bias. (Reprinted from [200], ©2012 with permission from Elsevier)

if no resonant tunneling states are present (step MIIM), as discussed and shown by Grover & Moddel[200](see Figure 27). Adding extra insulators with resonant levels further increases rectification[201].

MIIM devices were first introduced for solar based applications by Phiar Corp. and patented by Eliasson and Moddel[202,203]. The performance of MIM and MIIM diodes as infra-red detectors was compared by Hegyi *et al.*[204] by simulating their responsivity. It was shown that the MIIM diode has 10 times higher responsivity than a derivative MIM diode. This was experimentally shown by Maraghechi *et al.*[205] who recorded up to 10 times better nonlinearity for a Cr/Al_2O_3/HfO_2/Cr diode compared to Cr/Al_2O_3/Cr and Cr/HfO_2/Cr diodes. A more applicable example, already referred to, is by Grover & Moddel[200], who compared their W/Nb_2O_5/Ta_2O_5/W structure to an MIM Diode with equivalent barriers as that of a W/Nb_2O_5 on one side and a W/Ta_2O_5 on the other side, again clearly showing improved response from the MIIM device (Figure 27).

Material selection for MIIM diodes has similar criteria to that of MIM, in that the structure has to exhibit one kind of tunneling in one direction and another tunneling mechanism in the other, thus promoting highly asymmetrical nonlinear I-V curves. A significant challenge is fabricating two ultra-thin, stoichiometric, high quality insulators. The appropriate technique for research purposes is RHEED PLD, although ideally ALD would be the better option in terms of prospects for industrial scaling. Alimardani *et al.*[206–208] have researched the use of ALD for depositing the double insulators required to produce efficient MIIM diodes. A recent patent[209] proposes the use of a triple-insulator barrier which adds further complexity to the fabrication process. The models created by Hashem *et al.*[192] will help identify which material systems to concentrate experimental efforts on. Improved performance from multiple barrier tunnel diodes is yet to be realised but the few reports that exist suggest significant potential. Integration with antenna for solar rectenna would also have to be researched as the addition of extra insulators may have deteriorating effect on the *RC* constant preventing these devices to be used at high frequencies although their rectification properties are clearly superior.

D. Geometric Diodes

Geometric diodes are devices that display rectification properties due to the difference in charge carrier transport probabilities from one electrode to another as a result of a geometric constraint. An increasingly popular concept patented by Moddel[210] consists of a thin film patterned into an inverse arrowhead[214] configuration shown in Figure 28(a). The electrodes are placed on top of the thin film at both ends of the structure. The width of the neck, d_{neck}, is of the same magnitude as the mean-free path length (MFPL) of the thin film material in order to obtain rectification[211–215]. Looking at Figure 28, an assumption is made by which charge carriers experience specular reflections at the boundaries[211]. At zero bias, the distribution of carriers is random and scattered across the left and right side of the structure and no net current flow is observed. Upon applying a bias, carriers gain

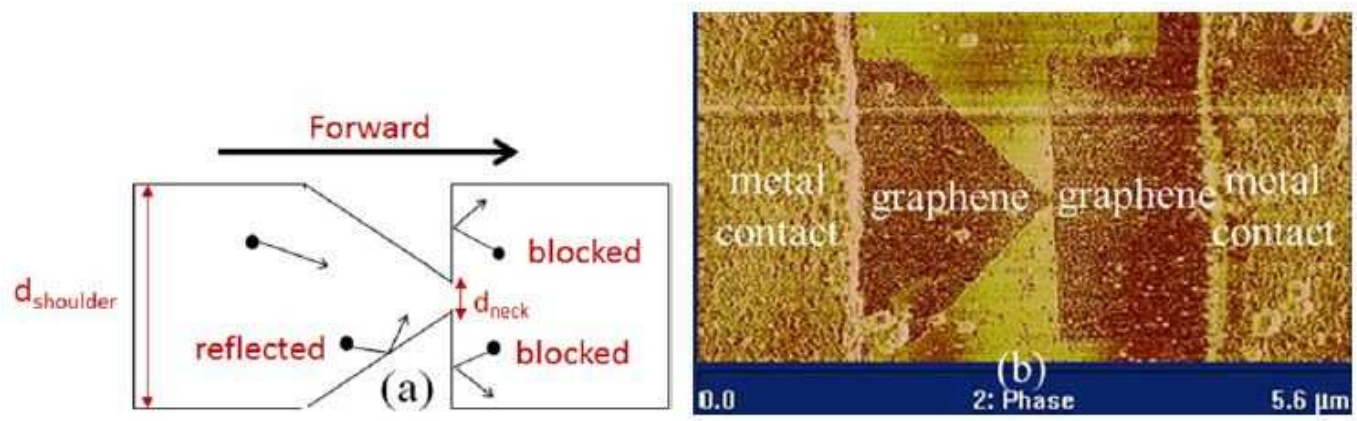

FIG. 28. (a) Schematic of a geometric diode theory of operation. (b) SEM image of a graphene geometric diode with metal contacts developed by Zhu *et al.* (Reprinted from [214], ©IOP Publishing. Reproduced by permission of IOP Publishing. All rights reserved.)

extra velocity in addition to their random thermal drift. For a plain non-constrained geometry, there will be equal net flow from one end to the other, which would define a completely linear I-V characteristic (Ohmic behaviour for perfect conductors). By applying a geometric constraint as the one shown in Figure 28, the motion of the carriers is influenced and favoured in one direction. Carriers moving from the left to right either pass directly through the neck or collide against the angled edge and eventually channel through the neck[211–214]. On the right hand side, most of the carriers are blocked and reflected away from the neck by the vertical blocks[211–214]. The probability of electrons passing from the left to the right is enhanced over the probability of them passing from right to left due to the *funnel-like* construction in the forward direction. The neck is required to be of the order of the MFPL, otherwise the probability of electrons passing in reverse direction will increase significantly and compromise the rectification performance.

Neck design is crucial to successful geometric diode performance and is therefore one of the governing factors in the material selection criteria for the device. The material would also have to withstand high current densities through the neck[214]. Metals are suitable to be used[168], however, their MFPL at room temperature is 10-30 nm[216], which complicates the patterning process and requires expensive techniques such as electron-beam lithography. Graphene has been identified as a suitable and promising alternative to be used in geometric diodes[210–212,214,215]. Advantages of graphene are that the MFPL can be tailored up to 1 μm[217] which means that common lithographic techniques can be used for device patterning and fabrication, resistances are low enough to be matched to the antenna impedance[214], and very low capacitance values of the order of 1 aF[212] lead to a low RC time constant of around 1.6 fs[211]. All these benefits identify their potential to be used at infrared and even optical frequency rectennas. Recent work on graphene geometric diodes has shown optical frequency rectification at 10.6 μm wavelength radiation (equivalent to 28 THz) matched with both a metal or a graphene bowtie antenna[214]. Further improvement in the design of these diodes could improve the performance of the device and potentially reach operational frequencies in the visible regime.

VI. RECTENNA DESIGN

Learning from the success in optimising the microwave rectenna, it can be seen that appropriate circuit design is of paramount importance for increasing the performance and efficiency of the device. The solar rectenna is an entirely different challenge as it is constrained by physical limitations and complex material selection criteria and trade-offs. Research is mainly concentrated towards manufacturing and characterisation of antenna and rectifier components, where novel technologies are emerging and great improvement has been seen over the years. Nevertheless, designing the best rectenna architecture is as equally important as optimising its two main constituents. There are many publication on antenna-coupled rectifiers used for optical[94,172,218–220] or infrared[108,134,173,176,177,221–223] sensing whereas, to the best of our knowledge, there is no antenna-rectifier device reported to harvest electromagnetic energy at the high solar frequencies. The gap between sensing and harvesting lies in how efficiently the incoming signal is converted and this is what limits the realisation of a true working solar rectenna. We review a few rectenna architectures proposed in the literature, which could result in future success.

Rectennas can either be designed as a planar device or have a geometrical constraint. The diode is used as a passive component with the sole purpose of rectifying the AC signal generated from the antenna. In this case

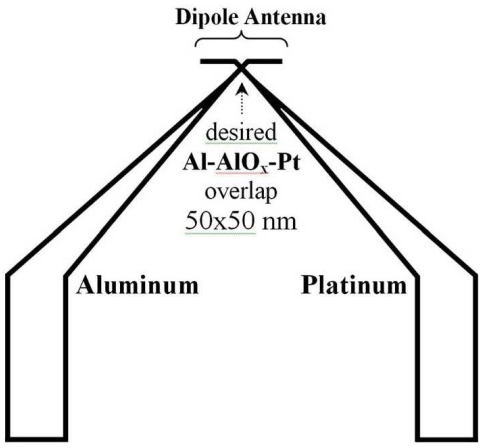

FIG. 29. Schematic diagram of an infrared detector proposed as a suitable design for a solar rectenna. The structure consists of a dipole antenna coupled to a metal-oxide-metal diode. (Reprinted from [173],©2009 with permission from American Vacuum Society)

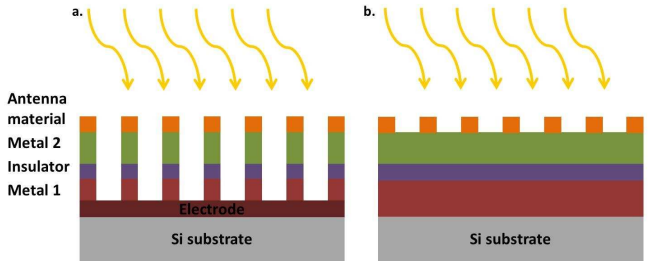

FIG. 30. Schematic diagram of a MIM-based planar-style rectenna architecture with **a.** rectenna array and **b.** antenna array with common rectifier.

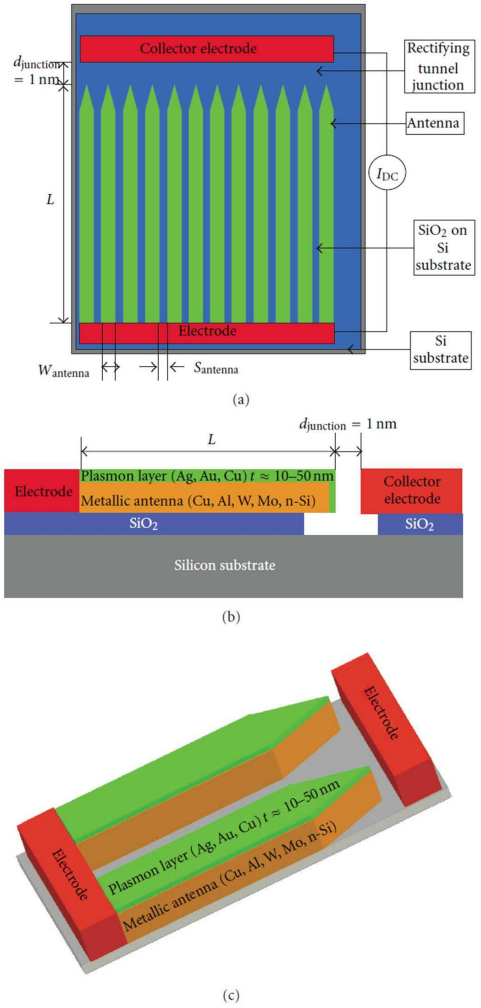

FIG. 31. Schematic diagram of the rectenna design proposed by Miskovsky *et al.* showing a top (**a**), side (**b**) and 3D (**c**) view. (Reprinted from [105], ©2012 N.M. Miskovsky *et al.*)

the requirements for the diode are emphasised on low resistance and capacitance (resulting in high cut-off frequency), and high I-V asymmetry at a small bias (implying low leakage current and low turn-on voltage). Both planar and geometric designs are suitable for employing this function of the diode. The following three architectures utilise the diodes ability to rectify current.

Figure 29 shows a dipole antenna coupled with a metal-oxide-metal diode based on an Al/AlO$_x$/Pt structure. This type of architecture is used for IR detection[134,173,177,221] and up to 28 THz[177] can be sensed with a Ni/NiO/Ni diode. Arrays of the structure can be fabricated either with e-beam lithography or a more economical nanotransfer printing process, which does not compromise the quality of the tunnel junction[221]. This design gives the benefit of producing small area diodes directly coupled to an antenna, which can be tailored to the length scale of the desired operating frequency. With appropriate material selection and improved impedance match, the cut-off frequency can be increased[177] and electromagnetic energy could potentially be harvested rather than just detected.

A common approach in rectenna design is a simple planar structure which is composed of antenna-rectifier arrays on a single chip (Figure 30a). The size of the individual Rectennas in the array depends on the aimed harvesting frequency, i.e. for the visible range the rectennas should be of nano-scale dimensions whereas micro-scale would suffice for the near-infrared. Alternatively, the device can be designed as having a common rectifier with an array of antennas (Figure 30b) – bowtie, patch, spiral, etc. The limitations are impedance matching and antenna and rectifier cut-off frequency. With the ever increasing technological advances and device modelling, the necessary goals are seen as realistic and feasible.

Finally, Figure 31 shows schematics of the approach proposed by Miskovsky *et al.*[105]. This design consists of an array of needle-like nanostructures, which have been designed to utilise a geometric constraint for the tunnel-

ing mechanism. At the tip of each nanostructure, a 1 nm junction is formed which can either form a MVM-type barrier or if an insulator is placed then the barrier will be an MIM-type. The fabrication of this type of structure is very complex, but was recently optimised by use of selective area atomic layer deposition – a technique developed and patented by Prof. Brian Willis of the University of Connecticuit[197]. Similar design can be implemented with the described Graphene geometric diode[214] where instead of leaving a tunnel junction, the tip of the needle-like nanostructure is brought close to the collector electrode. This rectenna design is very promising and yet to be optimised in terms of material selection, ease of manufacturing and reliability.

Another planar device design has already been introduced in Section V.A, whereby the rectifier is employed as an active component producing a current enhancement as a result of hot electron injection into the metal and crossing over a Schottky barrier, which is seen as a reverse current enhancement in an I-V plot (similar to what is observed during the photovoltaic effect). The design necessitates a diode with low barrier height, low leakage current and a suitable top metal to increase the amount of electrons excited to a higher energy state. It must be made clear that this device, although having components similar to a rectenna, is fundamentally different to the rectenna. With rectennas, the aim is to optimise the absorption by a load, whereas for hot-electron devices it is in optimising the absorption efficiency of the LSPR nanoparticle. A good review of hot-electron devices can be found in [224]. Efficiency estimates for rectennas prevail to those for hot-electron devices, although this remains an intriguing field for future development.

VII. SOCIO-ECONOMIC IMPACT & FUTURE WORK

The defining milestone for the rectenna was the Raytheon development of the microwave rectenna in the 1960s[13]. The ability to capture background radiation to demonstrate a working device, a helicopter no less, was a remarkable achievement. Concerns regarding energy security have led to a growing interest in harvesting solar radiation – a huge source of energy offering roughly 350 W/m^2. In 2011, the International Energy Agency predicted that solar energy technologies such as photovoltaic panels, solar water heaters and power stations built with solar collector mirrors could provide a third of the world's energy by 2060. Unsurprisingly, there was no mention of a rectenna device because there has never been a successful demonstration of a solar rectenna with even modest efficiencies of a few percent.

Solar cells made of silicon have already made a huge impact in a whole range of devices that use Si cells for power and they have also made a tremendous socio-economic impact in developing countries. It is worth recalling that around 1.2 billion people on our planet have no access to power and about 2.8 billion people use solid fuels (wood, charcoal, coal and dung) for cooking and heating[225]. Every year fumes and smoke from open cooking fires kill approximately 1.5 million people mostly women and children, from emphysema and other respiratory diseases and therefore a key responsibility for scientists and engineers is to carry out research to address such inequality. The advent of "plastic electronics" offers the possibility of inexpensive, flexible solar cells using semiconductors albeit at lower efficiencies of around 5-10%.

The rectenna is simply another means of collecting background radiation whether it be at optical frequencies in the solar spectrum (430-790 THz) or at IR frequencies (0.3-430 THz) meaning that cells could operate at night. The ultimate goal then of a rectenna is to augment current technologies and with current low frequency efficiencies of over 90%, the incentive to carry out research is obvious. However, the situation is not so simple and the key observation is that as the frequency of operation of the rectenna rises, the efficiency drops so that at solar frequencies most predicted efficiencies are a fraction of one percent. Here then is the first research challenge: to increase the efficiency to match at least the photovoltaic efficiencies offered by low cost plastic electronic solar PV (5-10%). Second, a rectenna device capable of operation at solar frequencies, which is a tremendous fabrication challenge with diodes of nanometre dimensions needed. Using expensive e-beam lithography techniques may demonstrate proof of principle but are too costly for commercialisation. Therefore, the engineering challenge is to find inexpensive fabrication techniques capable of scale-up and able to provide the efficiencies required.

So what are the prospects? There is little doubt that the task is hard – low cost fabrication of nano antennas and diodes of nm dimensions is non-trivial. But the rewards are significant. Perhaps most important is that, as noted in Section III, there is no scientific reason suggesting that a rectenna device operating at solar frequencies should not be capable of efficiencies in the region of 10% and ideally far greater. This then is the challenge and the potential reward is reason alone why there are several laboratories exploring such technologies. Let us be bold and assume success in this goal. What would be the implications? First of all, to have developed the technologies to fabricate the nanoantennas and diodes using scalable manufacturing processes would provide an extra option to the generation of energy. Second, success would not only impact upon a wide range of energy technologies but would be transferable such that it would also transform wide range of technologies associated with for example the Health, Transport and Infrastructure sectors. These sectors are fundamental to our socio-economic progress.

This review has identified many positive points on the development of the solar rectenna. Modelling the conversion efficiency has been attempted on many occasions, however as seen in Figure 8 the many different assumptions predict a wide spread of efficiency values. The sci-

entific community understands the operational theory of the device but further work is required to confirm and identify the major contributing loss and gain effects in order to accurately predict the efficiency. There is also lack of experimentally derived efficiency results at the high solar frequencies as research was until now mainly concentrated on developing new technology for nanofabrication and optimisation of antennas and diodes, modelling device response and theoretically estimating matching suitability. In the course of this review, new developments have been highlighted, which have given promising results for both the antenna and the rectifier. The technology is mature enough for it to be used to fabricate and characterise prototype rectenna devices. Testing prototypes will help identify further work, which needs to be carried out on the antenna and rectifier. A very useful methodology has been developed to characterise materials for MIM diodes and some experimental results of actual devices have been reported, identifying potential diodes which could be branded with having ideal I-V characteristics and far exceed the minimum figure of merit requirements. However, these diodes need to be characterised for their cut-off frequency and matching with an antenna. Work on the other rectifiers (MIIM and geometric diodes) is yet too undeveloped to have conclusive results, but provisional tests show great potential and they must be pursued and optimised.

In summary, despite the fact that Tesla suggested the transference of energy through electromagnetic radiation in the 1890s and despite the practical development of rectennas in the 1960-70s, the goal of solar rectification, or even large transfers of high-frequency power, has not yet been realised at the efficiencies we need. The two key issues that we need to address are to increase the efficiencies to useable levels, here suggested at 5-10%, and to develop low cost scalable manufacturing routes. The secondary goal is to increase the efficiency and here we can only speculate but we should harbour an ambition to obtain efficiencies exceeding that of the best solar cells tested to date of around 45%[226].

VIII. SUMMARY

In this article, the history and operation of the rectenna device have been reviewed from its initial concept as a receiver in microwave power transmission through to developments in pursuit of high-efficiency solar harvesting. Rectennas have been studied extensively for application in wireless energy transmission by use of man-made microwave energy with conversion efficiencies as high as 92%, which brings optimism to the goal of beating the Shockley-Queisser limit by achieving high-efficiency solar rectenna energy converters. Efficiency trends have been reviewed, where experimentally obtained efficiency values for rectenna devices have shown an overall decrease with an increase in operating frequency. Although there is no agreement on an optimised model for characterising the performance of a rectenna, all theoretical work suggests that to improve efficiency, three criteria must be met – 1) efficient absorption by the antenna at the desired frequency, 2) a high cut-off frequency diode to efficiently rectify the incoming signal and 3) impedance matching between antenna and rectifier to avoid signal transfer losses. Solving these three challenges would result in efficient device operation, which has the potential of operating at higher thermodynamic efficiency than current photovoltaic cells. Work on improving the performance of the antenna and rectifier has been reviewed showing substantial technological advancement and improved theoretical understanding of these two device components. Rectenna design also plays a major role in optimising the device and a few architectures have been discussed for their suitability. It was finally argued that the most essential future work required is to build rectenna devices based on optimised technology and design, as this is currently lacking in the literature. Attempts have been made on antenna-rectifier devices which have been aimed to work as IR or visible light sensors. Fabricating rectenna prototypes will enable scientists to characterise and assess their performance, giving them opportunity to identify new areas for necessary optimisation.

RF Energy Harvesting System And Rectennas

Riboy Cheriyan, Amsu Thejus. M, Jagadish Chandran G, Dr. K P Zacharia

Abstract —Recent advances in ultra-low power wireless communications and energy-harvesting technologies have made self-sustainable devices feasible. Typically, the major concern for these devices is battery life and replacement. Applying energy harvesting techniques to these devices can significantly extend battery life and sometimes even eliminate the need for a battery. This technique is widely applicable in low power circuits such as wireless sensors. One emerging wireless sensor networks (WSN) application is in agriculture sector, where sensor nodes are deployed in fields to monitor humidity, temperature and soil moisture. Energy supply to such sensors is an issue as they are typically powered by conventional batteries which have a limited lifespan. Cost is often prohibitive when replacing exhausted batteries since the sensor devices need to be unearthed. An attractive solution is to use radio frequency (RF) energy harvesting, in which the radiated RF energy from ambient is extracted and converted into usable energy to power up the sensors.

Index Terms — Harvesting energy, Patch antenna, Wireless sensors, Ambient energy , Schottky diode, Resonant circuit.

1. INTRODUCTION

Radio frequency energy is emitted by sources that generate high electromagnetic fields such as TV signals, wireless radio networks and cell phone towers, but through using a power generating circuit linked to a receiving antenna; this free flowing energy can be captured and converted into usable DC voltage. Most commonly used as an application for radio frequency identification tags in which the sensing device wirelessly sends a radio frequency to a harvesting device which supplies just enough power to send back identification information specific to the item of interest. The circuit systems which receive the detected radio frequency from the antenna are made on a fraction of a micrometer scale but can convert the propagated electromagnetic waves to low voltage DC power at distances up to 100 meters. Depending on concentration levels which can differ through the day, the power conversion circuit may be attached to a capacitor which can disperse a constant required voltage for the sensor and circuit when there isn't a sufficient supply of incoming energy.

We are being bombarded with energy waves every second of the day. Radio and television towers, satellites orbiting earth, and even the cellular phone antennas are constantly transmitting energy. What if there was a way we could harvest the energy that is being transmitted and use it as a source of power? If it could be possible to gather the energy and store it, we could potentially use it to power other circuits. In the case of the cellular phone, this power could be used to recharge a battery that is constantly being depleted. The potential exists for cellular phones, and even more complicated devices - i.e. pocket organizers, person digital assistants (PDAs), and even notebook computers - to become completely wireless.

Of course, right now this is all theoretical. There are many complications to be dealt with. The first major obstacle is that it is not a trivial problem to capture energy from the air. We will use a concept called energy harvesting. Energy harvesting is the idea of gathering transmitted energy and either using it to power a circuit or storing it for later use. The concept needs an efficient antenna along with a circuit capable of converting alternating-current (AC) voltage to direct-current (DC) voltage. The efficiency of an antenna, as being discussed here, is related to the shape and impedance of the antenna and the impedance of the circuit. If the two impedances aren't matched then there is reflection of the power back into the antenna meaning that the circuit was unable to receive all the available power. Matching of the impedances means that the impedance of the antenna is the complex conjugate of the impedance of the circuit.

This paper is considered to be one of the first steps towards what could become a standard circuit included in every wireless sensors, and quite possibly every electronic device made. A way to charge the battery of an electric circuit without plugging it into the wall would change the way people use wireless systems. However, this technology needs to be proven first. It was decided to begin the project with a cellular phone because of the relative simplicity of the battery system. Also, after we prove that the technology will work in the manner suggested, cellular phones would most likely be the first devices to have such circuitry implemented on a wide scale. This advancement coupled with a better overall wireless service can be expected to lead to the mainstream use of cell phones as people's only phones. This paper is an empirical study of whether or not this idea is feasible. This first step is to get an external wireless circuit to work with an existing phone by transmitting energy to the phone (battery) through the air.

2. POWER SOURCES

The main technological advancement that has allowed these harvesting devices to generate sufficient power is through the development of receivers which can sense broad ranges of frequencies, not just limited to television UHF signals, while capturing the highest concentration of generated waves. Since the

propagation of wave energy dissipates with distance from source, sensors located at far distances must extract energy at low power density which is related to the distance through $1/d^2$ [1]. A typical television antenna linked to the correct conversion circuit if located approximately 4 meters from the source of radio frequency generation of 677 mega Hertz and 960 kilowatts of effective radiation power is able to produce a detected voltage of 0.7 across an 8 kilo ohm load which is approximately 60 microwatts of harvested power and enough to power an LCD display thermometer[1].

Fig 1. Ambient power sources.

The output power of is limited by regulations, such as Federal Communication Commission (FCC), USA due to safety and health concern offered by EM radiations. The maximum theoretical power available for RF energy harvesting is 7.0 *u*W and 1.0 uW for 900 MHz and 2.4 GHz frequencies respectively for a free space distance of 40 meters.

A 1V/m electric field can yield power density of about 0.26uW/cm2. RF emissions from 800MHz range mobile equipments are significantly stronger signal than others, such as 2.4GHz range, which is mostly used by wireless LAN. A preferable range for RF energy harvesting is between 500 megahertz and 10 gigahertz, in which many different radio communication signals lies[4].

3. BASIC BLOCK DIAGRAM

Figure 2 shows the basic block diagram of RF energy harvesting system.

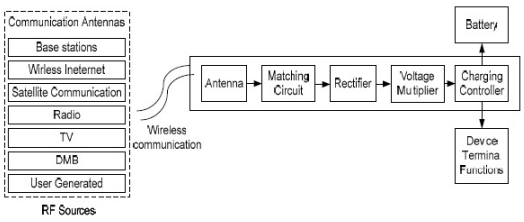

Fig. 2. Basic block diagram

Here we harvest energy from different sources such as mobile base stations, Wi-Fi, Radio waves etc. An antenna is used to capture signals, it may be a broadband antenna or separate antennas for different frequencies[2] .At high frequency we can use small antennas like patch antenna, but at lower frequencies we need a large antenna such as telescopic antenna in our FM radios[2]. Matching circuit consists of a variable capacitor for giving good impedance matching at the output of antenna at different frequencies. Rectifier is used to convert the ac at the output of antenna into DC. Here we prefer Schottky diodes because of its high frequency capability. Voltage multiplier consists of capacitor diode network which is used to increase the voltage level for charging the battery.

4. A SIMPLE GERMANIUM DIODE BASED ENERGY HARVESTING SYSTEM

Here a germanium diode based simple RF energy harvesting is shown in figure 3. Antenna used here is a stick antenna that is used in FM radios. The Gang capacitor and MW coil act as a matching circuit, resonating at a particular frequency.

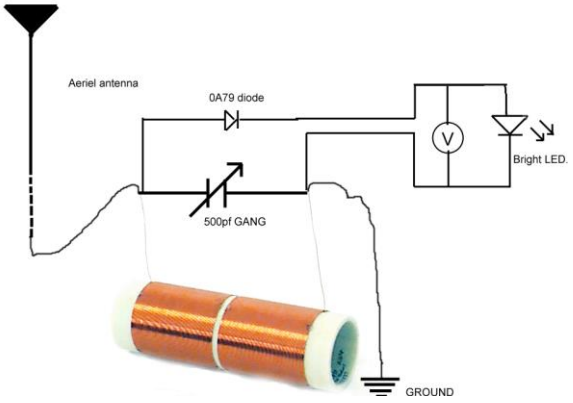

Fig. 3 OA79 Germanium diode based energy harvesting circuit.

OA79 Diode is used as rectifier because of its low turn on voltage. The gang capacitor tuned in such a way that the matching circuit resonates with the strong frequency that the antenna can capture. If the RF signal is strong, the circuit can drive a LED.

5. RF ENERGY HARVESTING SYSTEM BASED ON SCHOTTKY DIODE

Schottky diode offer low forward voltage and high switching speed, and consider as an ideal component for RF energy harvesting.

This circuit uses HSMS2820 schottky diode. RF signals can be captured using multiband antenna as

shown in figure. It is capable of receiving 900Mhz/1800MHz/1900MHz/2.4GHz. Small patch antennas can be used at higher frequencies.

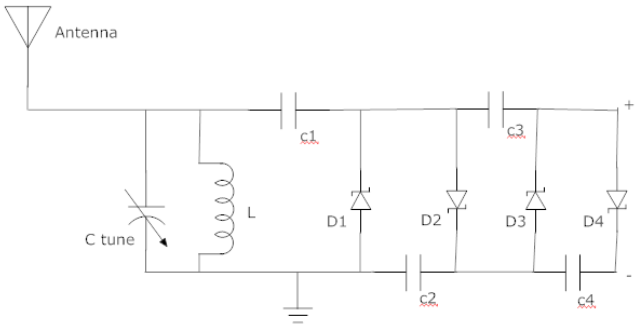

Fig. 4. Schottky diode based RF energy harvesting circuit with voltage multiplier.

Here combination of variable capacitor Ctune and inductor L forms the matching circuit for antenna at different frequencies. Using the Ctune in antenna matching circuit we can tune the antenna at its resonant frequency. The capacitor Ctune in tuning circuit can be varied using following formula to resonate with the antenna inductance L , were f is the frequency of operation.

$$2\pi f = \frac{1}{\sqrt{L_{antenna} \times C_{tune}}}$$

At higher frequencies such as 800 or 1900MHz the low values of inductors are difficult to construct especially at board level circuit design. But using the inductor along with capacitor at integrated circuit level design greatly improves the performance. Resonant frequency is also influenced by diode capacitance as it is related with reverse diode voltage and input voltage[4].

For converting Radio frequency to DC, a rectifier circuit is used .A charge pump circuit such as a voltage multiplier circuit can be used as rectifier. In figure there is a two stage voltage multiplier consists of two diodes and two capacitors in each stage. Here the diode used is a schottky diode (HSMS2820) because of its low forward voltage and high switching speed.

The voltage output of multiplier is twice input peak voltage minus the diode twice the diode threshold voltage.[4] The charge drained (Delta q) by the load current (I load) per period, where f is input signal frequency is

$$\Delta q = I_{load}/f$$

The circuit can be extended to n stages, producing the required output level. For a n stage multiplier the output capacitance can be calculated as

$$V_o = nV_{in} - \frac{n-1}{fC} I_{load}$$

From this, there should be a diode with very low turn on voltage and high operating frequency. Schottky diode has all this parameters so here a schottky diode is used.

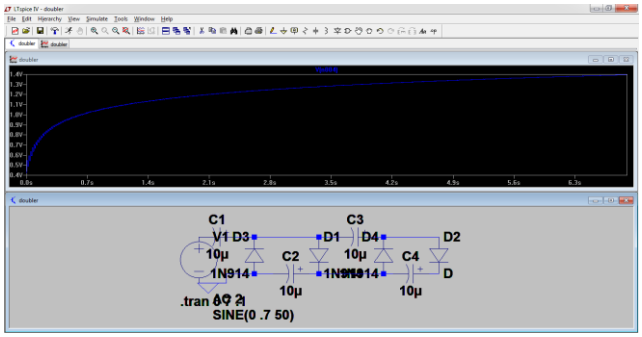

Fig. 5. Simulation result of two stage voltage multiplier.

Figure 5 shows the simulation result of a two stage multiplier with 0.7V input using LT Spice.

6. RECTENNAS

The rectenna termed as rectifying antenna, is combination of an antenna and a nonlinear rectifying element (Schottky diode, IMPATT diode…etc.) where the two elements are integrated into a single circuit. Since the rectenna is a receiving module collecting power from a radiation field, its sensitivity is defined by

$$S_R = \frac{output\ voltage}{power\ density\ at\ the\ antenna}$$

Division of this value with the effective antenna aperture leads to the normally used quantity for detectors.

$$S_D = \frac{output\ voltage}{input\ power}$$

This characterizes the nonlinear element with its matching.

A rectenna is useful as the receiving terminal of a power transmission system where dc power needs to be delivered to a load, through free space, for which physical transmission lines are not feasible. It is also suitable in applications where dc power needs to be distributed to more numbers of load elements that are spatially distributed. Such power distribution is achieved by the dispersive nature of microwave energy in space, eliminating the need for physical interconnects to individual load elements.

Figure 6 shows a rectenna for 899 Mhz. Here antenna consists of ainset fed rectangular patch with ground plane. It uses HSMS 2820 schottky diode as rectifying element

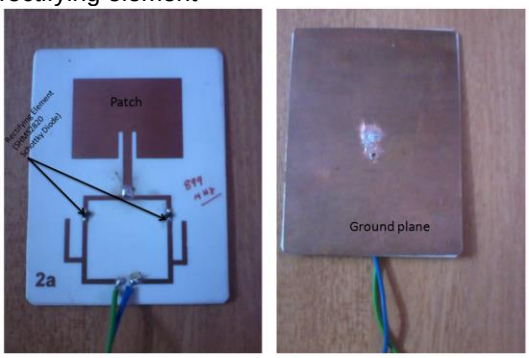

Fig. 6. Rectenna For 899 Mhz.

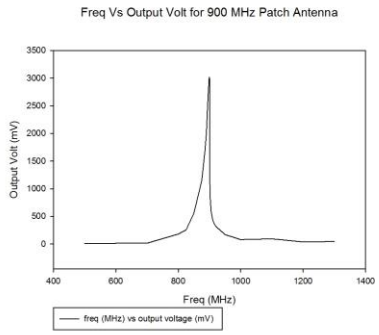

Fig. 7. Frequency Response of a 899 MHz Rectenna .

Figure 7 shows the frequency response of a 899Mhz rectenna. Here the peak is at 895 MHz. At this frequency we obtained an output dc voltage of 3.2V. In general it is difficult to predict how the rectenna system is optimized for the maximum conversion efficiency. However, there are several theoretical methods to overcome this problem.

The main objective with the design of rectenna is to obtain high conversion efficiency, and there are two approaches to achieve this goal. In first maximum power is collected and delivered to the rectifying diode, while in the second one harmonics generated by the diode are suppressed, which re-radiate from the antenna as power lost. In order to increase conversion efficiency by the first method, several broadband antennas, large antenna arrays and circularly polarized antennas have been designed and experimented. The broadband antenna enables relatively high RF power to be received from various sources while the antenna array can increase incident power delivered to the diode by enlarging antenna aperture and antenna gain. Antenna array is an effective means to increase the receiving power for rectification. However, a trade-off arises between the antenna size and the radiation gain. The circularly polarized antenna offers power reception with less polarization mismatch. However in second method, the rectenna consist of an LPF between the antenna and the diode, as well as an additional LPF on the dc output side of the diode. The main reason for the rise in the efficiency was the improvement in the diode and circuit construction for high input power levels.

7. CONCLUSION

In this paper, a study of various methods used for RFenergy harvesting has been made. It is found that we can harvest energy in micro watt range from ambient RF sources. Here the harvested power highly depends on the distance between the transmitter and RF harvesting system. By using an array of harvesting antennas we can harvest considerable amount of power.

ABSTRACT

With the introduction of the fourth generation (4G) of cellular mobile communications, there has been an increase in the frequency bands that a generic mobile phone should be able to operate. This requirement poses some challenges in the design of the transceiver modules of the device as well as the RF front-end and the antenna.

From the antenna design point of view, the newly added frequency bands especially LTE bands 12-13-17 which goes down to 700MHz creates the main design challenge: covering 700-960MHz (30% bandwidth) in the low-band, considering also backward compatibility with the former technologies like GSM850/900. Since the space reserved for the antenna is electrically small in this frequency range, special design techniques are necessary to obtain the required bandwidth for a generic mobile terminal antenna.

It should also be taken into account in the design phase, that the antenna needs to be appropriate for operation in the data-rate enhancement techniques like MIMO (multiple input multiple output) and carrier aggregation in LTE-Advanced. Furthermore, considering the real use cases of the mobile terminal, the effect of the user (hand, head and both) on the antenna performance should also be investigated.

In this thesis, several antenna designs for 4G coverage in mobile terminals are proposed. Different antenna topologies are evaluated consisting of tunable/passive antennas as well as single/multi-feed structures.

The "Introduction" chapter starts with a summary about the evolution of cellular communications starting from the first analog systems evolving to the fourth generation. General information about mobile phone antennas from the past decades is then presented ending with some examples of today's smartphone antennas. Electrically-small antennas are then presented briefly with their basic specifications and some state-of-the-art antennas for mobile terminals proposed in literature. The chapter concludes with a comparison between single-feed and multi-feed solutions with their advantages/disadvantages in LTE-Advanced technology.

Some tunable antennas, designed within the scope of the Artemos Project are presented in Chapter II. Firstly, two antenna designs using MEMS switches for band-switching between low-band (700-960MHz) and high-band (1.7-2.7GHz) are proposed, using antenna-parasitic strips for bandwidth enlargement. A circuit model is also proposed, modeling an antenna in combination with a grounded parasitic strip. A problem seen as radiation efficiency drop in these structures is also addressed with some solutions. Finally, a tunable antenna using tunable BST capacitors at the antenna feed is presented in this chapter.

A novel coupling element (CE) type antenna is proposed in Chapter III, which enables a more space-efficient design in comparison to plain CEs. First, the characteristics of the novel "hollow CE" is compared with a plain CE and two dual-feed antenna solutions are presented, using hollow CEs. As an application example, a MIMO structure using two hollow CEs is then given, using the neutralization line technique for higher isolation and lower correlation.

In Chapter IV, two single-feed antenna designs are proposed, manufactured using Laser Direct Structuring (LDS) technology. The first antenna can cover low-LTE/GSM/UMTS bands (700-960MHz and 1.7-2.2GHz) and the coverage of higher LTE and Wi-Fi bands (2.4-2.7GHz) is added in the second antenna. The effect of the user (hand and head) is investigated through measurements. An antenna resistant to detuning (due to the user) is then evaluated from these results as a future perspective.

A new use case of CE antennas is introduced in Chapter V, exploited to cover the 4G cellular communication bands in electronic eyewear devices, which are gaining popularity nowadays. First, a feasibility study is presented introducing the devices under design by several different companies. The bandwidth potential and SAR levels are evaluated according to different positioning of the CE in the eyewear device. Afterwards, three different antennas are proposed considering realistic casing and spectacles for the device.

Finally, a conclusion is done in Chapter VI, summarizing the general results from this thesis with some low-term and mid-term future perspectives.

CHAPTER I
INTRODUCTION

1. EVOLUTION OF CELLULAR COMMUNICATIONS

For more than thirty years, cellular communication has been under a substantial growth, according to the user demand. The first mobile communication systems were launched approximately around 1980s, giving the telephone users the freedom to make or accept calls, without the need for a fixed landline.

A cellular communication system is basically composed of three layers which are the core, the edge and the access subsystems [1]. Among these, the core is the nucleus of the network, that performs the handling of the voice calls, traffic control, user authentication and user profile (like charging the customer for the used services). The edge subsystem is an interface between the core and the access subsystems. The access subsystem (also called NodeB or Base Transceiver Station) is then responsible for establishing the air link with the mobile user equipment (UE). Different multiplexing schemes are used to serve a number of mobile users and duplexing techniques like FDD (Frequency Division Duplexing) and TDD (Time Division Duplexing) are used to establish a two-way communication (uplink and downlink) between the base station and mobile terminal. The land to be serviced is divided into some cells where these cells are served by base stations. The user can move between different cells and the handover is done automatically, transparent to the user.

The first mobile communications services (first generation or 1G) were launched in different parts of the world after 1979 [2]. These networks were based on analog systems for voice communications. The system used frequency modulation for modulating the voice signal and each user was assigned a specific frequency by Frequency Division Multiple Access (FDMA).

Approximately ten years later, the second generation of mobile communications (2G) was announced and the modulation scheme was changed from analog to digital, allowing also data transfer for services like Short Message Service (SMS). Multiple number of users were handled by using either TDMA (Time Division Multiple Access) or CDMA (Code Division Multiple Access). The most popular of the 2G standards is the GSM (Global System for Mobile Communications), which uses TDMA for multiplexing and FDD for duplex communication as uplink and downlink. GMSK (Gaussian Minimum Shift Keying) was chosen as the modulation scheme to provide better spectral efficiency. A main advantage of the GSM standard for the users was also the Subscriber Identity Module (SIM card), a card that carries the subscriber information and mobile number so that a user can change between different handset hardware by simply changing the SIM cards.

GPRS is a service launched on 2G systems, providing the user data services like MMS (Multimedia Messaging Service) and Wireless Application Protocol (WAP), making it being accepted as the 2.5G. GPRS was able to provide data rates up to 80kbit/s, which was increased later up to around 200kbit/s with the evolution to EDGE, called as the 2.75G.

With the release of the IMT-2000 standard by International Telecommunication Union, the downlink data rates of several Mbit/s started to be achieved. Systems like UMTS (W-CDMA), WiMax and CDMA2000 are examples of so-called 3G mobile communications, which introduced high-speed internet access, higher quality video and audio streaming. The most widespread radio interface is the W-CDMA using 2100MHz frequency for transmission over 5MHz bandwidth and FDD for duplexing. The downlink data rate was increased to 14Mbit/s and 28Mbit/s with the improvements called HSPA and HSPA+ (in the year 2008) respectively. A further improvement on the 3G systems towards 4G was the LTE (Long Term Evolution, 3.9G), targeting downlink data rates up to 100Mbit/s. LTE specification allows the usage of QPSK, 16QAM and 64QAM modulation types and channel bandwidth of up to 20MHz, with FDD and TDD for duplexing schemes. Additional usage of MIMO

(Multiple Input Multiple Output) can increase the maximum data rate from 100Mbit/s to 326Mbit/s. The access scheme used for the downlink is OFDMA (Orthogonal Frequency Division Multiple Access) for downlink and SC-FDMA (Single Carrier Frequency Division Multiple Access) for uplink.

2. GENERAL INFORMATION ON 4G TECHNOLOGIES

The successor of the 3G communication systems is the LTE-Advanced (LTE-A) which is accepted to be the fourth generation (4G) of the cellular communication systems. With this technology, the modulation schemes of QPSK, 16QAM and 64QAM are used to obtain peak data rates of up to 1Gbit/s for a low-mobility user in downlink (100Mbit/s for high mobility) and 500Mbit/s for uplink. OFDMA is used for multiple access in the downlink whereas SC-FDMA is used for uplink. The exploitation of multi-antenna systems (both for receive diversity or MIMO) is also available to reach the peak data rates. The available frequency bands for the 4G systems are shown in Figure 1, including also the 3G bands. A 4G mobile terminal should also be able to operate in the former 3G bands for backward compatibility since there is a risk of the lack a 4G base station everywhere the user may be located.

Figure 1 Frequency Allocation for 4G Systems

The LTE/4G frequency bands are presented in Table 1 and Table 2 for FDD LTE and TDD LTE respectively. It can be seen that the channel bandwidths allocated to each band is variable between 1.4MHz and 20MHz. Generally for the lower frequency bands (like bands 12 and 13) the maximum allowable channel bandwidth is up to 10MHz whereas for higher frequency bands (like band 3 or 10), bandwidths up to 20MHz is possible per channel. The multiple access scheme used in the 4G systems is OFDMA (Orthogonal Frequency Division Multiple Access), making the system more robust to fading, allowing higher data rates.

Another novelty introduced with LTE-A is the carrier aggregation, which is basically the utilization of more than one available channel for a single user. This way, the maximum achievable data rate offered to the customer can be increased. Three types of carrier aggregation are available for LTE-A as shown in Figure 2. The first type marked as (a) uses two adjacent frequency channels for a user which is called contiguous intra-band carrier aggregation. In the second type, two channels in the same band are aggregated, which are separated by other channels, making it non-contiguous intra-band carrier aggregation. Finally in the final case, two channels from two different bands are used together, which is called inter-band carrier aggregation. For example for a service provider with a license for transmitting in LTE Band 2 and Band 13, it is possible to provide data to a user over these two channels (20MHz in Band 2 and 10MHz in Band 13, making a total of 30MHz maximum bandwidth) simultaneously using inter-band carrier aggregation. A maximum bandwidth allocation of 100MHz per user is possible through carrier aggregation in LTE-A.

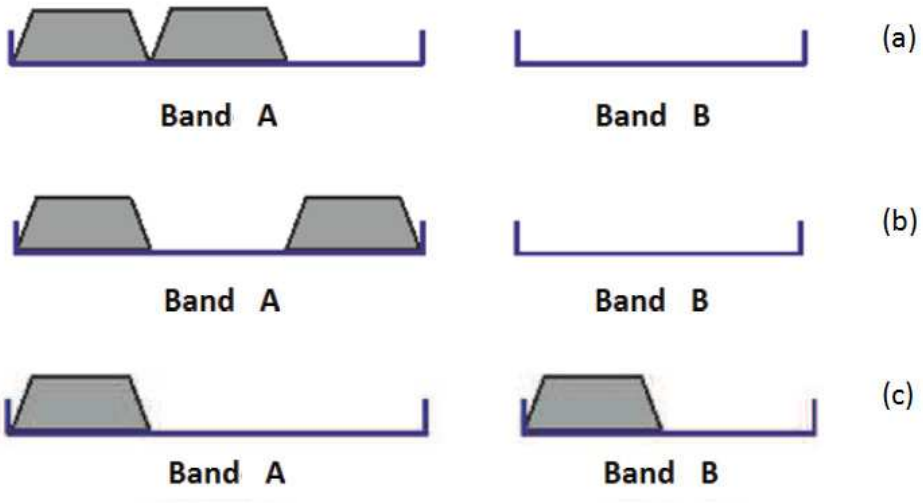

Figure 2 Carrier Aggregation Methods in LTE-A

Table 1 LTE FDD Frequency Bands

LTE Band	Area	DL Frequency	UL Frequency	Bandwidth (MHz)

3. EVOLUTION OF MOBILE PHONE ANTENNAS

The evolution of the cellular mobile communications systems have also changed the characteristics of mobile phone antennas. This evolution was sometimes driven by technical requirements like newly added frequency bands as well as user demand about aesthetical properties. Detailed analysis about the evolution of mobile terminal antennas and possible techniques are presented in [3] and [4].

Older mobile phones had an external antenna on the top of the chassis through the end of 1990s. These antennas were generally either helix type, monopole (whip) type or a combination of both for dual-band operation. The length of the whip antenna was arranged as a quarter of the operating wavelength, forming an even better configuration if the metallic chassis of the phone or the PCB was also a quarter wavelength long, therefore having a full structure like a dipole. To reduce the length of the whip antenna, a good alternative was the helical (or helix) antenna, which can be thought of the convoluted version of the whip antenna (Figure 3). To obtain a multiband structure, it was possible to use a helix antenna with a whip passing through the center axis (Figure 4), two helix antennas with different radii sharing a common axis or two helical antennas with different pitches. Despite having very good efficiency performance, the external antennas had a drawback of having high Specific Absorption Rate (SAR).

Figure 3 Examples of External Antenna for Mobile Phones

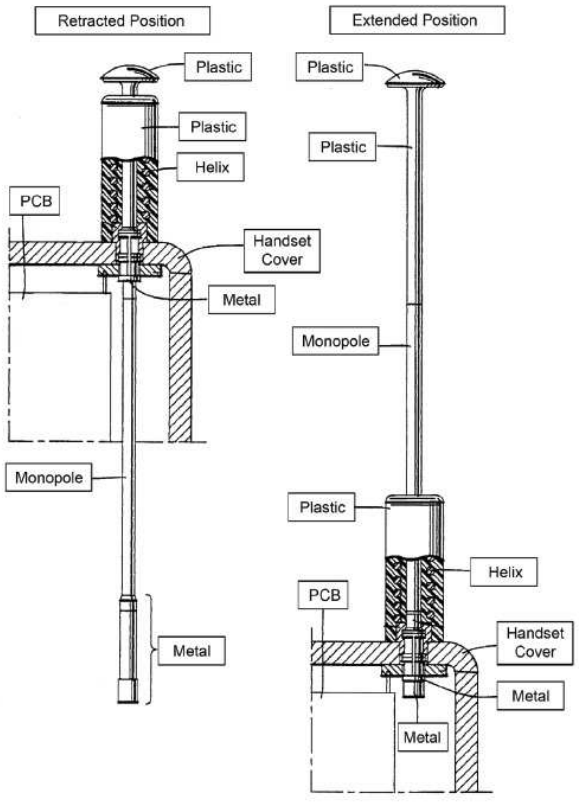

Figure 4 A Monopole & Helix Antenna for Mobile Phones, [3]

Through the end of 1990s, mobile phones having internal antennas started to be released on the market. Nokia released two models in 1998 and 1999 (8810 and 3210), which had internal antennas (Figure 5). One of the major internal antenna type, which was extensively used in mobile phones is the Planar Inverted F Antenna (PIFA), which can be thought of a patch antenna with a connection to the ground plane from some physical point of the antenna[5-6]. Multiband behavior was obtained easily by creating some slots in the rectangular plate to alter the current paths (Figure 6). Using some

parasitic elements either connected to ground plane on one end or left floating in both ends was also an alternative for multiband operation.

Figure 5 Mobile Phone Models Switching From External to Internal Antennas

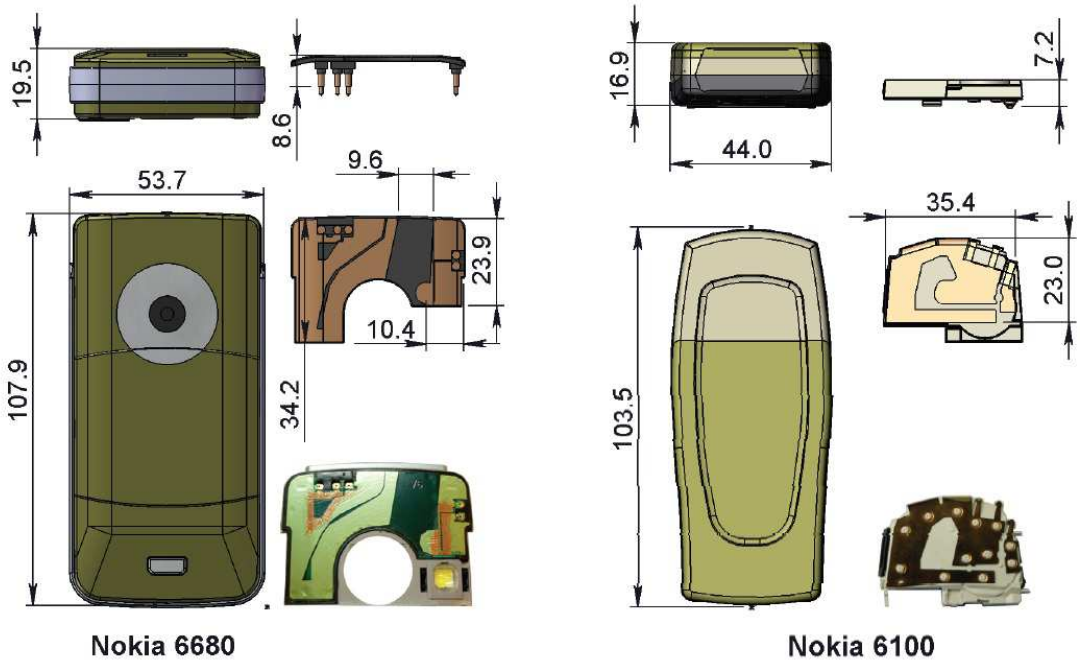

Figure 6 Examples of PIFA Antennas Used in Mobile Phones [3]

Another major internal antenna type used in mobile phones was the planar monopole antennas, which do not have a direct connection to the system ground plane. This type of antennas may require a ground clearance region in the vicinity (generally on one edge of the PCB) for acceptable performance. Techniques like adding parasitic elements or adding parallel branches to the radiating element can be used for multiband operation. This type of antenna was not used in the mobile terminals until recently due to the high SAR values exceeding the limits. The opportunity to place the antenna at the bottom of the mobile phone enabled their usage, since the SAR values were now suitable due to longer distance between the antenna and head when the antenna is on the bottom of the mobile terminal.

Throughout the evolution of the mobile phone antennas, it was generally needed to minimize the volume/area occupied by the antenna. Techniques like etching slots or meandering were used to alter the currents on the antenna element and/or the PCB, called inductive loading. Similarly, capacitive loading was also used for this purpose, this time to manipulate the electrical near fields (like bending the antenna closer to the ground plane). Dielectric loading was also a common method by covering the vicinity of the radiating structure with a relatively high permittivity material to decrease the resonance frequency.

As new standards and new frequency bands were introduced to the mobile communication systems, antennas with wider operating frequency bandwidth in approximately the same volume were needed. Parasitic elements (either grounded or floating) which are excited capacitively by the main antenna, creating additional resonances or changing the frequencies of existing resonances could be used for bandwidth enhancement. Another common technique is also the usage of matching networks, which can either be distributed along the antenna element (for example an inductor on the grounding point of a PIFA) or introduced directly at the feed for arranging the antenna input impedance in a desired way. The matching network can be either composed of completely passive elements (like SMD capacitors and inductors), completely active elements (like a tunable varactor at the antenna feed to tune the impedance) or a combination of both.

4. EXAMPLES OF ANTENNAS IN MODERN SMARTPHONES

This section aims to presents some examples of antennas and their placement in modern smartphones. The first example is the iPhone 4GS, which uses "coupling element" type antennas, whose general properties will be detailed later in this chapter. In iPhone 4GS, the metallic portions of the phone casing (referred to as bezel) are used as radiating structures. For this purpose the bezel is split into two, longer one forming the GSM/UMTS antenna and the shorter other forming the Bluetooth/Wi-Fi/GPS antenna. However, this structure had the problem of being very sensitive to user's hand, especially when the finger is placed between the gap separating the two metallic structures.

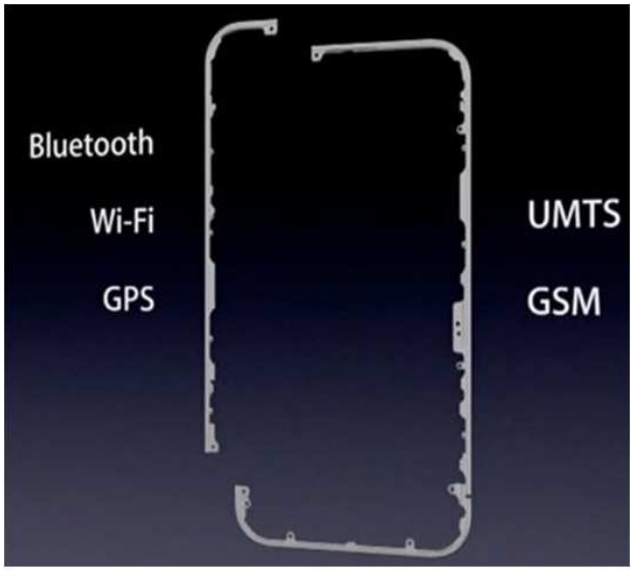

Figure 7 Antenna Placement of iPhone 4GS

In iPhone 5, the cellular antenna seen in Figure 8 was placed at the bottom of the phone and another antenna responsible for Wi-Fi operation was used at the top.

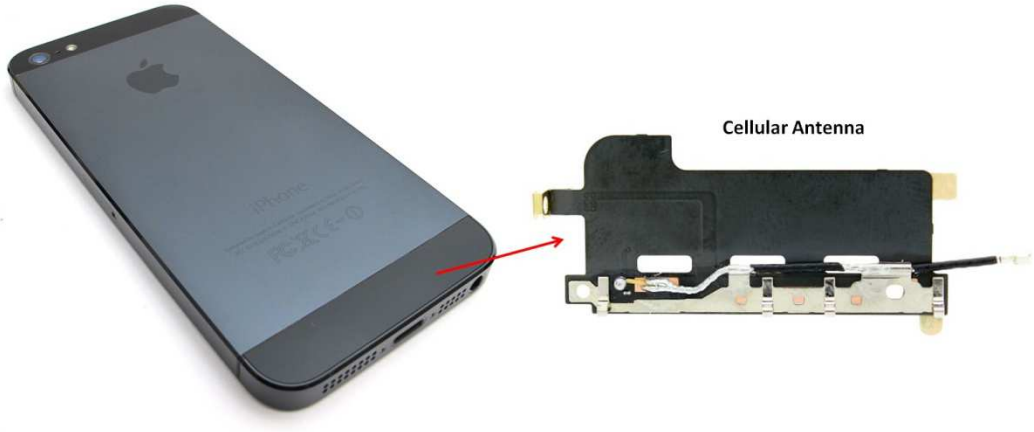

Figure 8 Antenna Placement of iPhone 5

A patent from Apple. Inc about a mobile phone antenna using again the metallic portions (bezel) of the phone casing as the radiating element can be seen in [7]. The antenna proposed in the patent is a loop antenna structure which is fed directly from the gap (shown as 18 in Figure 9), to minimize the fields across it and thus minimize any user effects due to the finger touching the gap (like the problem in iPhone 4GS). For impedance matching, a shunt inductance (formed by a metallic strip shown as 70 in the figure) and a series capacitance (shown as 100) is used at the antenna feed.

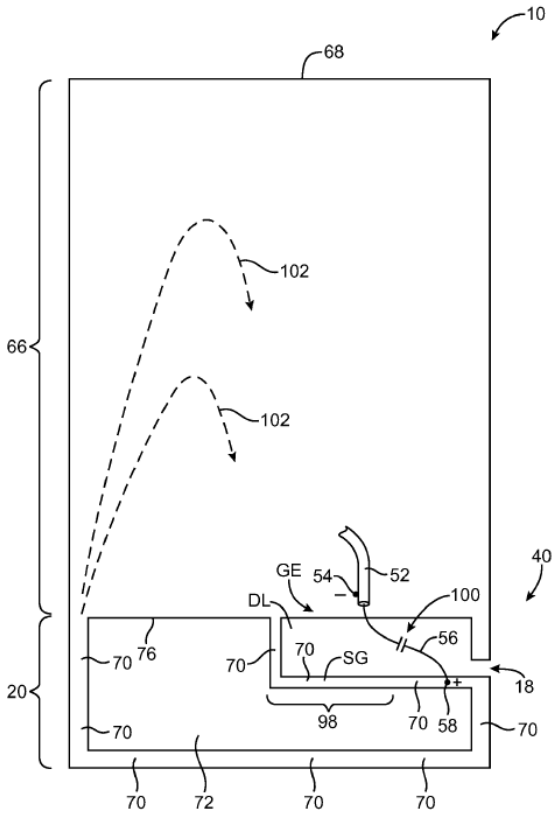

Figure 9 Antenna Structure Proposed in [7]

Another example is HTC Desire S as seen in Figure 10. This phone has three antennas realized using MID technology on plastic. The Bluetooth/Wi-Fi and GPS antennas are situated at the top of the phone whereas the IFA type pentaband antenna for GSM/UMTS is at the bottom.

Figure 10 Antenna Placement of HTC Desire S

The final example is Samsung Galaxy SII, which houses three antenna structures manufactured using MID technology, similarly as in HTC Desire S. In this phone, the GSM and Bluetooth/Wi-Fi antennas are located at the bottom and the GPS antenna is located at the top, just over the camera.

Figure 11 Antenna Placement of Samsung Galaxy SII

5. THEORY OF SMALL ANTENNAS

The popularity of internal antennas for mobile phones has gained a great popularity by the users after their introduction. This is why, the external antenna structures have quickly disappeared from the mobile terminal market. Since the frequency bands used for both GSM850/900, as well as the newly added frequency bands for LTE (like bands 12-13) go down to 700MHz, the free space wavelength rise up to 43cm for cellular communication bands. Considering the space that is available for the antenna in a mobile phone (generally lower than 20mm X 50mm X 7mm), it is evident that the antenna will be electrically small in the target frequency bands. It is also worthwhile to note that the space reserved for the antenna is subject to further decrease in smart phones having larger and larger touch screens and more and more electronic components to be placed like USB connector, camera, battery etc. The main drawback of an electrically small antenna is the low real part and high imaginary part of impedance, which makes it naturally narrowband. Electrically small antennas have been largely investigated in the literature [8-13].

A fundamental and intrinsic parameter of an electrically small antenna is its Quality Factor (Q), which is defined as the ratio of 2π times the energy stored in the near fields excited by the antenna to the energy radiated plus dissipated per cycle. The potential bandwidth of an antenna is inversely proportional to its quality factor, which results in low bandwidth potential for a high-Q antenna. The lowest obtainable radiation quality factor can be calculated from Equation-1 which is known as the Chu limit for electrically small antennas.

$$Q_r = \frac{1}{(ka)^3} + \frac{1}{(ka)} \qquad \text{(Equation-1)}$$

where k is the wavenumber (2π/λ) and a is the radius of the smallest sphere that can enclose the antenna. It is necessary to note that this value is an optimistic theoretical value considering a linearly polarized antenna radiating only in one (TE or TM) mode.

$$FBW = \frac{1}{Q}\sqrt{\frac{(TS-1)(S-T)}{S}} \qquad \text{(Equation-2)}$$

The obtainable frequency bandwidth can be calculated from Equation-2 as also presented in [14], where S is the maximum target VSWR and T is the coupling coefficient as given in [15]. For a value of T=1, Equation 2 reduces to:

$$BW_{cc} = \frac{1}{Q}\frac{(S-1)}{\sqrt{S}} \qquad \text{(Equation-3)}$$

This situation is called the "critically coupled" case, where the input impedance of the antenna is matched exactly to Z_0 (generally 50Ω) at a single frequency point (red curve in Figure 12). An alternative to get higher impedance bandwidth is to get optimal overcoupling, where the antenna is not matched exactly to Z_0, but matched in a wider bandwidth with a higher $|s_{11}|$ (for example with -7dB instead of -15dB), still under a predetermined target reflection coefficient level (blue curve in Figure 12). Some examples of using a matching network to obtain optimally overcoupled antennas are presented in [16-17].

For the calculation of the Q-factor of an antenna from its input impedance, Equation-4 was proposed in [13], which proposes a fast and reliable calculation method.

$$Q(\omega) = \frac{\omega}{2R(\omega)} \sqrt{[R'(\omega)]^2 + \left[X'(\omega) + \frac{|X(\omega)|}{\omega}\right]^2} \qquad \text{(Equation-4)}$$

where ω represents the angular frequency point, R(ω) and X(ω) stands for the real and imaginary parts of the impedance at angular frequency ω, and R'(ω) and X'(ω) are the first derivates of R(ω) and X(ω) according to the frequency. This formula is valid for a single resonant antenna close to its resonance frequency but it has proven reliable performance so far.

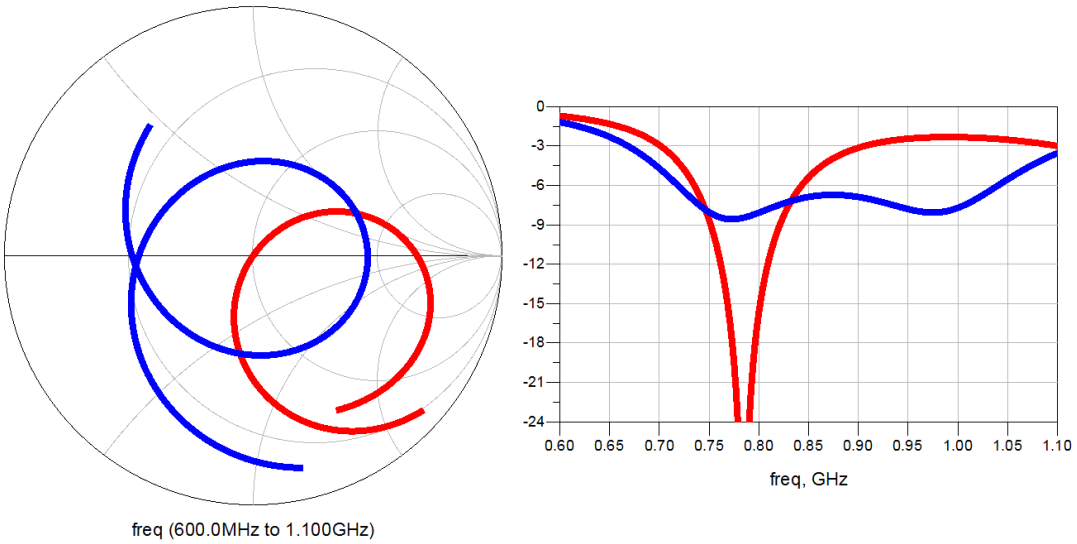

Figure 12 Critical Coupling vs Optimal Overcoupling

6. COUPLING ELEMENT ANTENNAS

As stated also in [18-21], the ground plane of the printed circuit board (PCB) in a mobile terminal plays the major role for radiation especially in the lower-frequency bands, where 90% of the total radiation comes from the PCB at 900MHz for instance[21]. The role of the ground plane in the lower frequency bands occurs regardless of the type of the antenna used, which is evident from the dipole-type vertically-polarized radiation pattern observed at low frequencies. The ground plane is also effective on the radiation in the higher bands being responsible for up to approximately 50% of the total radiation at 1800MHz.

Considering this fact, coupling element (CE) antennas were widely proposed mostly in the literature, to cover the cellular communication frequency bands in a mobile phone. Coupling element antennas are inherently non-resonant antennas, designed with the purpose of exciting the proper currents (chassis wavemodes) on the system ground plane [20-22]. In this antenna-scheme, the currents are induced on the PCB by capacitive excitation and the excitation is stronger close to the resonance frequencies of the PCB (which depends on its dimensions). For a 100mm ground plane length, the first chassis wavemode (longitudinal mode) occurs around 1.1GHz if a 10mm distance is set between the CE and this PCB. The feeding mechanism of the CE is similar to the one of a monopole, with no inductive contact to the PCB ground plane. In this way, the antenna-structure exhibits a low quality-factor and thus high bandwidth potential (BP) is obtained. Figure 13, which is taken from [14] explains the general behavior of a CE placed on a 100mm X 40mm ground plane without any ground clearance (CE placed directly on the ground plane). The major axis wavemodes

(first and second) are shown in the figure, occurring at 1.17GHz and 2.61GHz respectively. These wavemode resonances affect the input impedance of the antenna by slowing down the change of the impedance around these frequency points due to the low-Q property of the relatively wide ground plane, as presented in the smith chart. This effect can be best observed in the plotted quality factor, having some minima in these frequencies, corresponding to high bandwidth potentials. The antenna shall then be matched to the desired target frequency band using an appropriate matching network at the feed.

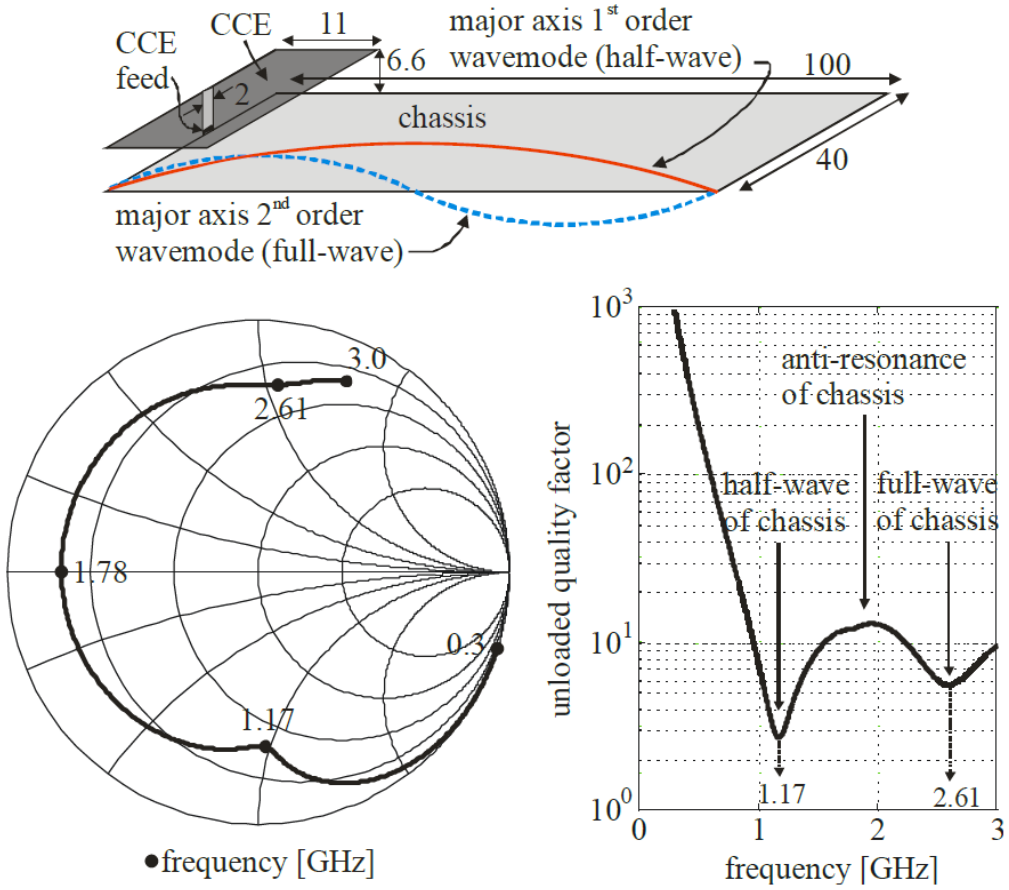

Figure 13 Summary of the Coupling Element Antenna Behavior

Despite the high obtainable bandwidth potential, the main drawback of this approach is the need for a tunable or a complex MN (complex in terms of design or large number of SMD components) if dual-band coverage is needed which increase the losses due to internal resistances of those SMD components. Another disadvantage is the necessity to keep the region between the CE and the ground plane clear from any metal components (ground clearance) that can distort the E-field distribution in this area and thus degrade the BP. Some CE designs targeting only the GSM/DCS/PCS/UMTS bands have been already presented in [23-24]. In [23], two CEs were placed on one of the short edges of the PCB, one responsible for the coverage of GSM frequency band (824-960MHz) and the other for DCS/PCS band (1.71-1.99GHz), with their associated MNs at each feed (Figure 14). To obtain a single feed topology in the final design, special attention was paid on the MNs, to get a high impedance behavior for the low-band MN at high-band frequency and vice versa. The two MN branches were then combined together. In [24], again a two CE configuration (called ground plane boosters) was proposed and this time, the two MN branches were connected together

after using notch-filters at each branch (Figure 15). In [25], two CEs which are separately fed have been used for dual-band operation for covering only GSM/DCS/PCS bands. A tunable MN topology for a CE has been proposed in [26] to cover DVB-H, GSM and UMTS frequency bands. In [27-28], two designs have been proposed to additionally cover the low LTE frequency band starting from 700MHz. Antenna proposed in [27] can cover low LTE and UMTS bands (700-960MHz and 1.7-2.2GHz) using a single CE. The matching network at the feed consists of a two-branched MN for dual-band operation, having 9 SMD components. In [28], the coverage band is increased as 700-960MHz and 1.7-2.7GHz, covering whole 4G communication band. The antenna is like a dual-feed structure, where the low-band (LB) feed uses the radiating element as a CE, whereas the high-band (HB) feed has an offset in the excitation region, using also the resonant properties of the radiating element (Figure 16). These two feeds are combined together to obtain a single feed, after introducing a two branch MN (of 8 lumped components) where each branch behaves as an open circuit to the other.

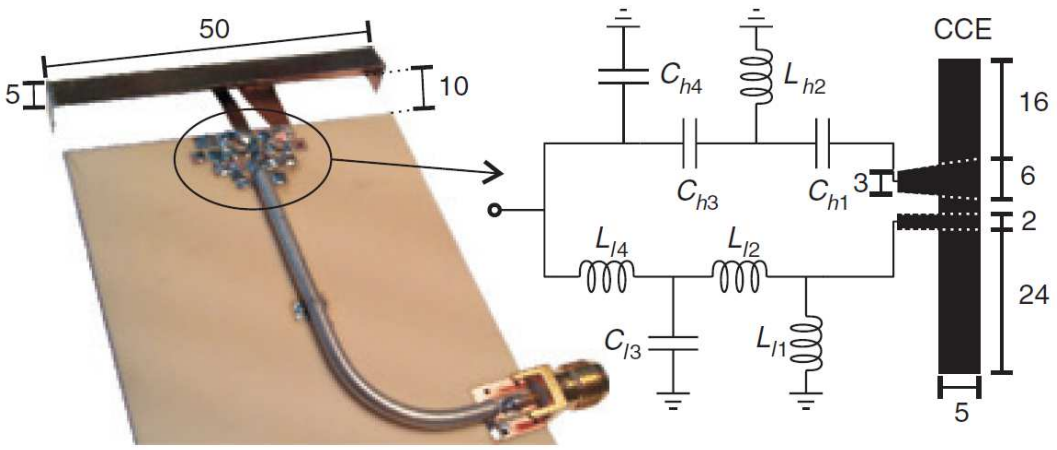

Figure 16 Multi-Band Mobile Terminal Antenna in [28]

7. ANTENNAS USING PARASITIC ELEMENTS FOR BANDWIDTH ENLARGEMENT

For operation in the main 4G frequency bands, wideband antenna behavior is needed covering 30% bandwidth in the low-band (700-960MHz) and 45% bandwidth in the high-band (1.7-2.7GHz). The coverage of the low-band (LB) is more challenging since the antenna is electrically small and thus the bandwidth potential is limited. For bandwidth enhancement, antennas using different kinds of parasitic elements have also been proposed in literature [29-38]. In these antennas, the main methodology is to capacitively excite a longer metal strip connected to the ground plane through a shorter driven strip. In [29-30], a monopole driven strip is used to excite a longer parasitic element connected to the ground plane on one edge. The LB coverage is mainly achieved by the capacitive excitation of the parasitic element and the HB is covered using the driven monopole and the higher order resonances of the parasitic strip. In [31-32], the parasitic element was connected to the ground plane on both edges forming a loop, again excited by a driven strip on the other side of the PCB (Figure 17). To increase the length of the loop parasitic, meandering was used making the design more complex and sensitive to manufacturing tolerances. In the antennas proposed in [33-36], casings for the PCB were also taken into consideration, whose loss tangent vary between 0.01-0.02 (Figure 18). In this way the advantage of dielectric loading was used to be able to achieve LB coverage more comfortably. Dielectric casings were also used in the antennas proposed in [37-38], with loss tangents between 0.02 and 0.06. Although they are called as PIFAs with coupled feeds, the main idea is the same as using a monopole like exciter (without ground connection), to excite capacitively a metal strip connected to ground in one end. The possible drawback of these antennas is the relatively complicated design and complicated antenna layout, which may be a problem when the manufacturing errors are concerned.

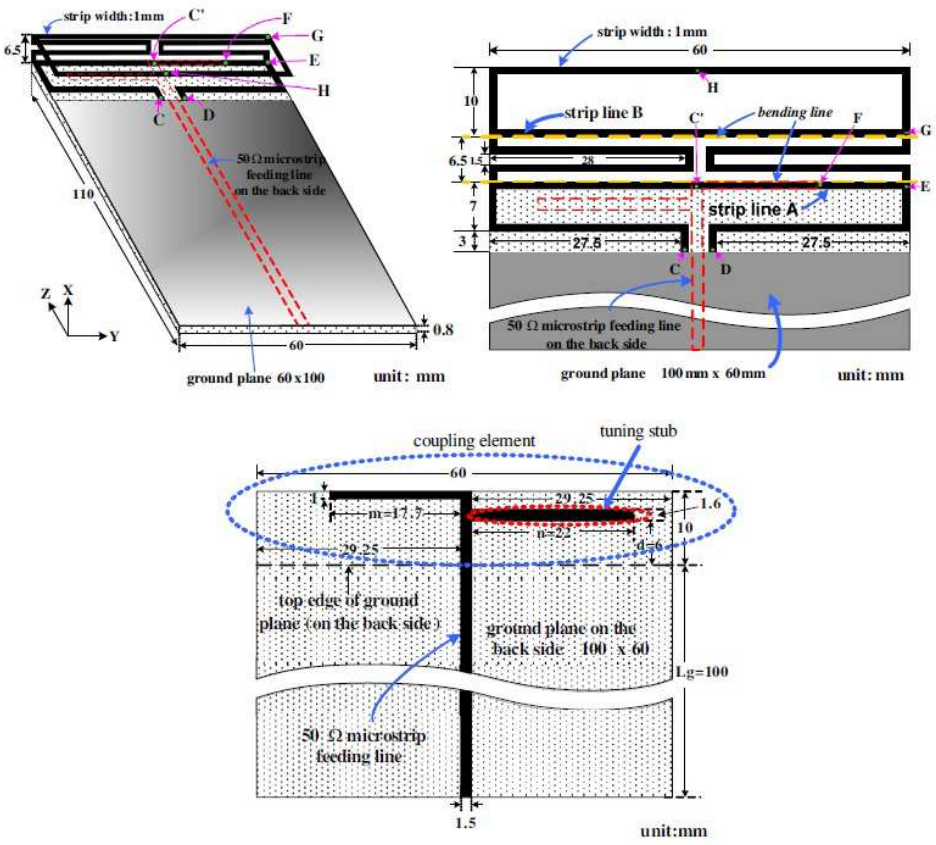

Figure 17 Meandered Loop Antenna in [32]

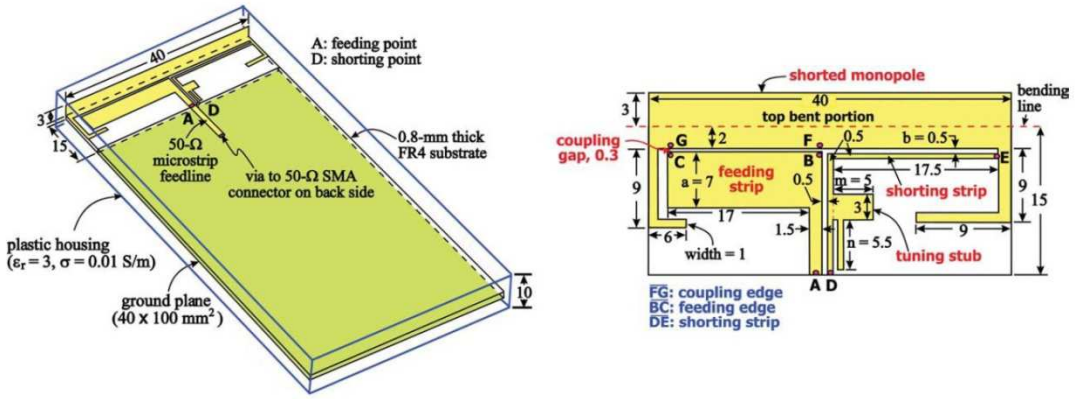

Figure 18 Small Size 11 Band Antenna in [34]

8. SINGLE-FEED AND MULTI-FEED ANTENNA STRUCTURES

The majority of the commercial mobile phones in the market use a single feed antenna design. A study about the advantages and disadvantages of using multi-feed antenna designs compared to single feed antennas was done in [39]. In the current single feed designs, an antenna which is able to cover the required standard frequency ranges (for example GSM850/900, DCS/PCS) is connected to a "Single Pole Multi Throw" antenna switch in the RF front end. According to the communication standard used at the instant, the output of the switch (considering the receive scenario) is changed to connect the signal from the antenna to the appropriate duplexer.

With the introduction of LTE-A, it is possible to receive cellular communication data over two different frequency bands (carrier aggregation), meaning there can be more than one receive chain in the front-end simultaneously. For the inter-band carrier aggregation, the signals picked up by a single feed antenna (for example one at 940MHz and one at 2150MHz) should be transmitted to the front end at the same time, which is not possible with a "Single Throw" switch. The switch should have a logic to have two active throws at the same time, which may results in worse linearity performance and higher insertion loss. In addition to these, special care should be given to prevent the two different front-ends (duplexers) from loading each other since they will be connected together at the switch.

Another solution different from having more than one active throws at the antenna switch, is to add a diplexer just after the antenna in the receive path, that will direct the different frequency signals to the appropriate duplexers, for inter-band carrier aggregation. However this will also result in increased insertion loss in the front-end.

Al alternative solution to overcome these complexities using single-feed antennas for inter-band carrier aggregation is to use multi-feed antennas, for example one covering the lower frequency band (700-960MHz) and other for higher frequency band (1.7-2.7GHz). In this way, the necessity of using a complex antenna switch or a diplexer is overcome for inter-band carrier aggregation. The drawback of this approach is the isolation between the antenna feeds. Isolation should be as high as possible (targeted better than 10dB as a rule of thumb), since it can otherwise cause efficiency losses due to unwanted coupling from one antenna to the other. Obtaining good isolation is also challenging, since the space reserved for the antenna is small in terms of wavelength (especially in lower frequencies) and the separate antennas have to be placed physically close to each other.

9. MOTIVATION OF THE THESIS

This study was done within the scope of the ARTEMOS project, a European Union project with a duration of 36 months. The main aim of the project is to obtain frequency agile, multimode, multi standard RF architectures for mobile communication devices, to decrease the bill of materials and cost of the systems. This target is represented in Figure 19, where the number of RF front-ends for several different communication standards in a typical system nowadays is reduced by proposing tunable front-end modules. Another aim of the project is to design and manufacture tunable components, which are BST capacitors, MEMS switches and MEMS varactors, to be delivered to the partners working on the RF front end and the antenna element.

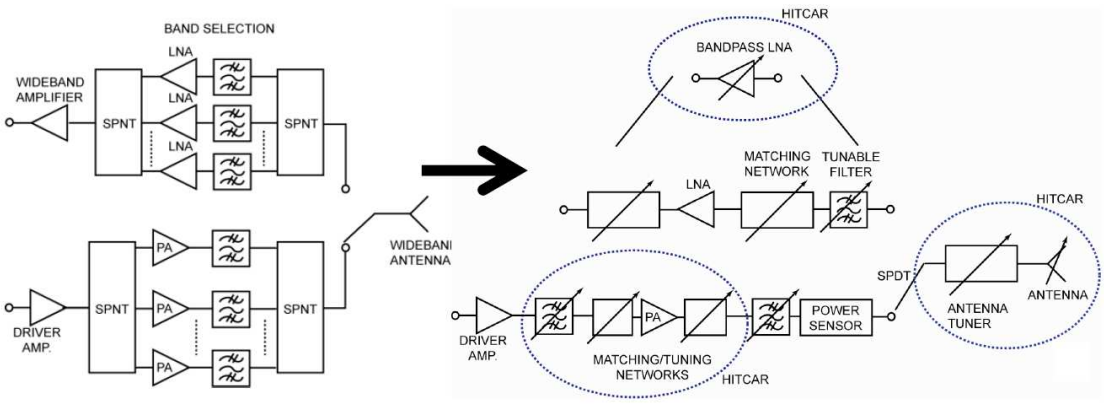

Figure 19 Tunable RF Front End Targeted in ARTEMOS Project

Keeping this in mind, the aim of this study is to design, manufacture and test some novel antenna topologies for handheld mobile terminals. Particular effort is to be focused on either covering the target bands with very simple antenna layouts or achieving lower reflection coefficient in the target band compared to the antennas in the literature mentioned before. Another aim is to investigate the effect of the user (hand and head) on the antenna performances and propose a novel antenna topology which minimizes these effects. Both passive and active antenna topologies are to be evaluated for the coverage of 4G frequency bands, decided as:

-Low-Band (LB): 700-960MHz
-High-Band (HB):1700-2700MHz.

With this target, the frequency bands of the communication standards low-LTE, GSM850/900, DCS/PCS, WLAN2400 and high-LTE will be covered. As a rule of thumb, -6dB in free space is accepted as the target reflection coefficient for the antennas. For the maximum limit of the antenna height, 5mm is taken, to be in compliance with the trends of current smart phone designs. For the same reason, maximum dimensions around 120mm X 60mm (for length and width respectively) was accepted for the PCB that will support the antenna. For the feeding scheme, both single-feed and multi-feed antennas were evaluated.

CHAPTER II
TUNABLE ANTENNAS

This section presents several tunable antenna topologies, designed for operation in the 4G-LTE frequency bands (i.e 700-960MHz, 1.7-2.7GHz). The antennas are designed and manufactured using tunable components provided by the ARTEMOS partners. To obtain tunability in the matching response, MEMS switches and BST capacitors have been considered.

1. ANTENNA DESIGNS USING MEMS SWITCHES

The utilization of MEMS switches in reconfigurable antenna design has been a popular topic in recent years, especially due to their low loss in the microwave frequency bands. The reconfigured antenna properties of the these antennas have a diversity, like pattern reconfiguration (both in single and array antennas), switching between two operating frequency bands, tuning the matching level by MEMS capacitors (varactors) and changing the properties of antenna feeding networks [1]. For example in [2], MEMS switches were used to change the ground connection point of a PIFA to achieve polarization reconfigurability. In [3-4], the switches were used to obtain reconfigurability in the operating band. Figure 20 shows the proposed reconfigurable MN topology in [3], together with the manufactured prototype in the same study.

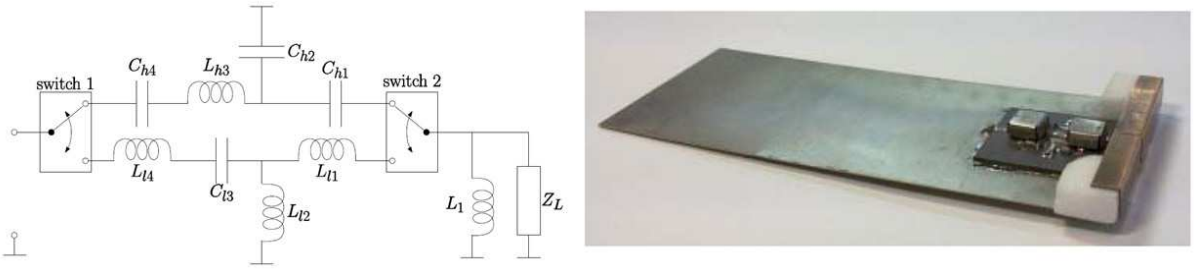

Figure 20 MN Topology and Manufactured Prototype in [3]

There are a number of COTS products available on the market, some of which are given in [5-6] and whose RF performance specifications are mentioned in Table 3.

Table 3 Specifications of Some Available MEMS Products

	MEMS-1	MEMS-2
Frequency Bandwidth	DC-40GHz	DC-10GHz
Insertion Loss at 2GHz	-0.29dB	-0.25dB
Isolation at 2GHz	-34dB	-45dB
Maximum RF Input Power	40dBm (cold sw.)	36dBm
Input IP3	>65dBm	
Switching ON Time	<10 µs	<100 µs
Control Voltage	90V	35V

In this study, the MEMS switches have been evaluated to achieve band-switching between the Low-Band (700-960MHz) and High-Band (1.7-2.7GHz) of 4G communication standards. Two antenna topologies are proposed, each using a parasitic strip connected to ground for the enlargement of matching bandwidth. The two topologies are different in the way the MEMS switches are exploited. In the first design, two MEMS switches are used to select between one of the two matching network

(MN) branches, like in [3] and [4]. The second design uses only one MEMS switch, to select between one of the driven strips.

The MEMS switches used in this study are designed and manufactured by DELFMEMS [7], who is also a partner in the Artemos project. DelfMEMS technology is different from the other RF MEMS switches on the market, i.e. classical cantilevers (clamped-free membrane) or bridges (clamped-clamped membrane). Indeed, based on a state-of-the-art IP, DelfMEMS switches enable high performances with their specific mechanical structures featuring two main innovations: a movable membrane without anchors in the substrate and two forced on/off states to obtain a push-pull behavior. The membrane used for the electromechanical function is simply supported by two pillars, and two sets of electrodes placed either side of the pillars allow the actuation of the device. As illustrated in Figure 21(on left), the two forced states are obtained when the electrostatic forces are generated with the different electrodes, respectively internal/external electrodes for a ON/OFF state. Such operation ensures good contact forces in the ON state thus reducing the contact resistance, and provides high restoring forces for the OFF state to counter potential stiction or self actuation phenomena while ensuring important isolation.

In addition to good RF characteristics, this new mechanical structure demonstrates high reliability performances mainly because of its anti-stiction capabilities and the limitation of bounces thanks to a smart use of the different internal/external electrodes.

The insertion loss of the devices is measured to be between -0.2 and -0.25dB at 2GHz (Figure 21, on right). A high level of isolation is observed in OFF state, better than 45dB below 3GHz thanks to isolated RF and DC paths and because a gap larger than the thickness of the sacrificial layer is obtained between the contacts placed on the membrane and those on the transmission line

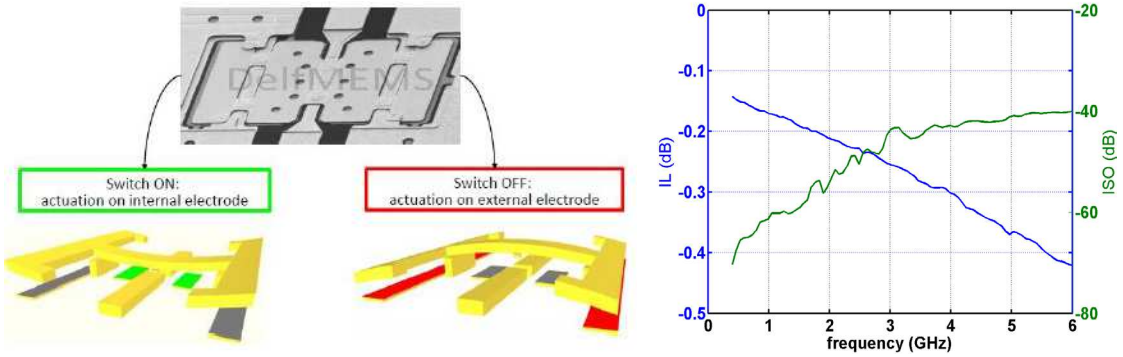

Figure 21 ON/OFF Switching Topology and Performance of MEMS

Table 4 Performance Summary of MEMS switches from DELFMEMS

Parameters	Value
Frequency bandwidth	0.3-5 GHz
Insertion loss	0.2-0.25 dB @2GHz
Reflection coeff.	< -15 dB @2GHz
Isolation	> 50 dB @2GHz
RF power	+33 dBm for cold switching +20 dBm for hot switching
Input IP3	> 70 dBm
Switching time	<10 µs for actuation voltage greater than 50V
Control signal level	50-70 V
Switching frequency	up to 10 kHz
Electrostatic self-actuation (OFF state)	< 50 V peak peak
Size	3,6 mm²
Packaging type	silicon cap

1.1. ANTENNA DESIGN-I

The proposed antenna layout can be observed in Figure 22. The antenna is directly printed on FR4 substrate, with the PCB dimensions of 120mm X 60mm X 0.8mm. There is a ground plane of length 107mm under the substrate on one side of the PCB, leaving a ground clearance of 13mm for the antenna. The antenna is basically composed of a driven strip, which capacitively excites a parasitic strip connected to the ground plane. The parasitic strip is connected to the ground plane over an inductor (12nH), which increases the electrical length of the parasitic strip. A MN, consisting of two branches is introduced at the antenna feed (Figure 23), to tune the antenna either in the LB or in the HB. According to the states of the two SPDT (Single Pole Double Throw) switches, one of the branches is connected to the antenna feed, which matches the impedance in different frequency bands. The LB MN branch consists of two inductors, whereas the HB MN is a single capacitor.

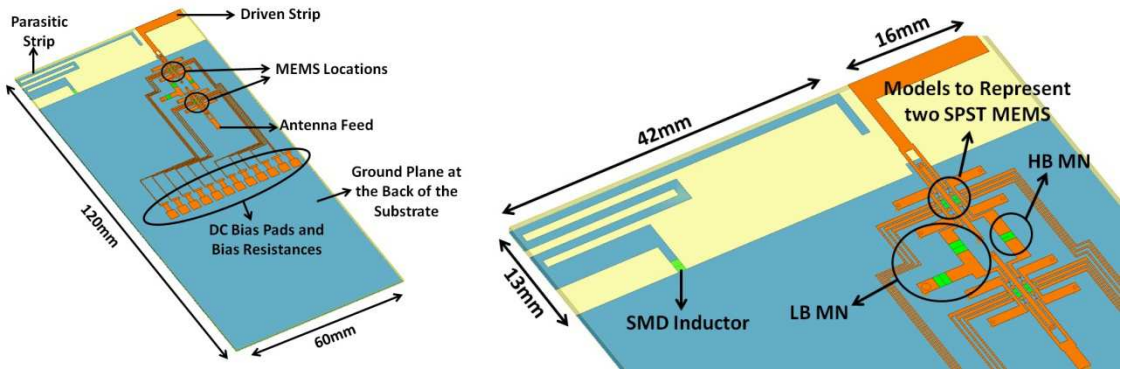

Figure 22 Layout for Antenna Design-I Using MEMS

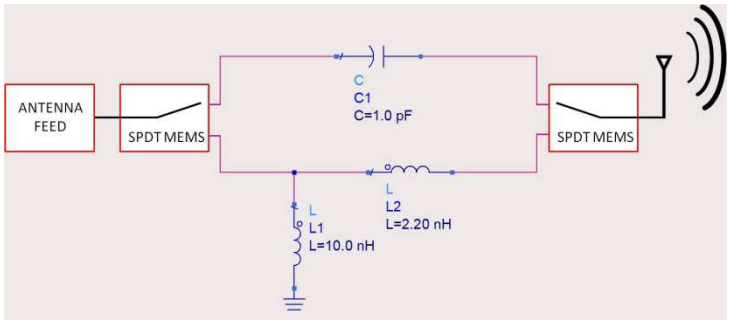

Figure 23 Switchable Matching Network Topology

1.1.1. Effect of the Parasitic Strip over the Bandwidth Potential

The effect of the parasitic strip has been studied in the absence of any matching network at the antenna feed. The simulated antenna input impedance with and without the parasitic strip can be observed in Figure 24, plotted between 700-960MHz. A significant increase can be noticed in the real part of the impedance, with the resonance appearing around 730MHz. Here, the term "resonance" is used to indicate a significant increase in the real part of the antenna (the loop forming in the smith chart), since under normal conditions the real part of the impedance of an electrically small antenna is low. The increase in the real part of the input impedance can be seen in Figure 25, for "with Parasitic" case.

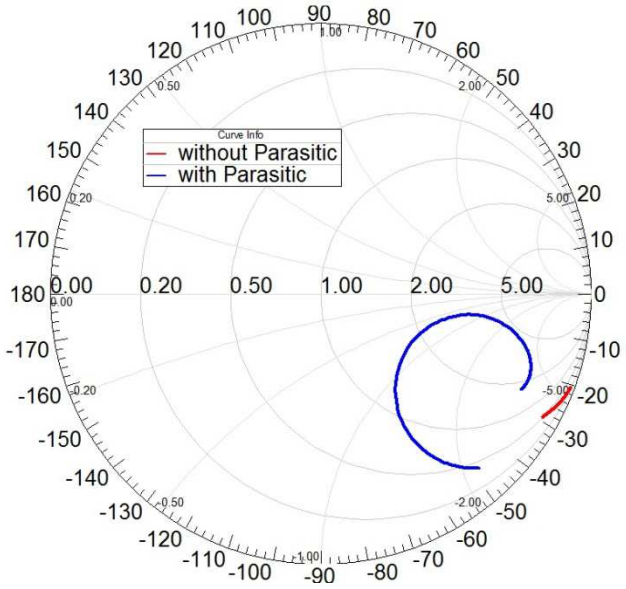

Figure 24 Input Impedance of the Antenna With/Without Parasitic Strip from 700 960 MHz

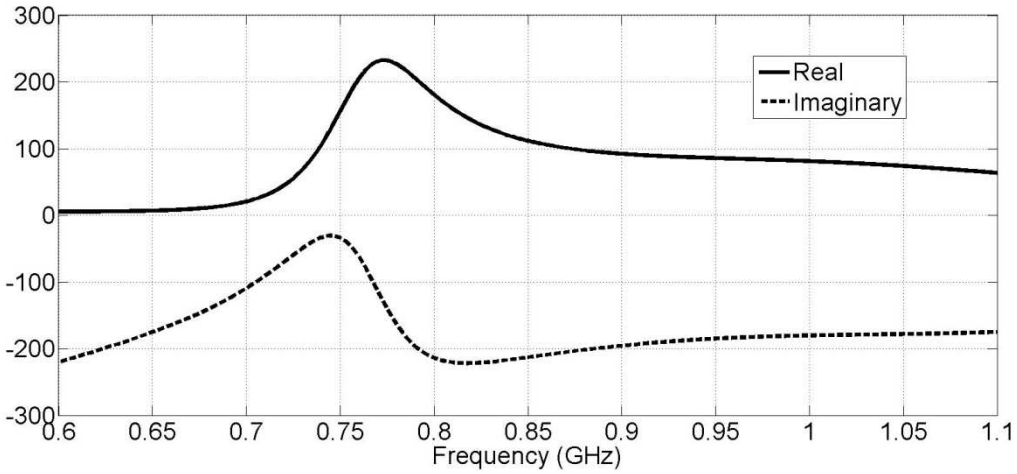

Figure 25 Input Impedance (Real/Imaginary) of the Antenna With Parasitic Strip

The surface current density of the antenna presented in Figure 26 also verifies this statement. At 700MHz, the currents induced on the parasitic strip are strong, creating a current path from the driven strip to the parasitic strip and returning to the feed through ground connection. At 950MHz, the currents are significantly weaker on the parasitic element. As previously discussed, the excitation of the ground plane plays a major role in the whole radiation mechanism of the structure and therefore the radiation efficiency and also the matching coverage of the LB. When the current distribution on the ground plane is investigated, it may be concluded that the first chassis wavemode of the ground plane is excited uniformly at 950MHz.

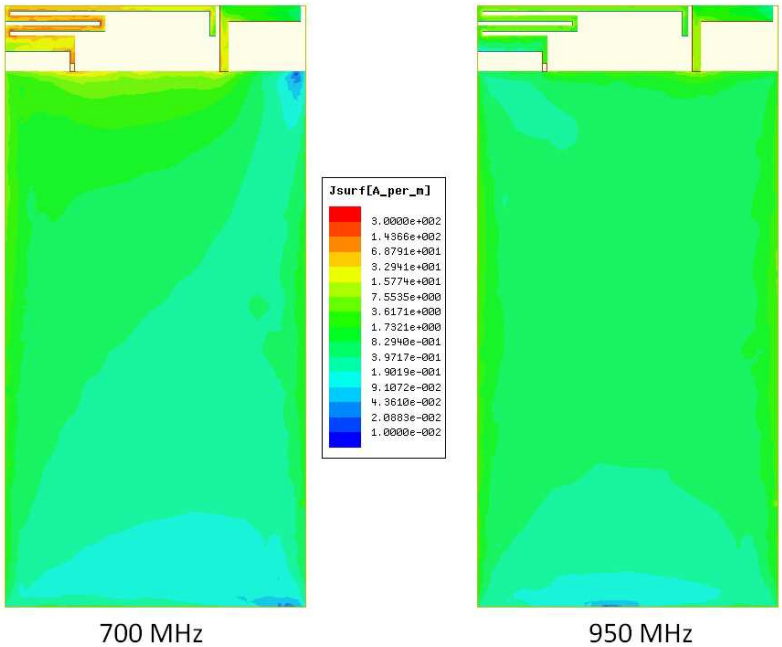

Figure 26 Surface Currents of the Antenna and The Chassis in LB

The bandwidth potential of the two cases (with/without parasitic element) has been investigated using the software Optenni Lab [8]. For this computation, the software optimizes a matching network (composed of two elements) for each frequency point and determines the frequency interval that rests under a pre-defined reflection coefficient value (-6dB chosen here). In this way, a realistic

bandwidth potential value is given instead of well-known, too optimistic theoretical maximum value. It can be seen in Figure 27 that introducing the parasitic strip increases the bandwidth potential considerably in the LB. The computed bandwidth potential gets closer to the target curve (in red), which states the bandwidth potential needed at each frequency point to cover 700-960MHz.The parasitic strip enables a bandwidth potential of approximately 250MHz at the center frequency (830MHz), with a two element MN.

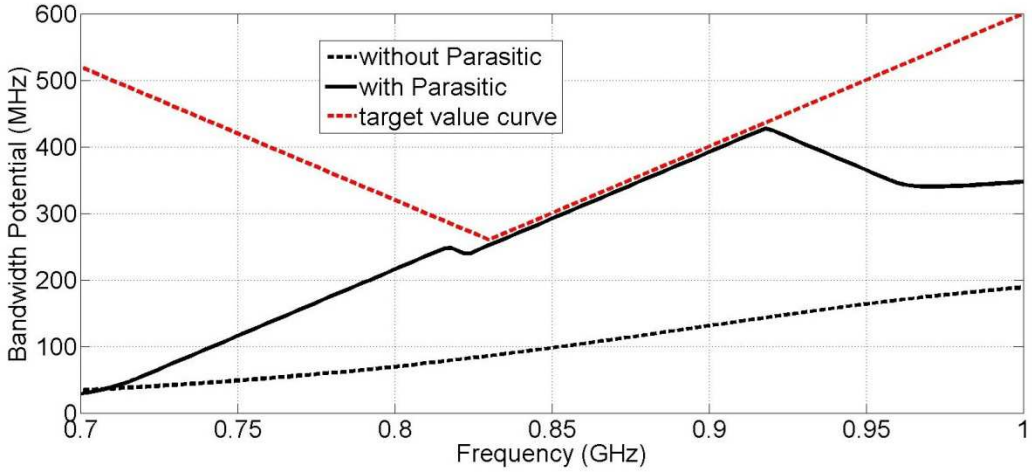

Figure 27 Comparison of BW Potential of the antenna With/Without Parasitic Element

The effect of the parasitic strip for creating an additional resonance in the LB was also investigated through circuit models. Circuit models were proposed for the driven strip in the absence of parasitic strip (Figure 28 on left) and for the parasitic strip alone when it is directly fed (Figure 28 on right). The circuit models for these two configurations are modeled as a series RLC circuit with a shunt capacitor in front which represents the capacitive coupling to the ground plane. A good correspondence between the simulated EM model and the circuit models can be observed (all smith chart curves are plotted between 700-960MHz).

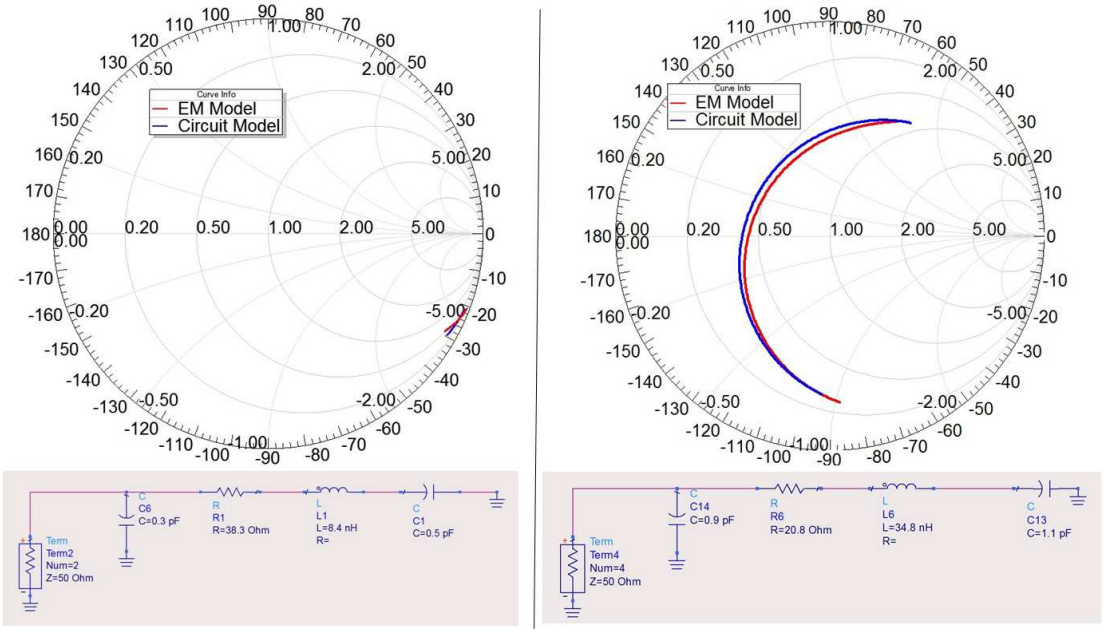

Figure 28 Circuit Model of the Driven (on left) and Parasitic Strips (on right)

Using these two circuit models as building blocks, the circuit model in Figure 29 is obtained. The circuits for the driven strip and parasitic strip are marked with the black and red circles respectively. A transformer model is used to stand for the capacitive coupling between the strips. The creation of the resonance in the LB can be observed for the circuit model, making a good compliance with the EM simulations.

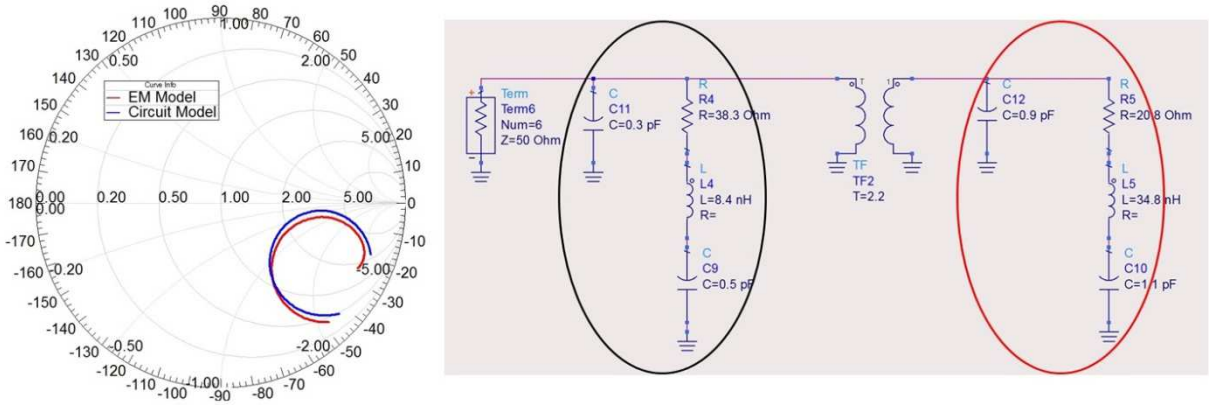

Figure 29 Circuit Model of the Combination of Driven and Parasitic Strips

The effect of the parasitic element in the HB (1.7-2.7GHz) can be observed in Figure 30. With the introduction of the parasitic element into the "driven strip only" case (red curve) two additional resonances are created around 1.85GHz and 2.4GHz. If the current distributions are observed at these two frequencies, it can be seen that the parasitic element is excited strongly in two different operating modes. Considering this fact, it can be concluded that the role of the parasitic strip is not only in the LB. It also contributes to the current distribution in the HB frequencies.

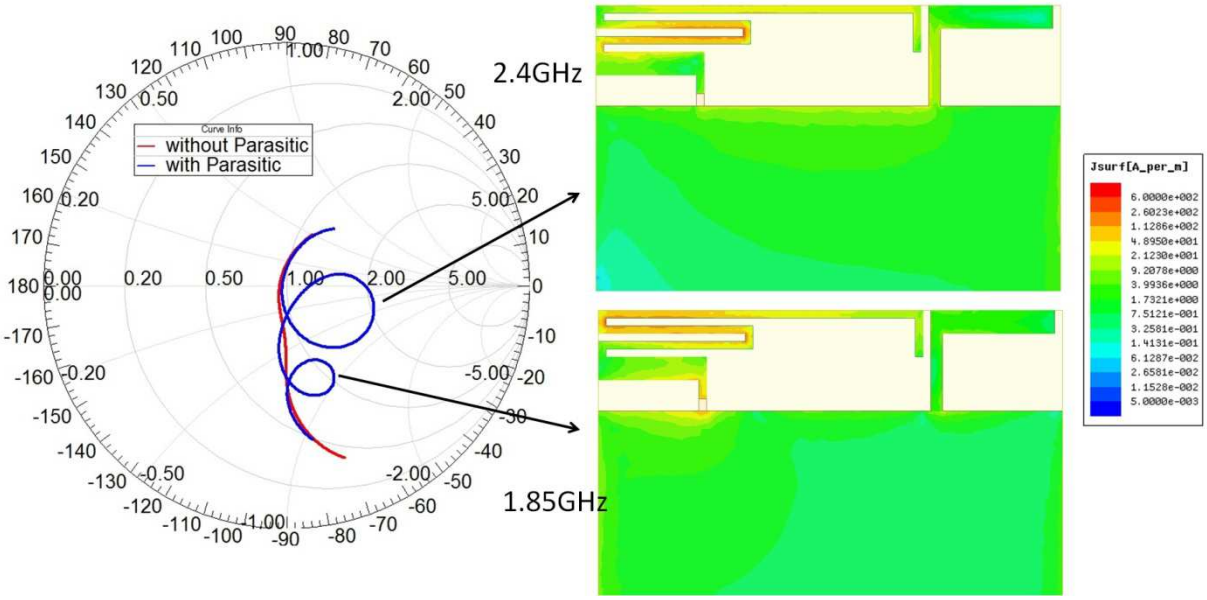

Figure 30 The Effect of the Parasitic Strip in the HB

1.1.2. Antenna Simulations With MEMS Switches and Matching Network

The antenna whose layout has been given in Figure 22 was simulated using Ansoft HFSS [9]. In the full EM simulations, the MEMS switches and SMD components were replaced by simulation ports and measured S-parameters from the manufacturers were used at those ports with a circuit post-processing simulation done in Agilent ADS [10], to obtain more realistic results. The DC bias pads for the MEMS switches and the wirebondings (to connect the MEMS die to the traces on the PCB) were also taken into account in the full EM simulation(Figure 31).

The main criteria when optimizing the antenna was to first obtain enough bandwidth potential for the LB coverage. The main antenna parameters that were tuned for this, were the coupling gap between the driven strip and the parasitic strip, the length of the parasitic strip (that changes the frequency of the resonance) and the inductance value on the ground connection of the parasitic strip (tuning the electrical length and thus resonance frequency). Since the antenna is longer in terms of wavelength, the coverage is simpler for the HB.

The simulated input impedances of the final optimized layout, with and without MN can be seen in Figure 32, plotted for LB (700-960MHz) on left and plotted for HB (1.7-2.7GHz) on right. It is worthwhile to note that the SMD component values in the MN were tuned taking into account also the transmission lines between SMDs and also the wirebondings. To show the effect of the transmission lines between MN elements, simulation were also done by connecting the lumped elements directly in the circuit simulator (dashed curves in Figure 31) and neglecting the wirebondings. It is seen that the transmission lines might have a strong effect depending on the input impedance of the antenna before the MN.

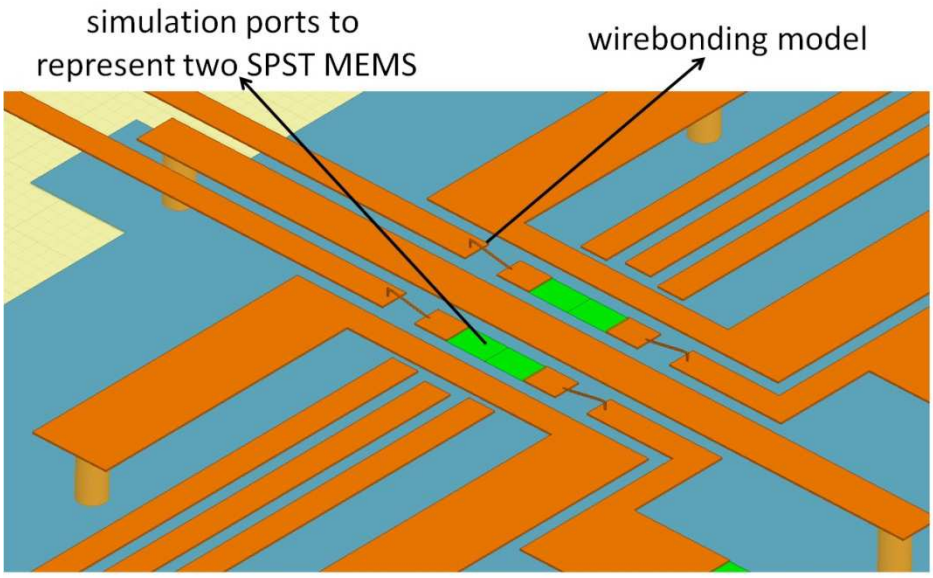

Figure 31 Simulation Model Showing Wirebondings and MEMS Modelling

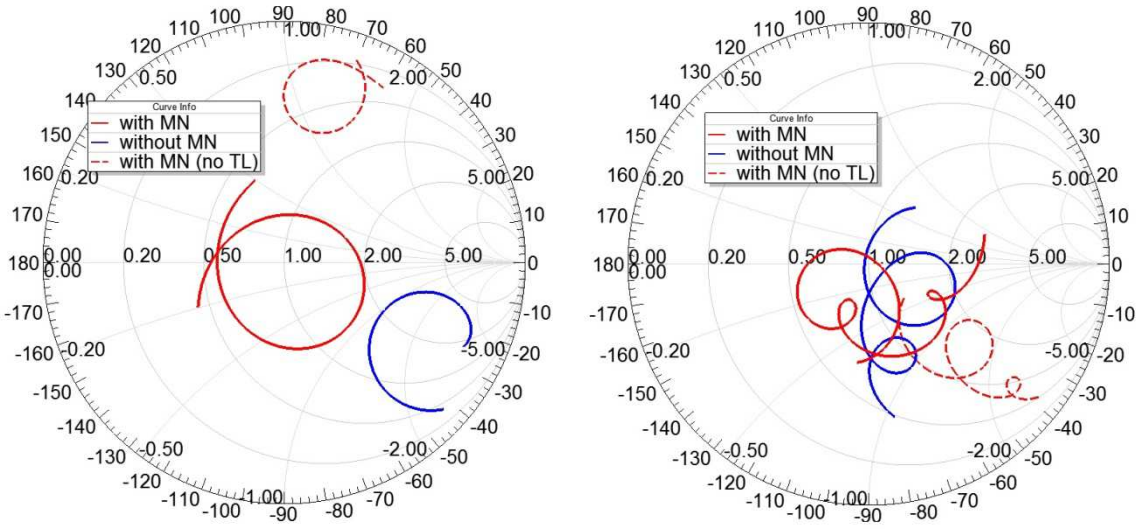

Figure 32 Simulated Antenna Impedance With/Without MN (LB on left, HB on right)

The simulated reflection coefficient of the antenna can be seen in Figure 33. Without any MN, the antenna is far from being matched in the LB (red dotted curve). With proper switching of the MEMS switches to select the LB MN (black curve), the antenna can be matched in the LB with a reflection coefficient below -6dB . Likewise, by choosing the HB MN branch, the antenna has a reflection coefficient below -6dB in the HB.

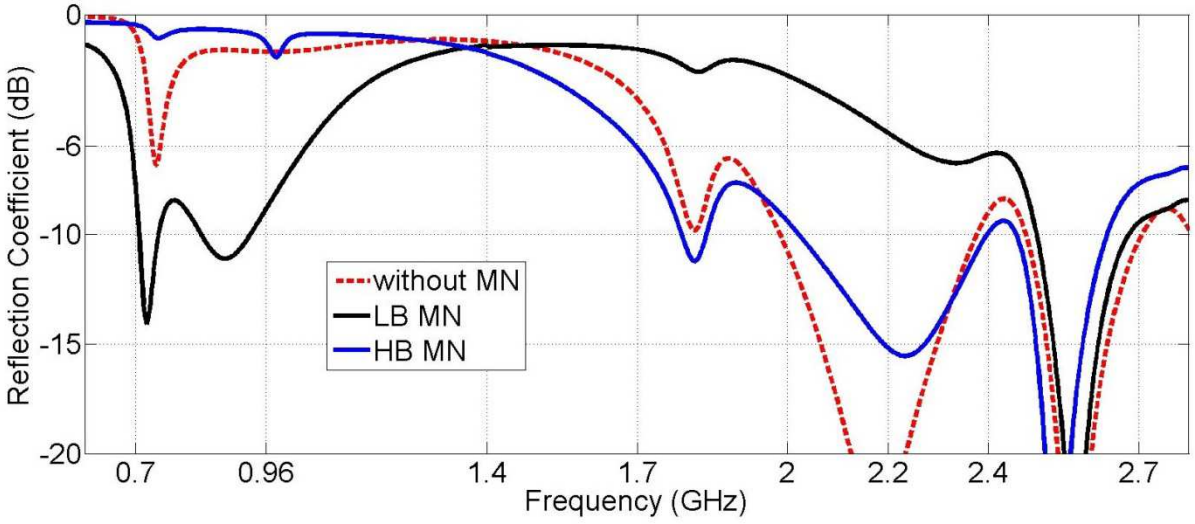

Figure 33 Simulated Reflection Coefficient of the Antenna With/Without MN

1.1.3. Measurement Results for Antenna Design I

The proposed antenna has been manufactured on FR4 substrate and the integration of the MEMS switches to the PCB was done using wirebonding (Figure 34).

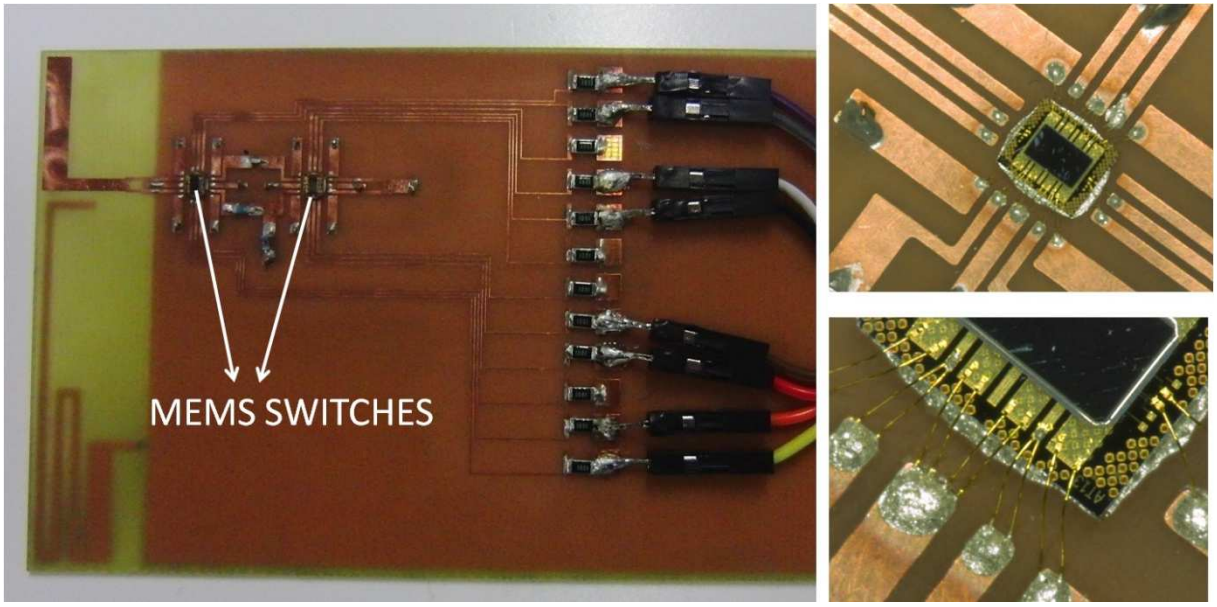

Figure 34 Pictures of the Manufactured Prototype for Antenna Design I

Due to the lack of encapsulation of the MEMS dies, problems were faced during the measurements mainly about the MEMS reliability and repeatability of the measurements. For this reason, as a backup solution, passive prototypes were manufactured where the MEMS switches are by-passed using soldered wires for ON state and left open for OFF state. The comparison of the measured reflection coefficient (for passive prototypes) and the simulation results can be seen in Figure 35 and Figure 36. A good correspondence is observed between simulations and measurements in terms of matching and input impedance behavior through both LB and HB.

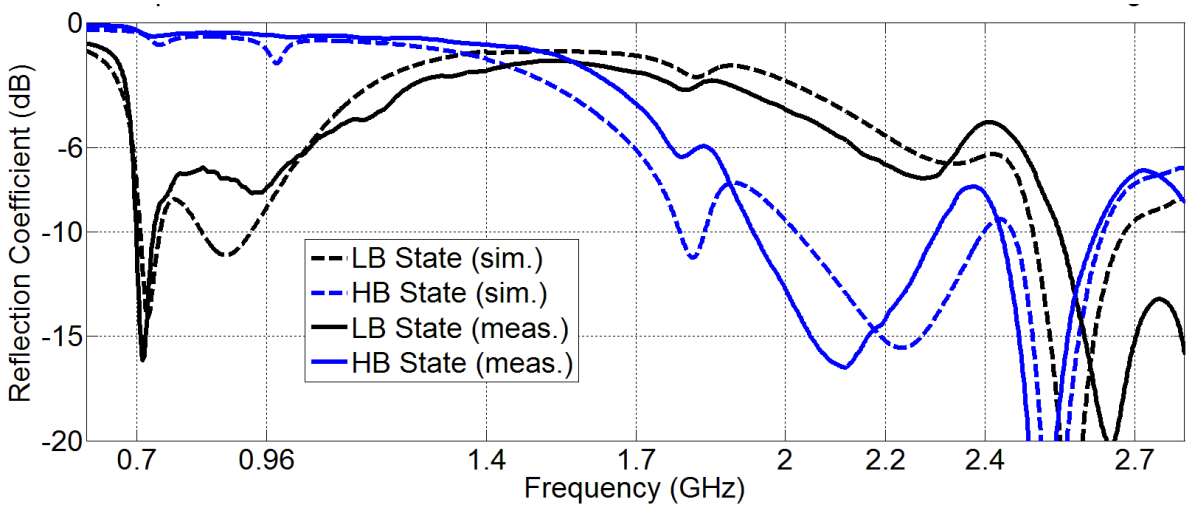

Figure 35 Comparison of Simulated and Measured Reflection Coefficient for Antenna Design I

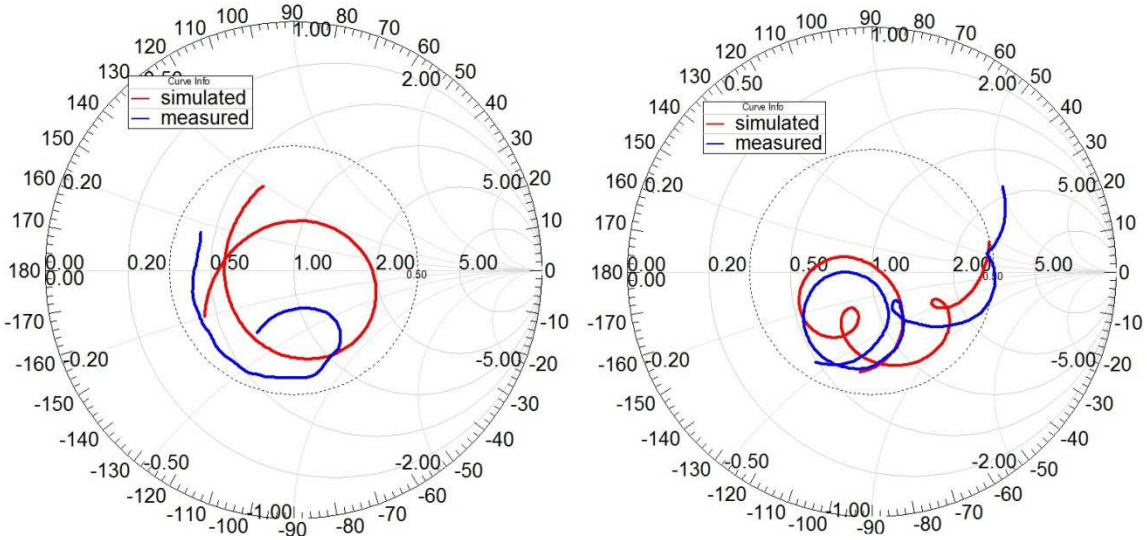

Figure 36 Comparison of Simulated and Measured Input Impedance for Antenna Design I (LB on left, HB on right)

The total efficiency of the passive prototype was measured in a Satimo Starlab station [11], in LB and HB (Figure 37). The measured total efficiency (including mismatch losses) can be seen in Figure 38 to be between -3.5dB and -1.5dB in the LB and between -3.5dB and -1.1dB in the HB.

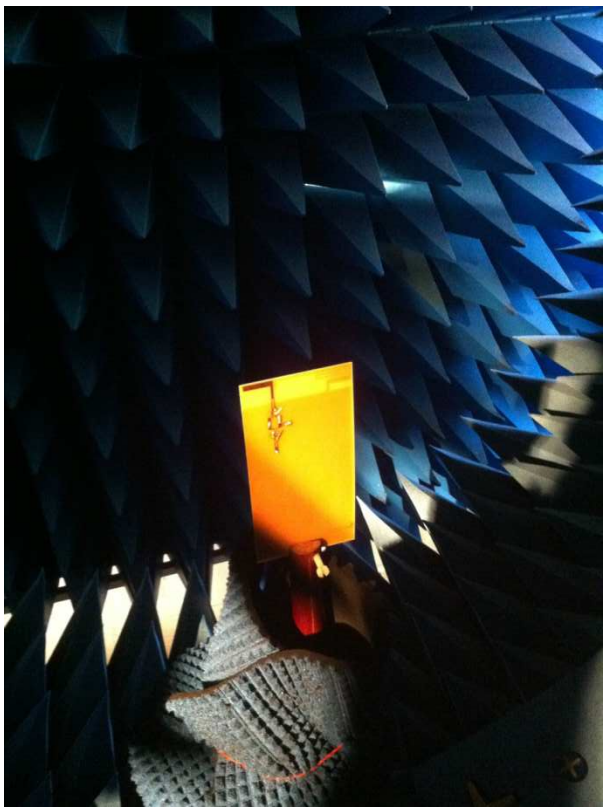

Figure 37 Efficiency Measurement Setup

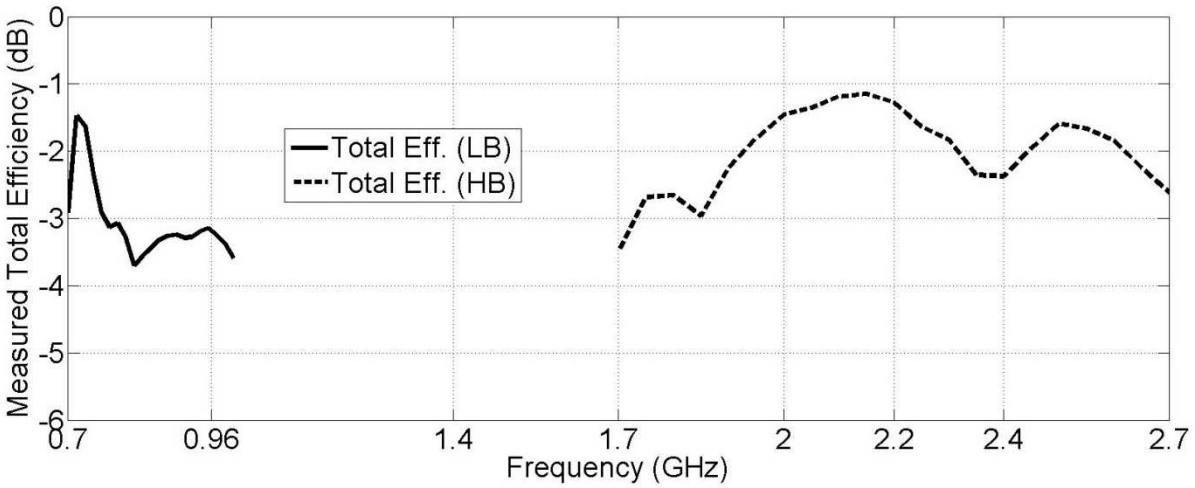

Figure 38 Measured Total Efficiency for Antenna Design I

The comparison of the simulated and measured 3D Gain pattern for the antenna in three different frequencies can be observed in Figure 39. A good compliance is seen between the simulated and measured patterns. In the LB, a dipole type radiation is observed as expected, since the ground plane is the main radiator. The antenna becomes more directive in the HB, as the electrical length of the antenna increases. The vertical polarization (when the PCB is held vertically) is dominant in both bands, where the measured maximum gain differs by more than 10dB in the LB and around 2-4dB in the HB when compared to horizontal polarization.

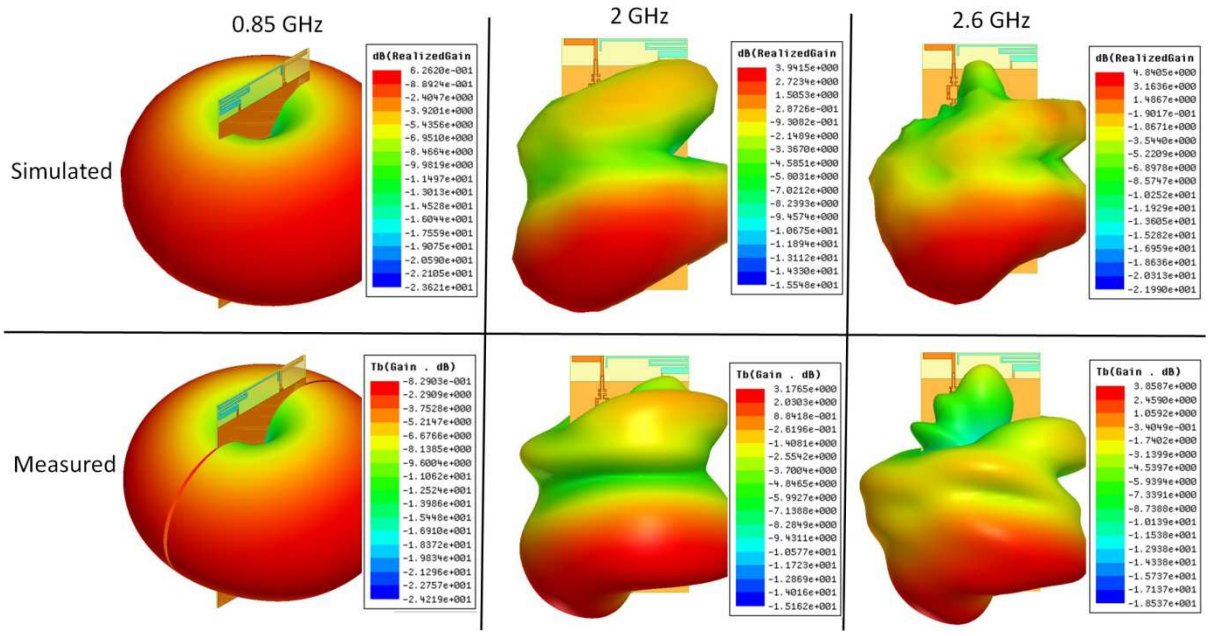

Figure 39 Simulated and Measured 3D Gain Patterns for Antenna Design I

A situation about the radiation efficiency was observed, having a closer look at the HB performance of the antenna. The simulated radiation efficiency is compared with the radiation efficiency calculated from the measured total efficiency (using the measured reflection coefficient) in Figure 40. Firstly, there is a difference of approximately 0.5dB between simulated and measured radiation efficiency, whose possible cause is the accuracy of the measurement set-up given as +/-1dB

in the product datasheet. Besides from that, a slight drop in the radiation efficiency can be seen around 1.85GHz and 2.45GHz both in simulations and measurements. As previously stated in Figure 30, these two frequencies correspond to the strong excitation frequencies of the parasitic strip in the HB. The cause of this radiation efficiency drop was further investigated and will be explained in Section 1.3 of this chapter because it's an important issue in many practical antenna designs for mobile phones.

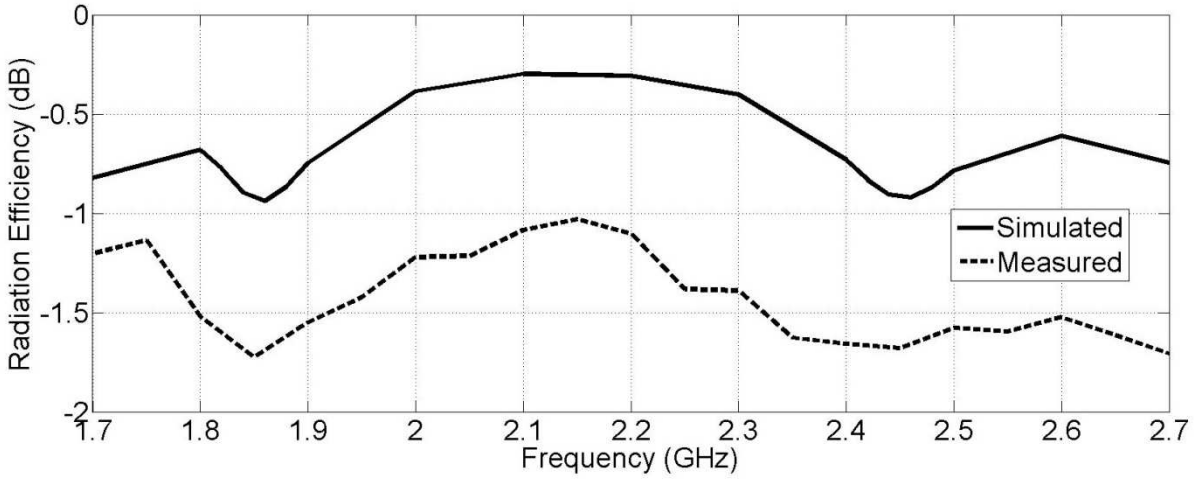

Figure 40 Simulated and Measured Radiation Efficiency in HB for Antenna Design I

1.2. ANTENNA DESIGN-II

A second alternative antenna design was also proposed, using MEMS switches again for band-switching between the LB and HB. The antenna excitation methodology was changed from selecting between two MN branches to selecting between two driven strips. The proposed antenna layout can be seen in Figure 41. The antenna is directly printed on the FR4 substrate having dimensions of 115mm X 60mm X 0.8mm, with a ground clearance of 15mm for the antenna. The antenna consists of two driven strips, one for LB coverage and one for HB coverage. To increase the bandwidth potential in the LB, a parasitic element (printed under the substrate) was again used, which is capacitively excited by the LB driven strip and connected to the ground plane over an SMD inductor (18nH) on the other end. The inductor used in the ground connection helps to increase the electrical length of the parasitic strip, thus decreasing the resonance frequency created by the parasitic strip. The number of SPDT MEMS switches is reduced to one (instead of two in the former case) and the switch is used to direct the excitation current either through the LB path or the HB path as seen in Figure 41. When the LB driven strip is excited, the parasitic strip is also capacitively excited, enabling a higher bandwidth potential in the LB.

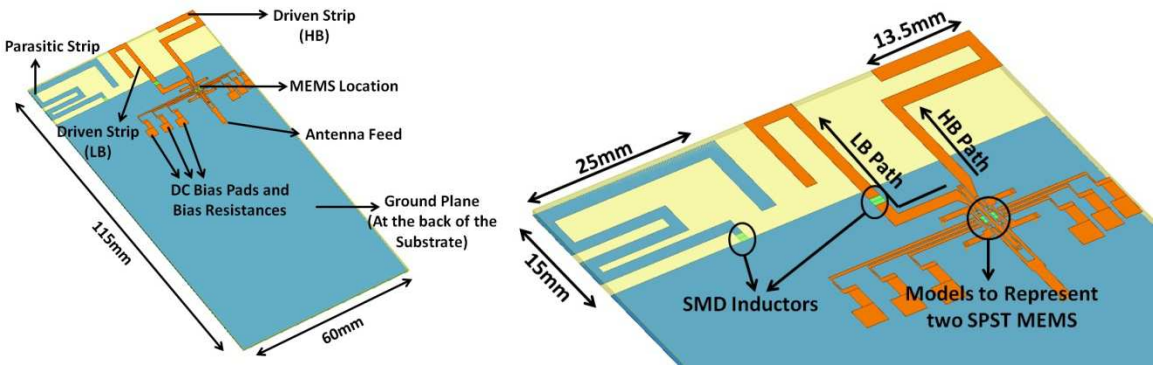

Figure 41 Layout of the Antenna Design-II Using MEMS Switches

1.2.1. Antenna Simulations With MEMS Switches and Matching Network

The simulated input impedance when removing the HB driven strip (considering only the LB driven strip with the parasitic element) can be observed in Figure 42 (Blue curve), on the left smith chart (plotted between 700-960MHz). A resonance is created by the parasitic strip similarly to the one created for Design I, which appears as a new loop in the smith chart. The LB response of the antenna is matched to 50Ω using a series inductor (27nH) on the LB driven strip. The red curve in the same figure presents the input impedance after the HB driven strip and the SMD inductor is introduced to the antenna. If the HB response of the antenna for "HB driven strip only" case is observed on the right smith chart, it can be seen that the parasitic strip creates a resonance in this band also at 1.76GHz.

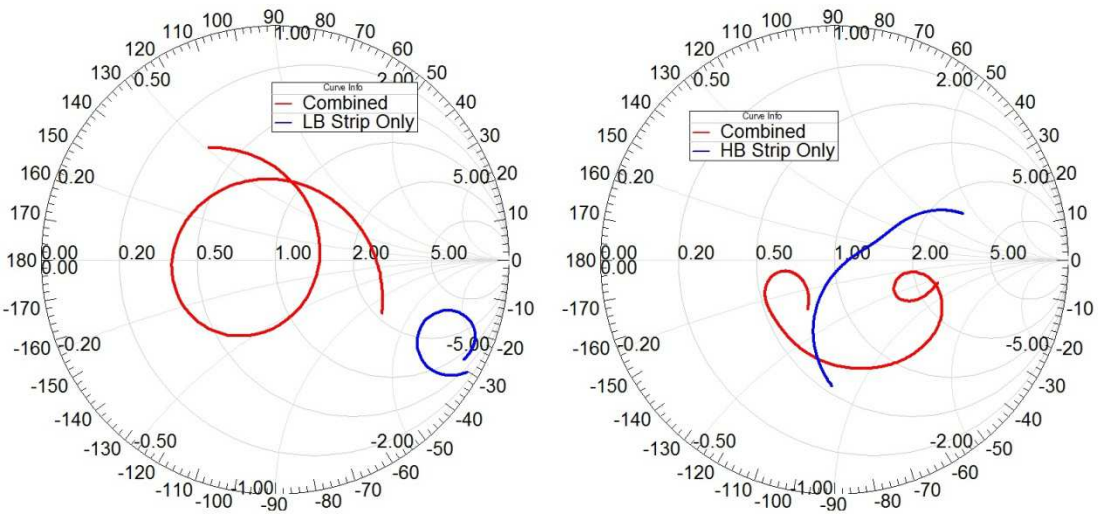

Figure 42 Simulated Input Impedance for Antenna Design II (LB on left, HB on right)

The role of the parasitic strip in the HB can be seen with the surface currents presented in Figure 43. At 1.76GHz, strong currents are excited on the parasitic strip, which appear weaker at any other frequencies (2.2GHz presented here).

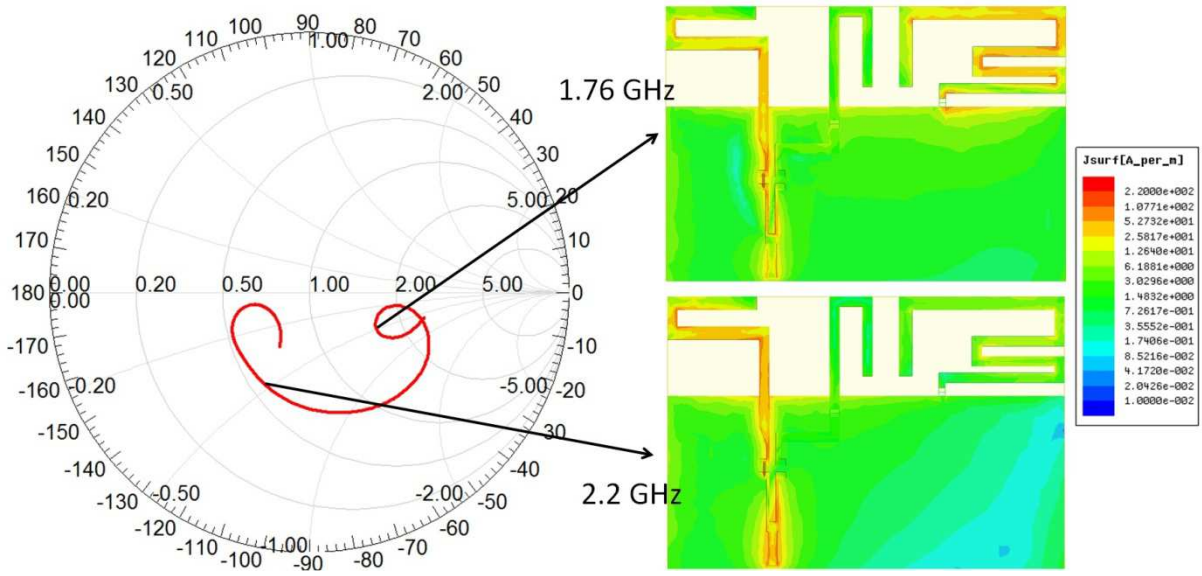

Figure 43 Surface Current Distribution for Antenna Design II in HB

1.2.2. Measurement Results for Antenna Design II

The S-parameter measurements of this prototype have been done both with real MEMS devices and with passive prototypes. In passive measurements, to represent the ON-state of the MEMS, a simple wire was soldered bypassing the MEMS and the connection was left open to represent the OFF-state. The measured reflection coefficient for the antenna in the LB and HB states can be seen in Figure 44. The target bands are covered with a reflection coefficient below -6dB in both passive measurements and real MEMS measurements, using the band-switching topology.

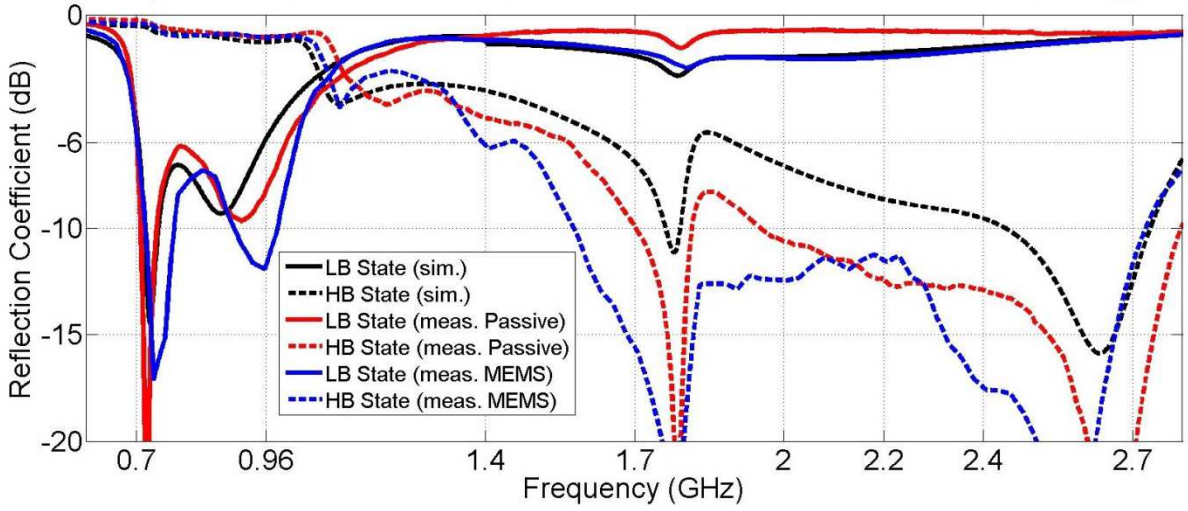

Figure 44 Comparison of Simulated and Measured Reflection Coefficient for Antenna Design II

The simulated and measured (with passive prototypes) input impedance makes a good compliance as seen in Figure 45. Comparing the simulated impedance response with the one measured with MEMS, it can be told that the MEMS switches turned out to be more lossy in the measurements than expected, since the locus in the smith chart is closer to the center (50Ω).

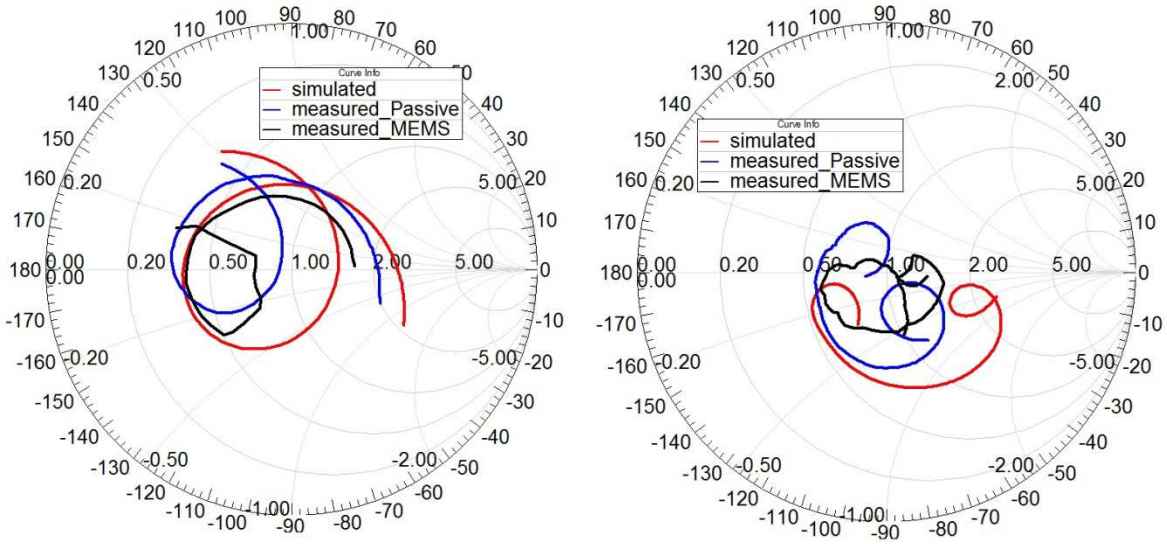

Figure 45 Comparison of Simulated and Measured Impedance for Antenna Design II (LB on left, HB on right)

The total efficiency of the antenna was also measured (for passive prototypes only, due to reliability issues) for LB and HB cases (Figure 47). The manufactured prototype can be observed in Figure 46.There is an efficiency higher than -3dB except around 700MHz in the LB and higher than -2.5dB in the HB.

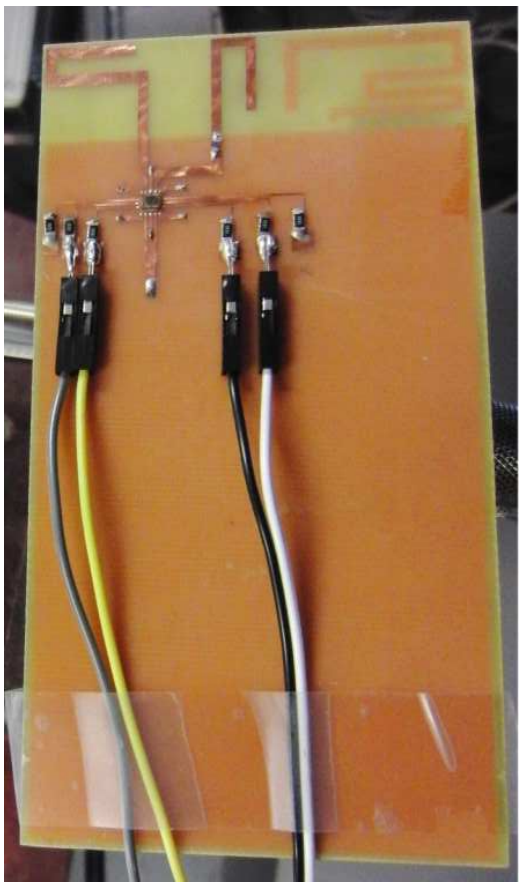

Figure 46 Manufactured Prototype for Antenna Design II

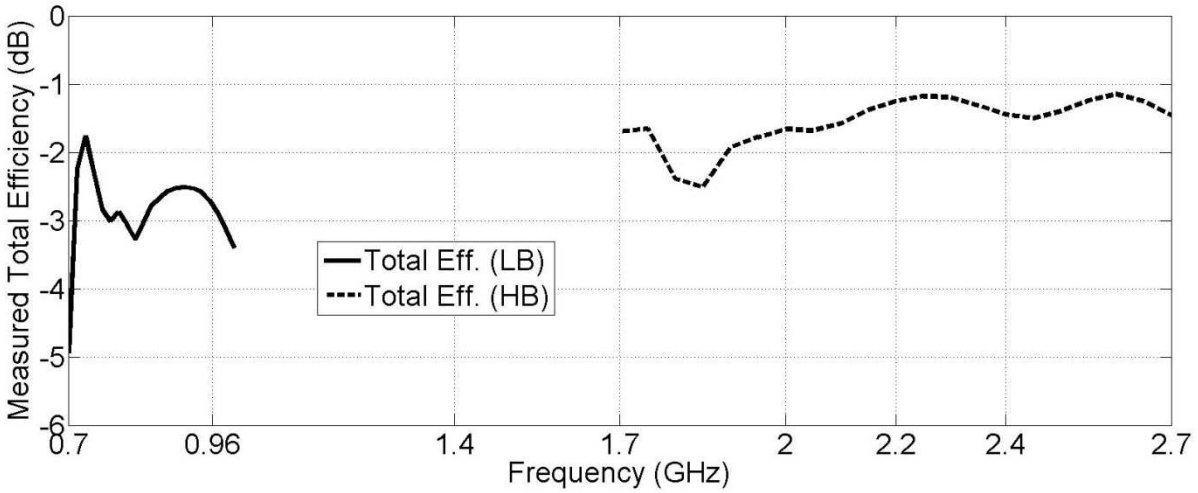

Figure 47 Measured Total Efficiency for Antenna Design II

The measured 3D gain patterns are compared with simulations in Figure 48. A good compliance in terms of pattern shape can be seen between simulations and measurements. As in the previous antenna, the LB pattern is a dipole type pattern and the gain increases in the higher frequency bands. The dominant polarization is again vertical, maximum gain being more than 10dB superior in LB and 1.5-2dB superior in HB when compared to horizontal polarization.

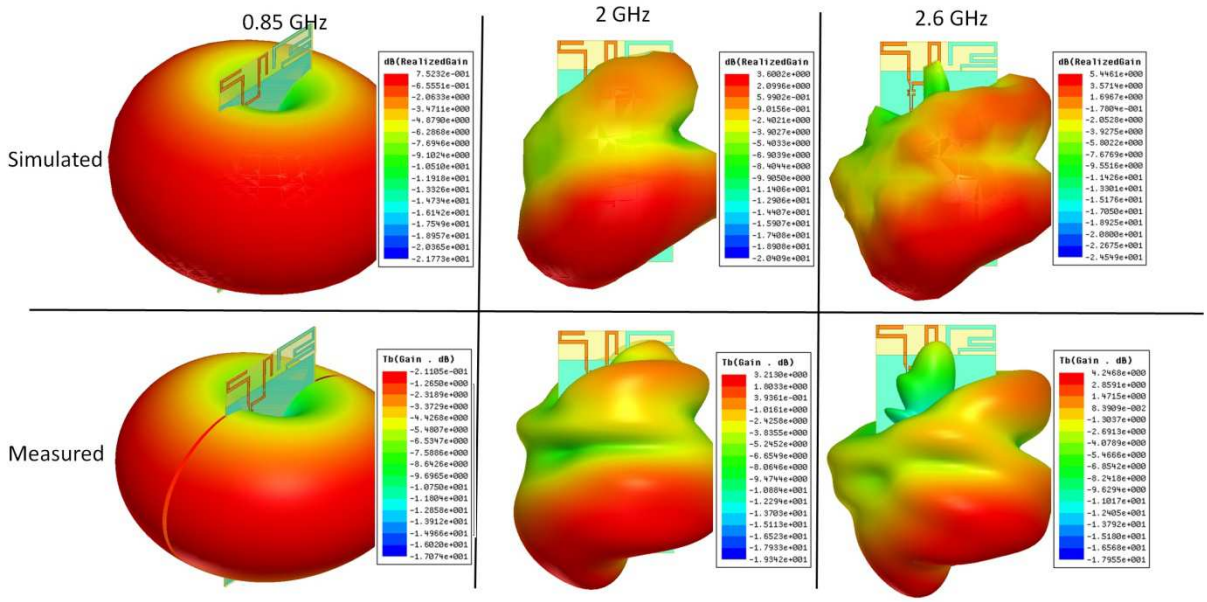

Figure 48 Simulated and Measured 3D Gain Patterns for Antenna Design II

A radiation efficiency drop issue can be also observed also for this prototype around 1.8GHz in Figure 49. It is worthwhile to note that the measured radiation efficiency in this figure is calculated from the measured total efficiency using the measured reflection coefficient. The efficiency drop is observed again at a frequency point, where the parasitic strip is strongly excited. Explanations about this problem will be given with some proposed solutions in next Section 1.3.

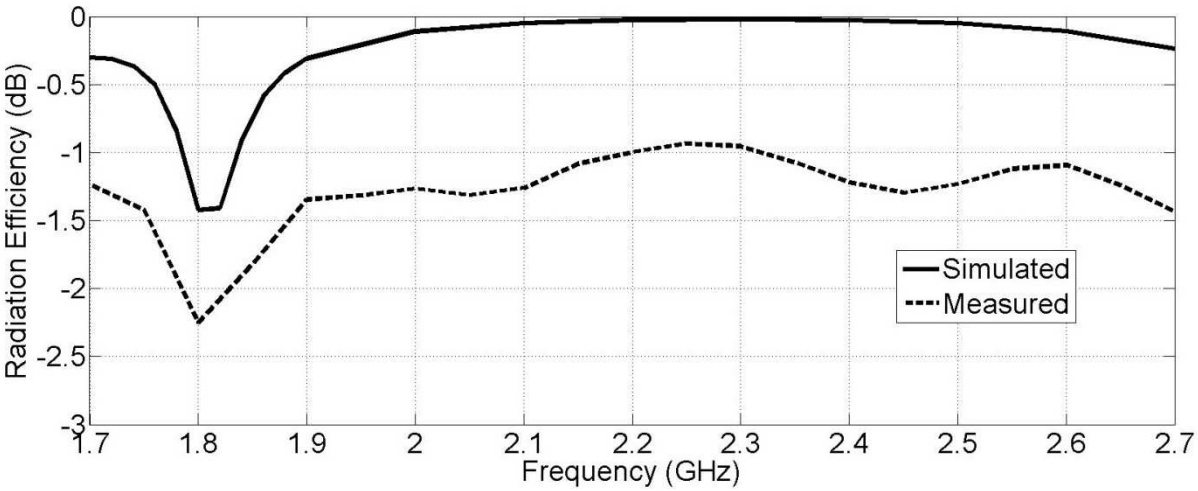

Figure 49 Simulated and Measured Radiation Efficiency in HB for Antenna Design II

1.3. RADIATION EFFICIENCY DROP IN ANTENNA PROTOTYPES

As presented in Figure 40 and Figure 49 of this chapter, a narrowband drop in the radiation efficiency was observed for both prototypes both in simulation and measurement, at the frequency regions corresponding to the excitation of the parasitic element in the HB. For the situation here, the drops observed are not causing a deep null in the radiation efficiency, but instead decreasing it as much as between 0.5-2dB from the general trend in simulations. However it should be noted that depending on the antenna topology, the problem may be more dramatic causing deep efficiency drops.

To investigate the reason of this situation, the surface currents were plotted in Figure 50 for antenna design I, at the frequency points of 1.86GHz and 2.46GHz, where a radiation efficiency drop of approximately 10% (-0.5dB) is observed from the general trend of the neighboring frequencies. Since the parasitic strip contributes to the HB frequency behavior at these two frequencies, strong currents can be observed on it (encircled with black ellipses in Figure 50). The direction of the current flow stays in opposite directions around the meander region, in a physically close manner. The fields created from these currents tend to cancel each other in the far-field region of the antenna, which leads to a radiation efficiency drop.

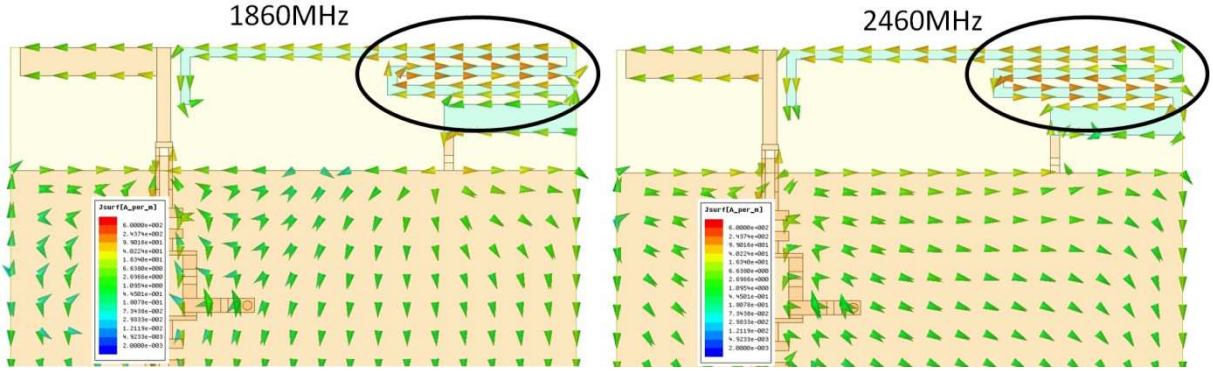

Figure 50 Surface Currents for the Efficiency Drop in Antenna Design I

To mitigate this effect and also for verifying the cause of the drop (suspected as the reverse currents on the meander region), the topology of the parasitic element was modified as seen in Figure 51, removing the meander line. Since the electrical length of the parasitic element is now shorter, the SMD inductor value on the ground connection is increased from 12nH to 16nH. In this way, the role of the parasitic element in the LB is maintained (for creating an additional resonance to increase bandwidth potential). For the simulations to be fair, no other property of the antennas nor the component values were changed. It can be seen in Figure 51 with the simulated reflection coefficient that the target bands can still be covered after this modification, although some tuning might be needed in the HB. The radiation efficiency of the modified structure is compared with the original case in Figure 52. The drops in the radiation efficiency are now satisfactorily solved with the modified structure.

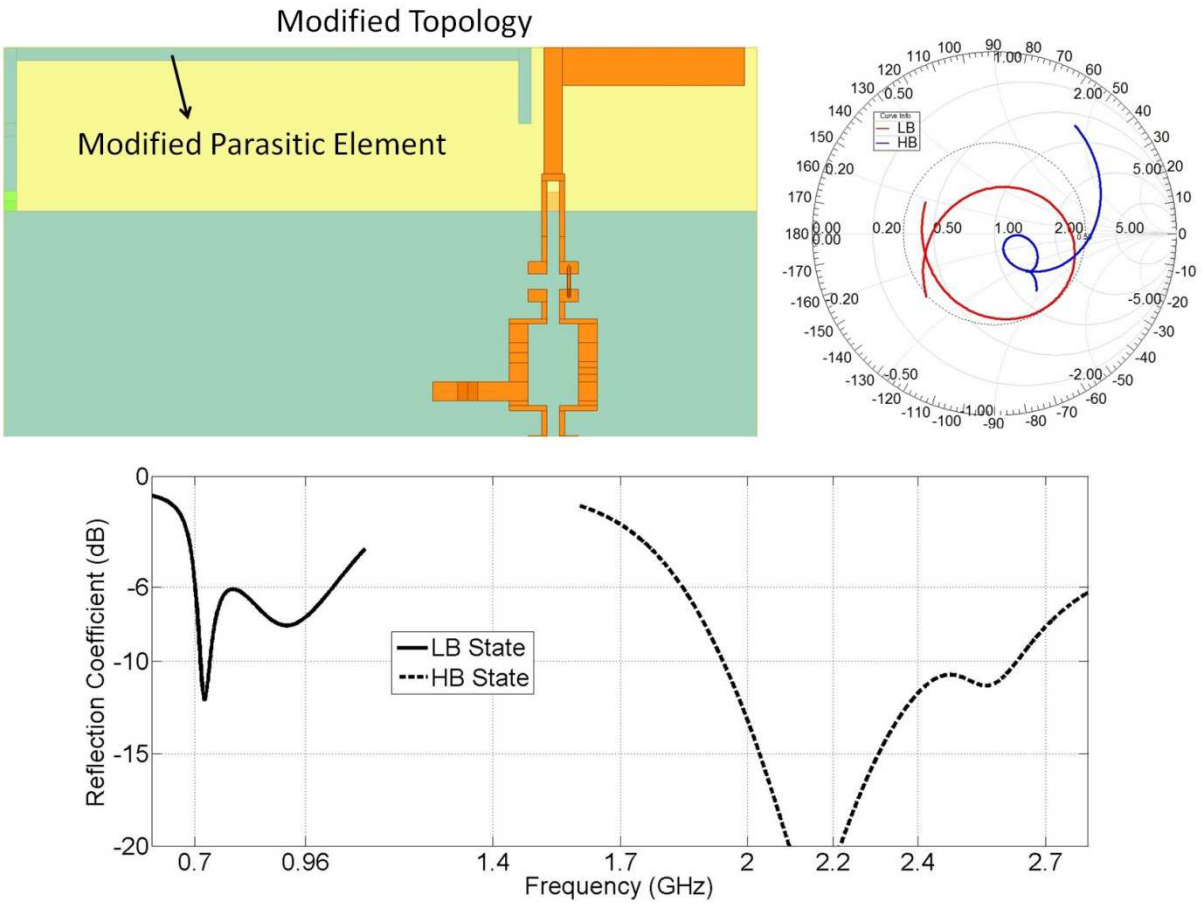

Figure 51 Modified Topology to Mitigate the Efficiency Drop for Antenna Design I and Simulated Input Impedance and Reflection Coefficient

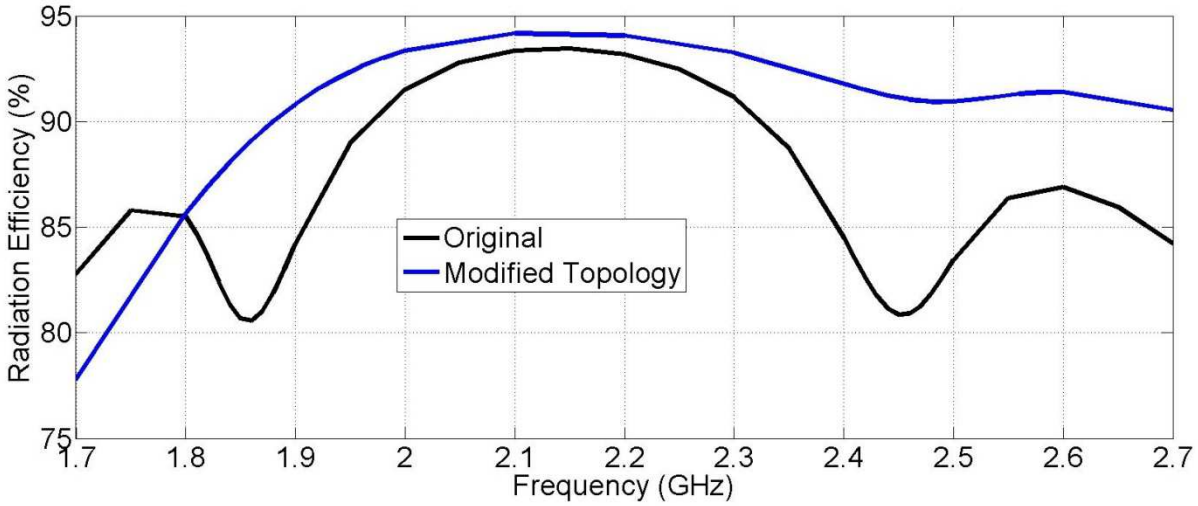

Figure 52 Simulated Radiation Efficiency of the Modified Topology for Antenna Design I

A similar study was done with antenna design II also. The surface currents in opposite directions on the meander line can be observed in Figure 53 at 1800MHz.

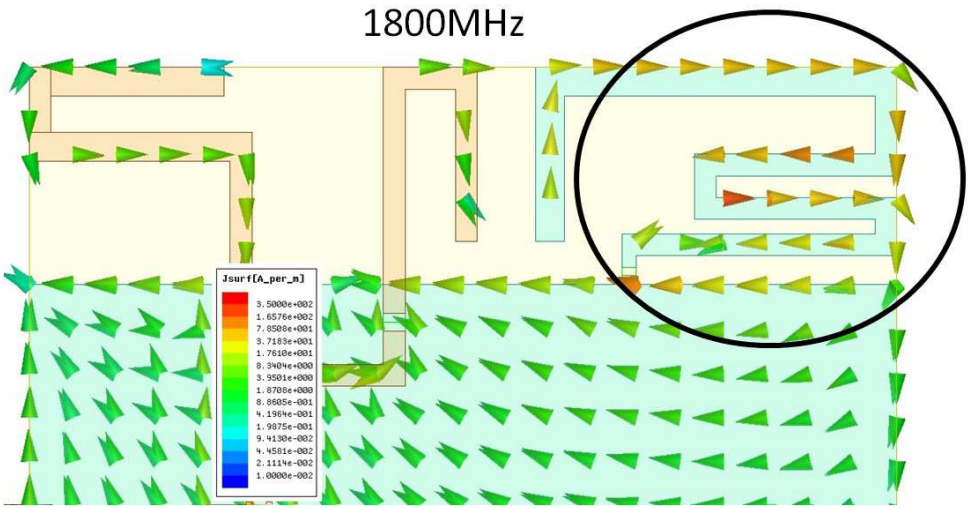

Figure 53 Surface Currents for the Efficiency Drop in Antenna Design II

Two different modified topologies are proposed in Figure 54, avoiding any meander line on the parasitic strip. To compensate the shortening of the electrical length of the parasitic element, the SMD inductor value on the ground connection point was increased to 27nH in modified topology-1 and to 29nH in modified topology-2 (from 18nH). A good matching behavior concerning the target frequency bands can be achieved with the two topologies.

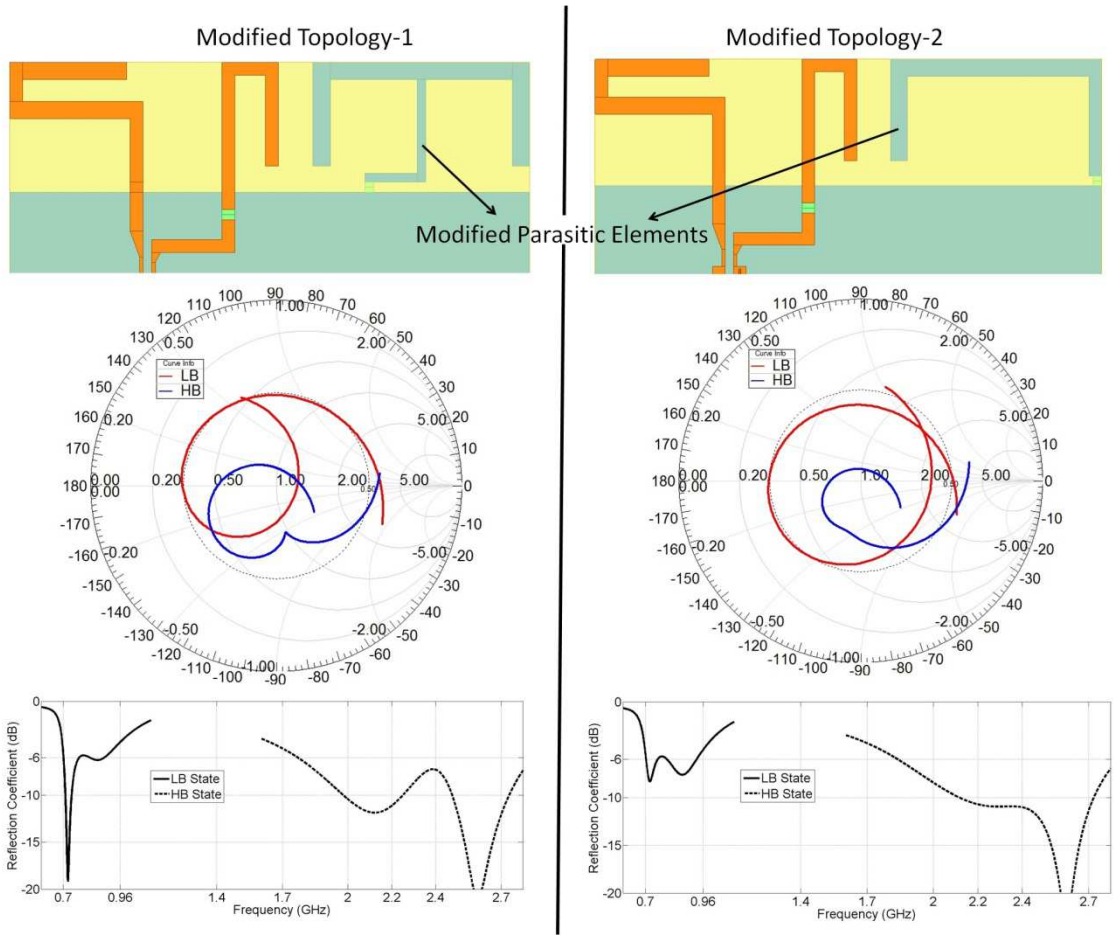

Figure 54 Modified Topology to Mitigate the Efficiency Drop for Antenna Design II

The effect of this modification on the simulated radiation efficiency is presented in Figure 55. Although the 25% efficiency drop at 1.8GHz is prevented, a drop of approximately 10% is again seen in modified topology-1 at the frequency where the parasitic strip is excited. This can further be avoided by modifying the layout as in modified topology-2.

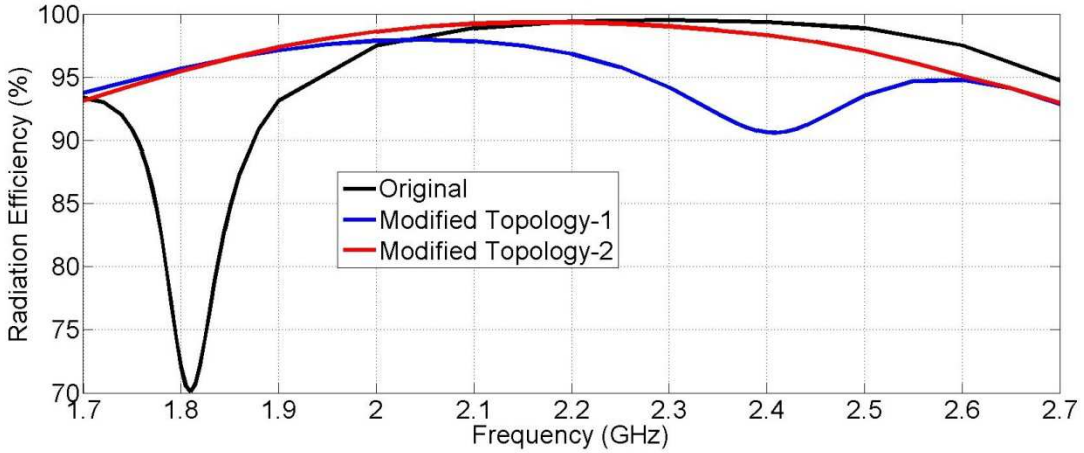

Figure 55 Simulated Radiation Efficiency of the Modified Topology for Antenna Design II

The fabrication of the modified antennas were not possible due to time constraints so the measurement results are not presented here.

2. ANTENNA DESIGN USING BST CAPACITOR

Another tunable component for use in the tunable antennas from the Artemos Project is the tunable BST(**B**arium **S**trontium **T**itanate) capacitors from CEA-LETI[12]. This type of tunable capacitors have been used for matching band reconfigurability in [13-14]. In [13], a tunable capacitor with a tuning range between 1.4-4.2pF was used in a tunable matching network at the feed of a COTS chip antenna to tune the matching bandwidth between 1.55-1.7GHz(Figure 56). A tunable dual-band IFA was proposed in [14], whose matching bands are tuned using a series LC resonator in parallel with a BST capacitor on the IFA. In this way the LB of the antenna is tuned between 822-1050MHz and HB is tuned between 1.42-2.2GHz using the BST capacitor having a tuning range of 3.3:1.

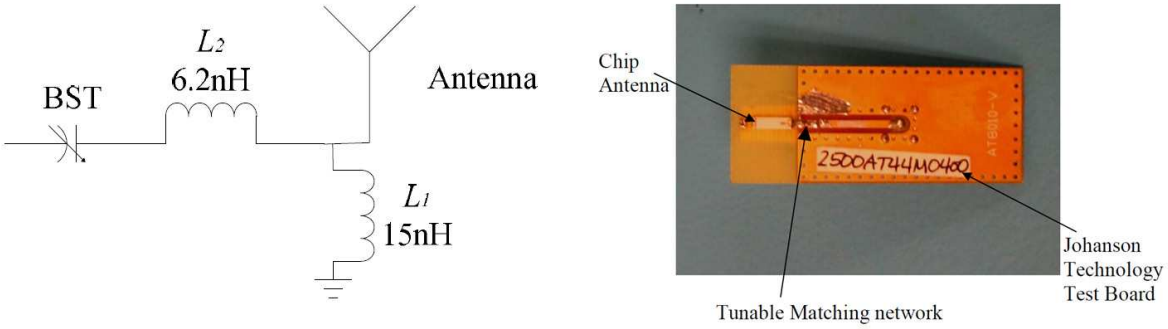

Figure 56 Tunable Matching Network and Test Prototype in [13]

For this study, CEA-LETI has implemented tunable Metal/Insulator/Metal capacitors using $Ba_{0.7}Sr_{0.3}TiO_3$ as the dielectric material. A general layout of the BST tunable capacitor can be seen in Figure 57. Tunability in the capacitance value is achieved by changing the applied bias voltage between the top and bottom metal plates. This voltage difference changes the permittivity of the BST material, which in turn changes the capacitance between the plates.

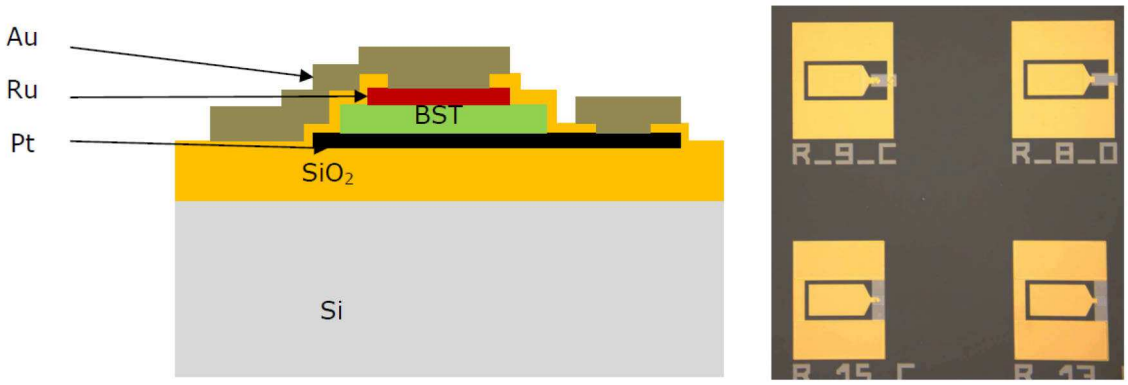

Figure 57 Layout of a BST Capacitor and Photograph of Manufactured Dies

The main challenge of using these tunable capacitors is the relatively low tunability range, which was agreed to be between 2.5-4pF with the manufacturer. The measured capacitance value versus the applied bias voltage for the BST capacitor can be seen in Figure 58. The tunable capacitor is exploited to achieve matching tunability in the LB, with a simple and low-cost antenna geometry. For the coverage of the HB, another antenna which is separately fed is used, obtaining a dual-feed configuration.

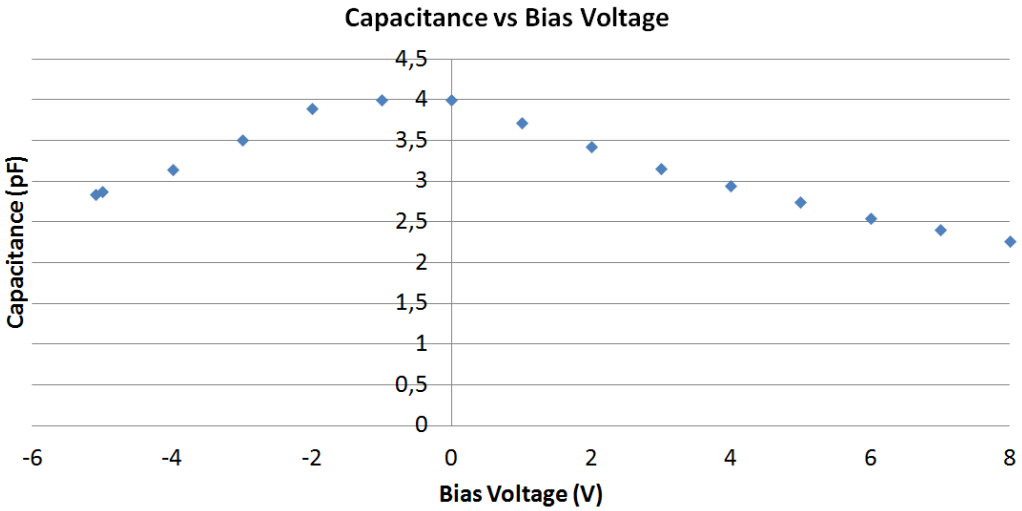

Figure 58 Measured Capacitance vs Bias Voltage for BST Capacitors

2.1. ANTENNA MODEL AND SIMULATION RESULTS

The proposed antenna model can be seen in Figure 59. As already mentioned, the antenna has a dual-feed structure, where one of the feeds is responsible for LB coverage and the other is responsible for HB coverage. All the antenna structure is again printed on FR4 substrate, having total dimensions of 120mm X 59mm X 0.8mm, with a ground clearance of 15mm on one of the short edges. The LB antenna is a simple coupling element (CE), which is tuned to the desired band using a pre-matching network and the tunable BST capacitor. The HB antenna is a simple monopole, fed through the second feed of the antenna.

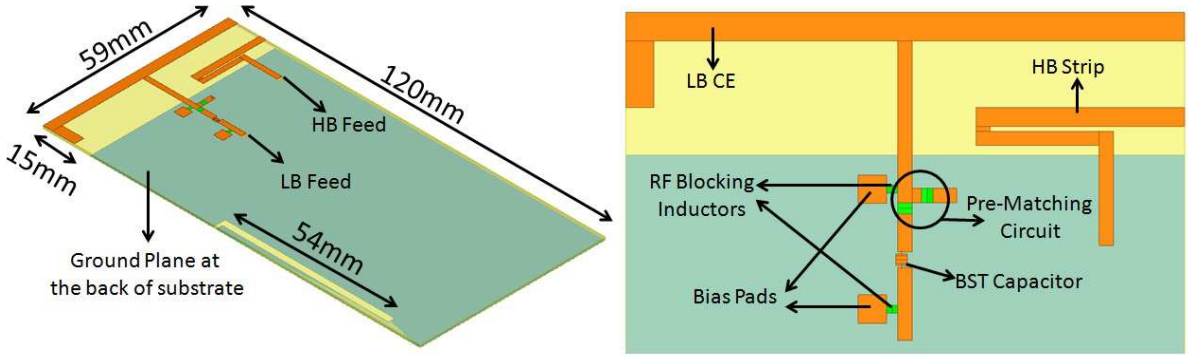

Figure 59 Simulation Model of the BST Antenna

Since the tunable capacitor has a relatively low tuning range (4 : 2.5), a slot of 54mm length was etched on the ground plane, to create an additional resonance around 950MHz, which makes the coverage of the LB easier. The slot basically changes the current distribution on the ground plane and the chassis resonance shifts to lower frequencies since the electrical length of the ground plane increases. The length of the slot is an important parameter in the design phase of the antenna. Changing this length modifies the frequency of resonance, seen in the blue curve in Figure 60. The length was optimized as 54mm after a parametric study. The effect of the slot can be observed in Figure 60, plotted between 700-960MHz.

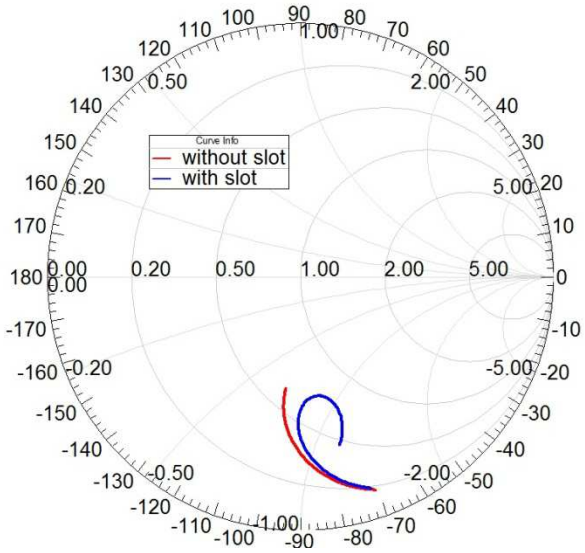

Figure 60 Effect of the Slot in the Ground Plane

The left smith chart in Figure 61 presents the simulated input impedance of the antenna when the LB CE is simulated in the absence of the HB monopole and vice versa. The red curve is plotted for frequency interval 700-960MHz and blue curve plotted between 1.7-2.7GHz. The response of the combined antenna structure, after the pre-matching using a shunt inductor of 30nH and series inductor of 22nH is given on the right in Figure 61. One thing to notice here is the additional resonance created in the HB around 1900MHz. According to the surface currents plotted in Figure 62, this new resonance comes from the currents induced on the LB CE. Afterwards these currents flow to the ground plane over the shunt inductor and also to the LB feed of the antenna, which should be kept under a specific level to achieve enough port-to-port isolation.

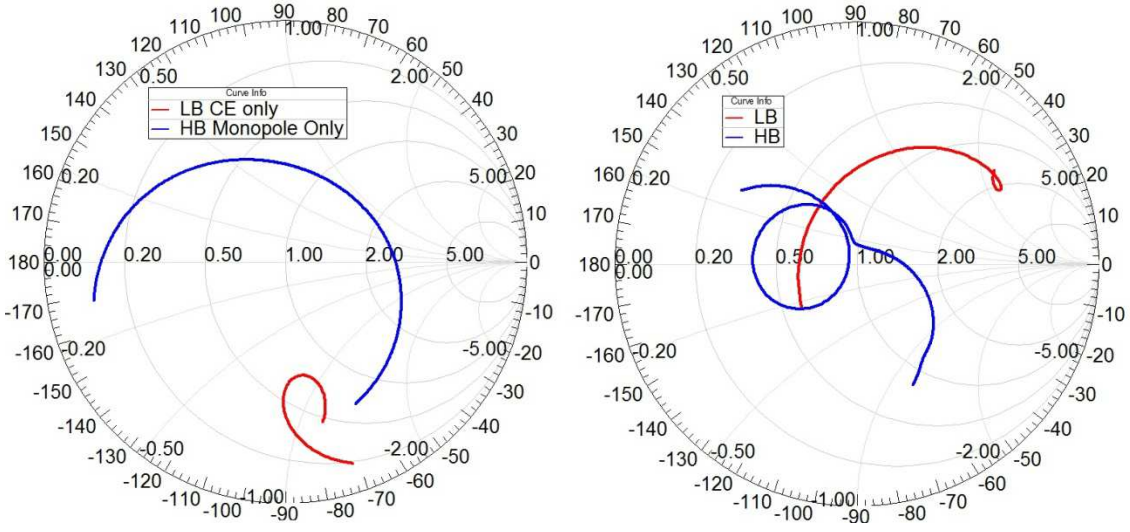

Figure 61 Simulated Input Impedance of the Antenna (LB CE and HB Monopole Simulated Alone on left, After Pre-Matching on right)

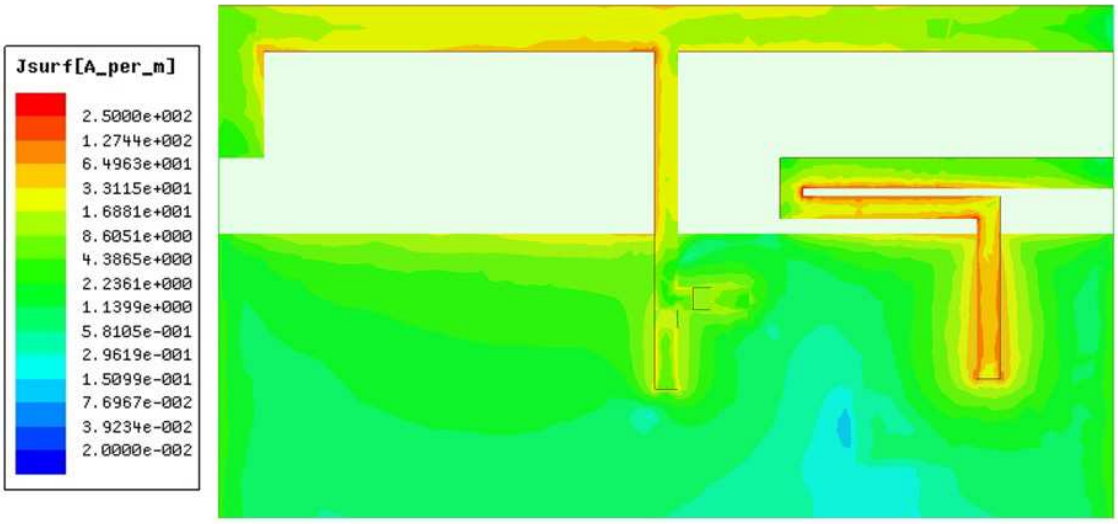

Figure 62 Surface Currents for BST Antenna at 1900MHz After Pre-Matching

Simulations were done for the antenna taking into account the wirebondings and RF Blocking inductors (120nH) for the DC bias pads, that are necessary for the integration of the BST capacitor. For the SMD components, the measurement results from the manufacturers were used. The simulated reflection coefficient in the LB for the BST capacitance changing from 2.5pF to 4pF is given in Figure 63. By increasing the capacitance value, the impedance curve moves in clockwise direction on a constant resistance circle in smith chart, enabling the coverage of lower frequencies. The resonance created by the slot in the ground plane helps considerably for the matching in the high-edge of the band. With this configuration, the frequency interval of 725-960MHz can be covered with a reflection coefficient below -6dB.

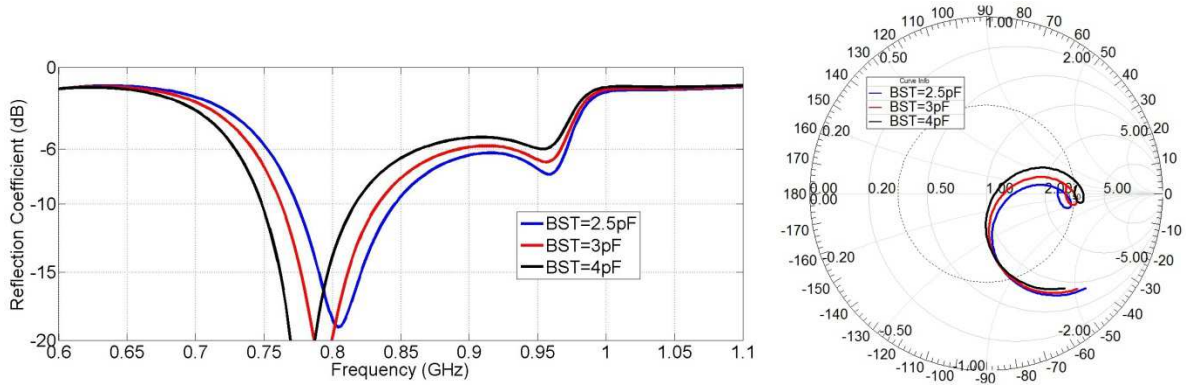

Figure 63 Simulated Reflection Coefficient in the LB for Different BST Capacitance Values

It was seen that the HB performance is not affected by the change in the tunable capacitor. Figure 64 shows the total antenna s-parameters when the BST capacitor is set to 2.5pF. The HB antenna can cover the 1.7-2.7GHz frequency interval with a reflection coefficient below -6dB. The isolation between the two ports is almost always higher than 10dB, making a minimum of 10dB around 2GHz. As shown in Figure 62, this frequency region is where the strong coupling to the LB CE from the HB monopole is observed.

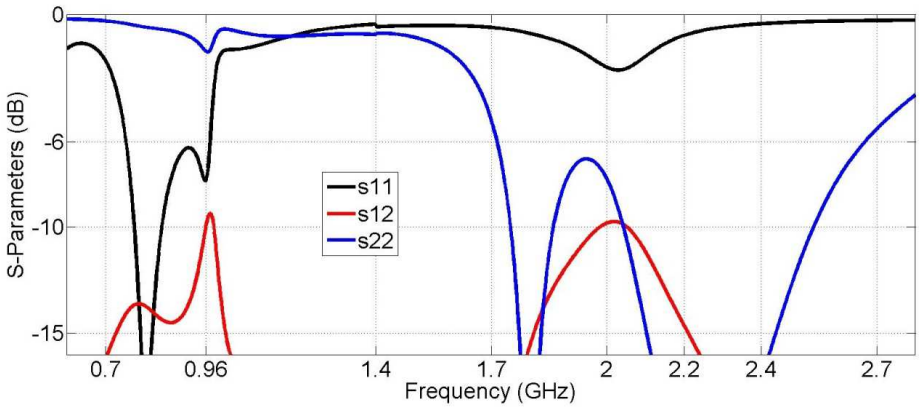

Figure 64 Simulated Reflection Coefficient for BST=2.5pF

The proposed antenna is currently under the manufacturing phase, which will be followed by the integration of the BST capacitor and the measurements to validate the simulation results.

3. CONCLUSIONS

In this chapter, three tunable antenna topologies have been proposed. Two of these antennas use MEMS switches to achieve band-switching between the LB (700-960MHz) and HB (1700-2700MHz), whereas the third antenna uses a BST tunable capacitor to tune the LB reflection coefficient.

The main difference between the two antenna using MEMS switches was the methodology of utilizing the switches. The first antenna uses two MEMS, to select between one of the MN branches and the second antenna uses a single MEMS to select between two driven strips. The simulation results have been validated with the measurements using manufactured passive prototypes for the first design and the antenna was shown to cover the target bands with a reflection coefficient below -6dB. For the second design, measurement results with both passive prototypes and real MEMS switches were presented.

In Section 1.3, a situation observed during the efficiency measurements of the antennas was investigated. A drop in the radiation efficiency was seen in both simulations and measurements, which is narrow-band and corresponds to the frequency regions where the parasitic element is excited capacitively in the HB. It was shown through simulated current distributions that the cause of this situation was the currents flowing in opposite directions on the meander line, which tend to create cancelling field in the far-field region of the antenna. Some modifications on the antenna topologies were successfully proposed to mitigate this effect.

Finally, an antenna design using a BST tunable capacitor was presented, that achieves tunability in the LB reflection coefficient. This antenna was a dual-feed structure where the HB antenna is separately-fed and is not affected by the changing capacitance value. It was shown through simulations that the frequency interval of 725-960MHz and 1.7-2.7GHz can be covered with a tunable capacitance ranging between 2.5-4pF, with an isolation higher than 10dB between the feeds.

CHAPTER III
THE HOLLOW COUPLING ELEMENT APPROACH

As previously mentioned in the Introduction part, coupling elements (CE) have been widely proposed in literature for mobile terminal antennas, to obtain a wide-band matching response using the space available for the antenna, which is typically electrically-small. In this scenario, the CE is used just as an exciter to induce the proper currents on the terminal ground plane, whose dimensions are generally close to a 0.25-0.3 free space wavelength in the frequency band of 700-960MHz. In this way, the quality factor of the antenna is significantly reduced thanks to the low-Q nature of the thick ground plane and a high bandwidth potential is enabled. Since they are inherently non-resonant, CEs need a matching network at the antenna feed, to be tuned to the desired operating frequency. The main drawback of using CEs for 4G/LTE standards is the necessity of MNs with a high number of components to achieve dual-band coverage which increases both the losses and the cost.

This chapter presents a new design, namely a modified version of the traditional plain coupling element approach, by removing the inner metal part of the CE. This way, a hollow structure is obtained and the space available inside the CE can be used to insert another antenna to cover other frequency bands. In terms of input impedance, negligible difference is observed in the LB, by making the CE hollow. Two antenna designs using the new approach are designed, optimized and presented to cover the 700-960MHz and 1.7-2.7GHz bands. Finally, a dual-antenna MIMO structure using the same technique is presented as an application example to operate in the LB frequency range.

1. THE HOLLOW COUPLING ELEMENT APPROACH

The proposed approach combining a non-resonant CE and a resonant antenna is presented in this section. The LB coverage is achieved using a 3D CE. The HB coverage is then achieved by integrating another antenna with a separate feed.

1.1. COMPARISON OF THE HOLLOW CE WITH A PLAIN CE

As previously mentioned, the traditional plain CE has been modified to obtain a more space-efficient structure with negligible performance trade-off. The main issue is to produce the same coupling behavior as the one produced with a plain element or more generally, to understand which section of a plain CE is important to couple to the PCB. This approach was first described for a single band CE with a 7mm height, covering only the LB 700-960MHz frequency range in the previous publications of the authors [1]. In [2], the HB antenna was inserted inside the hollow CE and the dual band coverage with good isolation was presented with simulations. Here, a further optimized CE layout in terms of occupied space (only 3mm height) is used to make a comparison between plain and hollow CEs in terms of impedance and bandwidth potential. For the comparison, the model given in Figure 65 have been used.

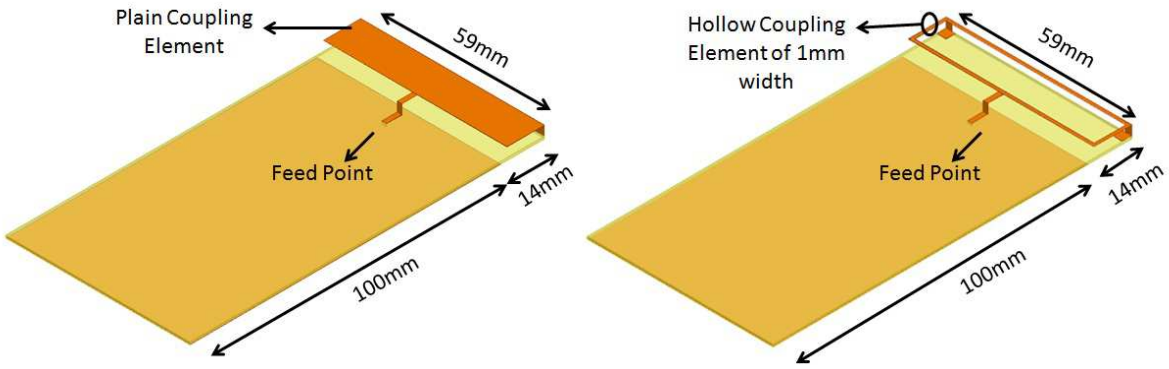

Figure 65 Antenna topologies used for the plain/hollow CE comparison

The plain CE consists of a rectangular metal sheet (59×14mm2) with 3mm height from the FR4 substrate. The feed of the CE is achieved through a vertical metal strip from the center of the PCB. The total PCB dimensions are 114×59×0.8mm^3 with a ground clearance of 14mm under the CE. For a fair comparison, all PCB dimensions and feeding location were kept the same for the hollow. The metal region inside the plain CE was removed to form the so-called hollow CE, leaving only a rectangular ring having a strip width of 1mm. The two CEs were simulated with the full wave electromagnetic simulator Ansoft HFSS. The simulated input impedance of the two CEs can be observed in Figure 66. The input impedance of the hollow CE shows minor deviation from the input impedance of the plain CE.

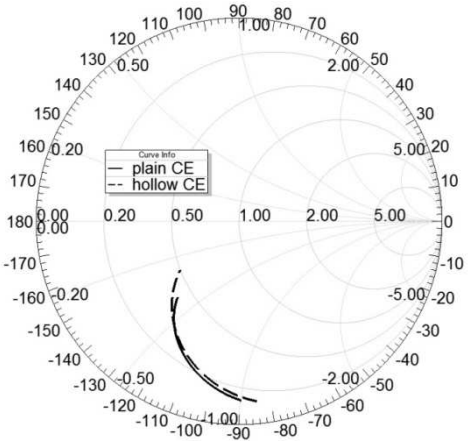

Figure 66 Input impedance of the plain and the hollow CEs (700MHz to 960MHz)

The currents induced on the system ground plane for the plain and hollow CEs can be observed in Figure 67. In both situations, the longitudinal mode (the fundamental) of the currents is induced almost at the same strength.

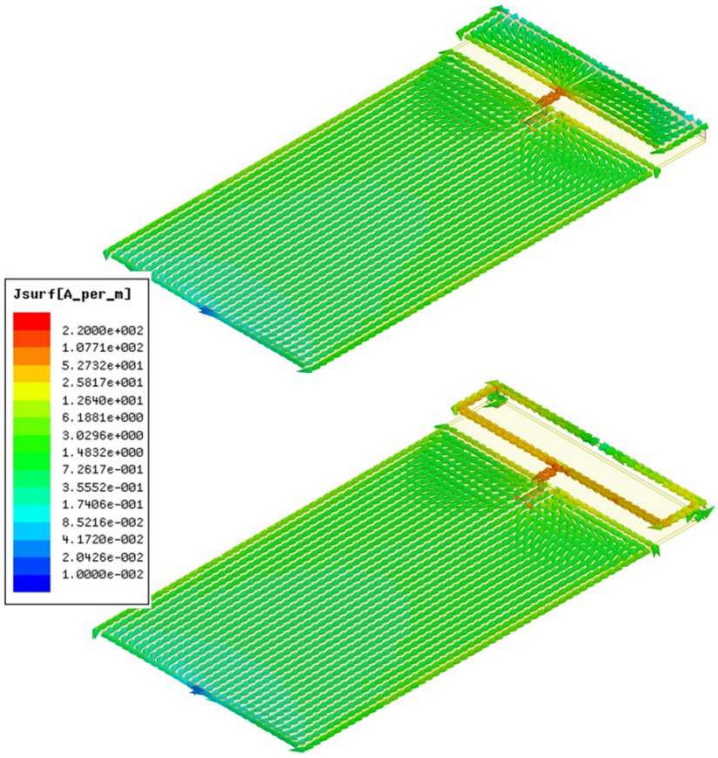

Figure 67 Comparison of the Ground Plane Currents (Plain CE on top, Hollow CE on bottom)

The E-field distribution under both CEs is observed in Figure 68. It can be told that fields under the hollow CE are weaker than the fields under the plain CE especially through the center of the hollow region. Using this fact, the HB antenna is proposed to be placed in this region, to get better port-to-port isolation.

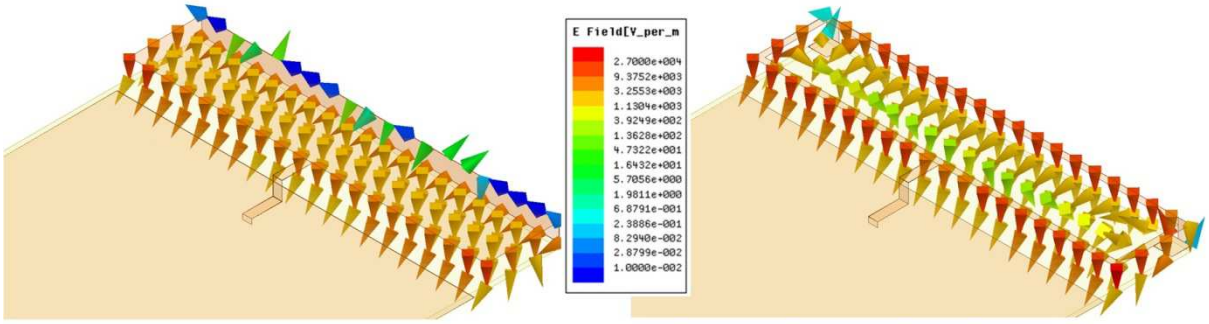

Figure 68 Comparison of the E-field Under the CEs (Plain CE on left, Hollow CE on right)

The bandwidth potential (BP) of the two CEs is compared with the help of the commercial software Optenni Lab. The BP is a realistic value computed from the input impedance of each CE (obtained from the full wave simulation) which is given for a certain number of matching components and a certain threshold for the reflection coefficient. At every frequency point f_0, the software generates a MN to match as much as possible frequency points around f_0 with a reflection coefficient below the threshold, chosen as -6dB here. The frequency interval around f_0 which gives a reflection coefficient below -6dB is given as the optimized BP (symmetrically around f_0). The BP obtained in this way is a realistic value compared to very optimistic theoretical values computed from the quality factor. As can be seen in Figure 69, the BP of the hollow CE is only slightly lower

(30MHz) than the BP of the plain CE in the LB, which proves again the equivalence between the plain and the novel hollow CE in terms of matching behavior. In the center of the 700-960MHz band, the obtainable BP is around 200MHz (for a -6dB reflection coefficient). It should be kept in mind that this BP value is obtained with a MN of two lumped components which is foreseen to be increased above the required 260MHz to cover the full LB by using more matching network components.

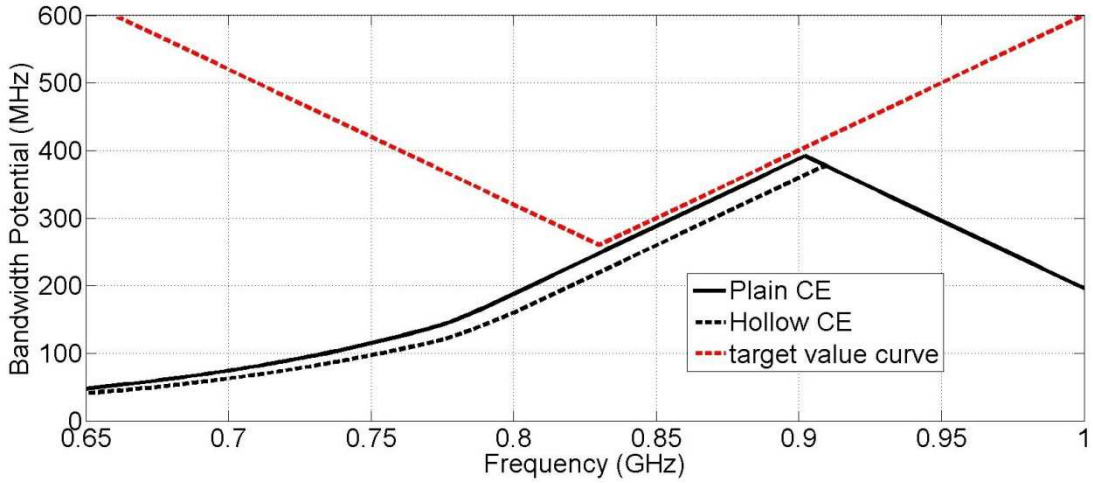

Figure 69 Bandwidth Potential Comparison of the Plain and Hollow CEs

1.2. INTEGRATION OF HIGH BAND ANTENNA WITHIN THE HOLLOW CE

As previously mentioned, the space gained by making the plain CE hollow can now be used to integrate a high-band antenna. For ease of manufacturing, it was decided to focus on a fully printed HB antenna design (directly on the FR4 substrate). Since it was observed that the E-field under the hollow CE was weaker through the center of the hollow region (Figure 68), the HB antenna was planned to be placed in this area to obtain high port-to-port isolation.

The optimized layout of the proposed antenna can be seen in Figure 70. The total PCB dimensions are 114×59×0.8mm^3, with a ground clearance region of 59×14mm^2 on one side of the PCB. A simple monopole is used for the HB coverage, placed 8.5mm away from the edge of the PCB. To tune the hollow CE as to cover 700-960MHz, a MN (seen in Figure 71) consisting of four lumped components was designed with the Optenni Lab software. The main objective of this MN is to get a reflection coefficient below -6dB for the hollow CE between 700-960MHz. There is also another functionality of the MN, which is to act as a band-stop filter in the HB frequency range to help in resisting the possible currents from the HB antenna to reach the LB antenna port. Very high isolation levels were possible using this strategy in the HB, so the matching response of the HB antenna was the primary goal when determining the exact location and orientation of the HB antenna.

After the circuit optimization of the MN, an additional full-wave optimization was performed to take into account the existing transmission lines between the SMD components and the vias connected to the ground plane.

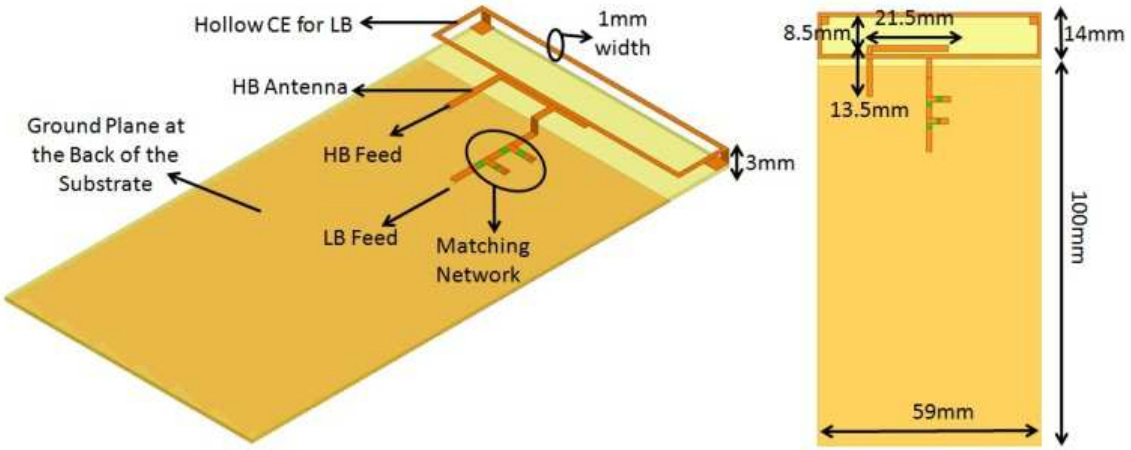

Figure 70 Simulation Model of the Hollow CE Antenna

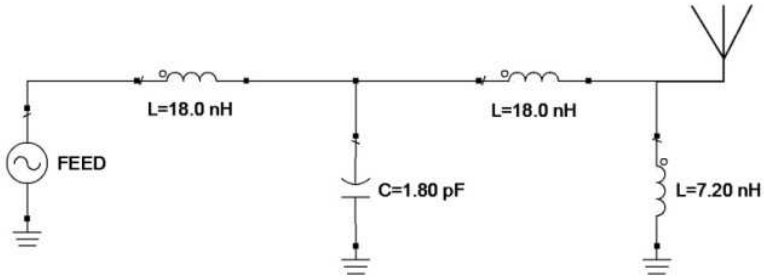

Figure 71 Matching Network used at the LB CE feed

The simulated input impedance of the LB antenna alone (without the HB antenna) with and without the MN can be seen in Figure 72, plotted from 700MHz to 960MHz. When the HB antenna is introduced, the S-parameters seen in Figure 73 are obtained. It can be seen that the target bands can be covered with a reflection coefficient below -6dB, except a small frequency range on the lower edge of the HB (1.7-1.75GHz). The port-to-port isolation is always higher than 9dB in the LB having a minimum value of 9.3dB at 740MHz. The port-to-port isolation is higher than 30dB in the HB.

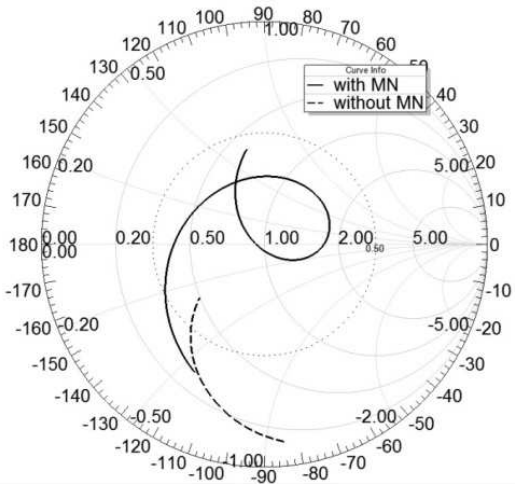

Figure 72 Simulated Input Impedance of the LB CE Alone (with and without MN)

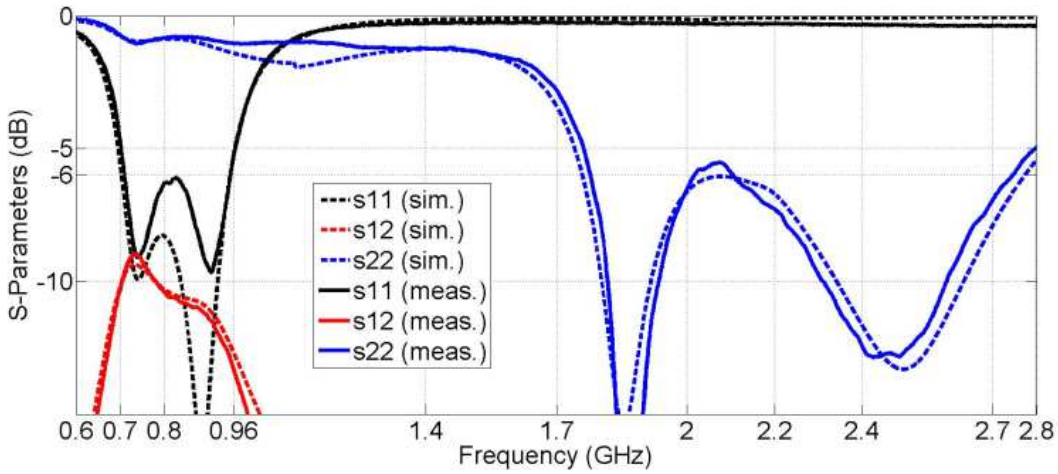

Figure 73 Simulated and Measured S-parameters of the Hollow CE Antenna

To investigate the role of the LB CE for the HB performance, the HB antenna was also simulated alone and with the CE. Figure 74 presents the simulated input impedance of the HB antenna (plotted between 1.7-2.7GHz) in these two cases. It is obvious that the wideband HB response is not due to the HB antenna alone. As can be seen from the input impedance shown in smith chart, an additional resonance in the HB is created by the coupling from the HB antenna to the LB CE. This coupling does not induce an isolation problem since the MN of the LB antenna is designed on purpose to provide a stop-band behavior from 1.7 to 2.7GHz. Proof is given in Figure 75, where the current distribution on the LB CE created by the HB antenna is observed at different frequencies. At 2GHz, it is seen that the currents on the HB antenna are weaker and the currents on the LB CE are stronger which suggests a high level of coupling. However, the current induced on the LB CE are shorted to the ground plane through the first shunt inductor (7.2nH) of the MN. In this way, the port-to-port isolation is kept high. If the currents at 2.3GHz are observed, it is seen that the HB antenna is strongly excited whereas the coupling to the LB CE is weaker.

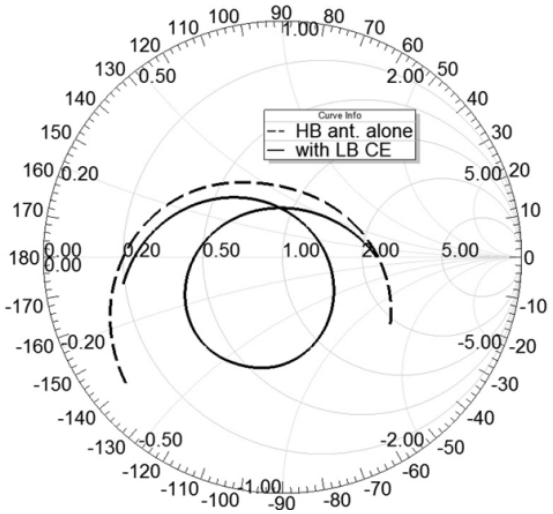

Figure 74 Simulated Input Impedance of the HB antenna alone and with the LB CE

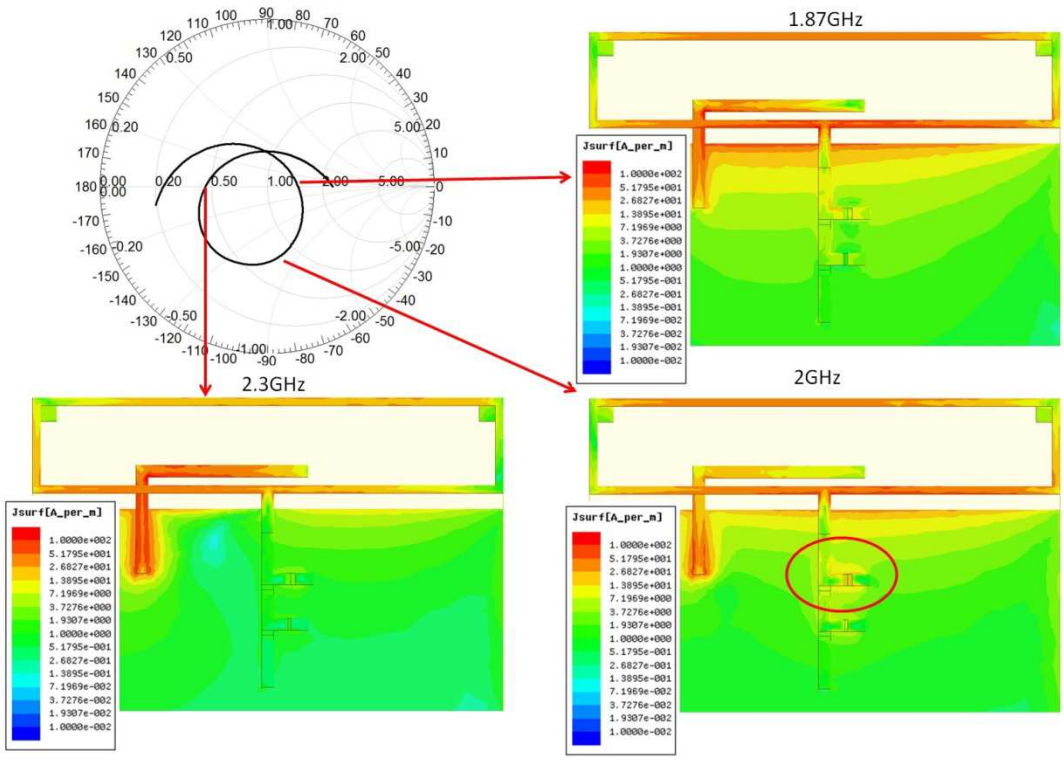

Figure 75 Current Distribution on the LB CE when the HB Port is Excited

1.2.1. Measurement Results

The proposed antenna was manufactured on FR4 substrate (Figure 76). As seen in Figure 73 and Figure 77, there is a fair agreement between simulated and measured S-parameters. The small differences between simulation and measurement are coming from the manufacturing tolerances in the 3D CE section and its orientation. The target bands are covered with a reflection coefficient below -6dB.

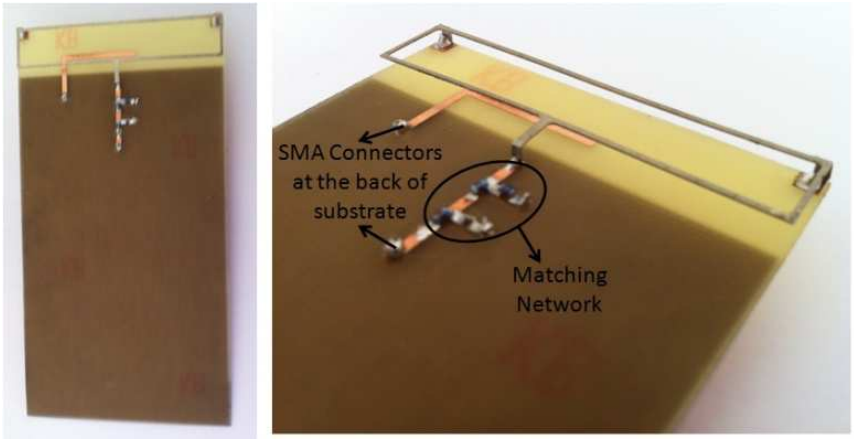

Figure 76 Manufactured Prototype of the Hollow CE Antenna

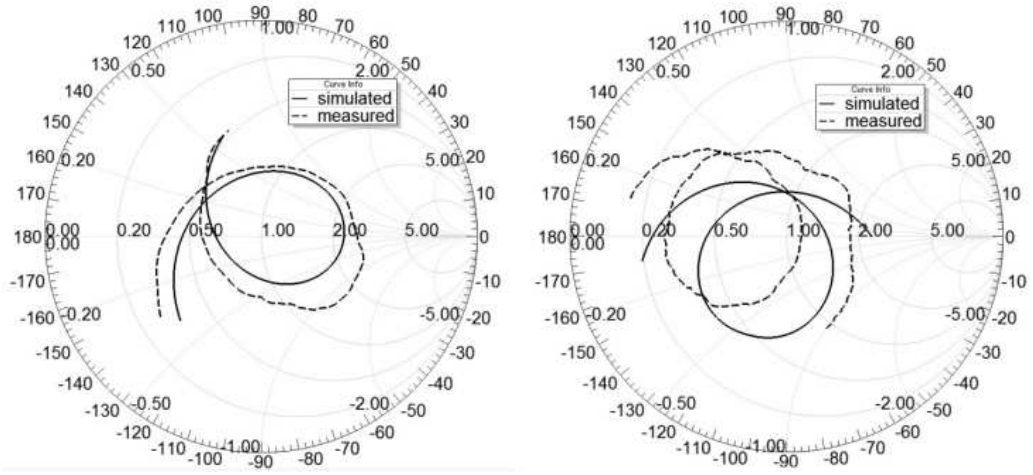

Figure 77 Simulated and Measured Input Impedance of the Hollow CE Antenna (LB on left, HB on right)

The total efficiency and the 3D gain patterns have also been measured in a Satimo Starlab Station. The total efficiency of the proposed antenna in LB and HB are presented in Figure 78 (the HB port is loaded by 50Ω when the LB efficiency is measured and vice versa). The measured total efficiency (including mismatch and component losses) in LB varies between -6dB and -2dB and between -4dB and -1dB in HB. When the simulated and measured 3D gain patterns are compared, a fair agreement is observed (Figure 79). In LB, a dipole-like radiation is observed (as expected) as the main radiator is the currents induced on the ground plane by the CE. Both in LB and HB, no wide-angle deep nulls are seen in the radiation patterns which is an important aspect for mobile phone communications where the base-station orientation is never known in advance.

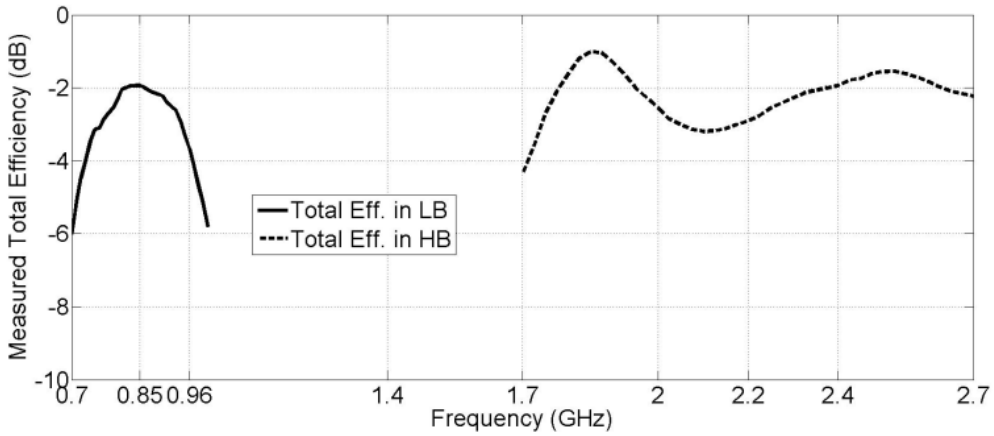

Figure 78 Measured Total Efficiency of the Hollow CE Antenna

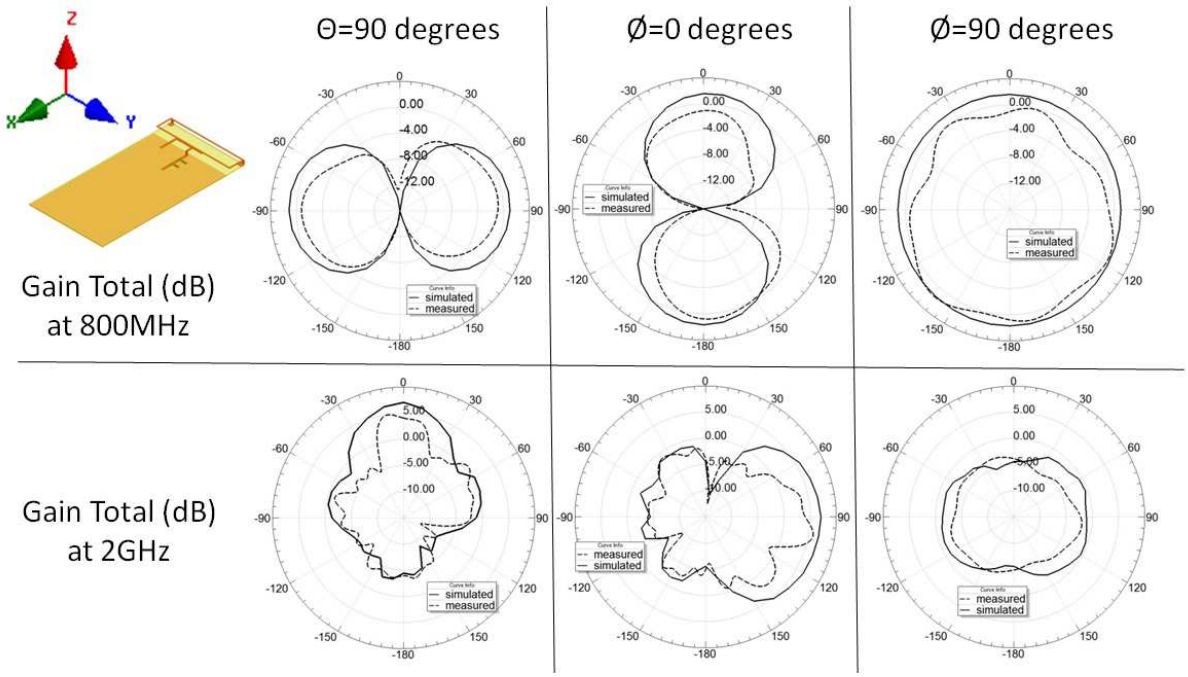

Figure 79 Simulated and Measured Total Gain Patterns for Different Cut Planes

1.3. PRINTED COUPLING ELEMENT ANTENNA

1.3.1. Antenna Design

The dual-feed antenna approach presented in Section 1.1 for a 3mm height 3D hollow CE was then enhanced to design an antenna-structure totally printed on the FR4 substrate for the ease of manufacturing and low cost purpose. The main difference with the previous antenna structure is the location of the printed HB antenna on the FR4 substrate. Since it was not possible to integrate the HB antenna inside the printed CE, it was placed on the left side of the PCB where the E-fields were found to be the weakest in simulations. The PCB and ground plane dimensions were set the same as the previous antenna structure (Figure 80). The dimensions of the hollow CE were set as 59×4mm2 with a strip width of 1mm. Moreover, a two-component MN was found to be necessary at the HB antenna port.

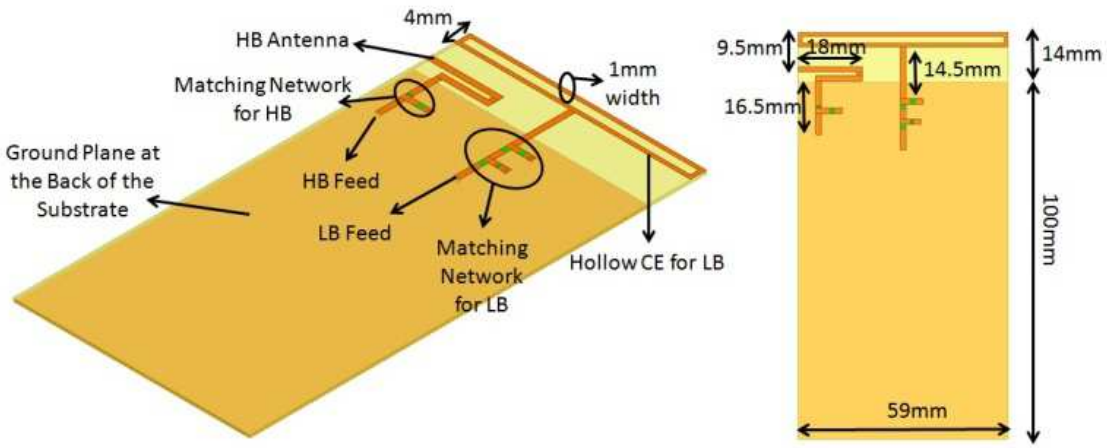

Figure 80 Simulation Model of the Printed CE Antenna

The effect of hollowing the printed CE instead of using a printed plain CE was investigated (Figure 81). Figure 82 shows a comparison of the bandwidth potential for the plain and hollow printed CEs, with the same dimensions. It was seen that making the CE hollow enables to cover an extra 25MHz around the center of the target LB. This is mainly due to the ring shape (loop) of the hollow CE which provides an inductive effect on its input impedance.

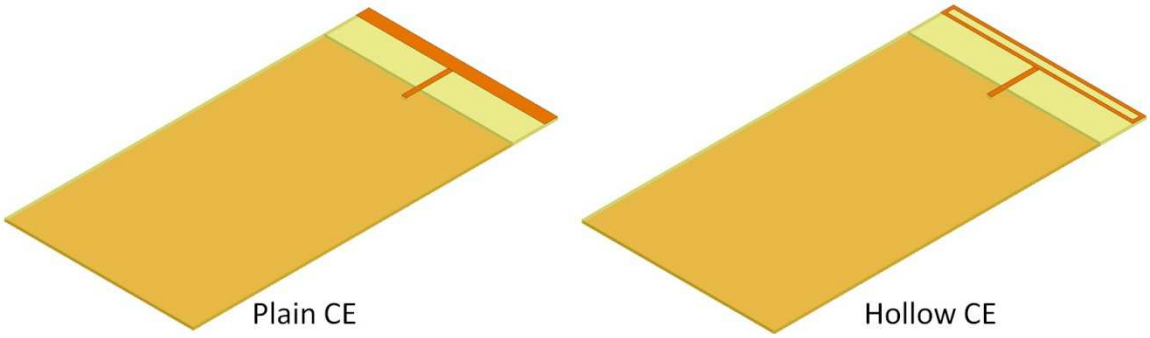

Figure 81 Plain and Hollow CE Geometries Used for Comparison

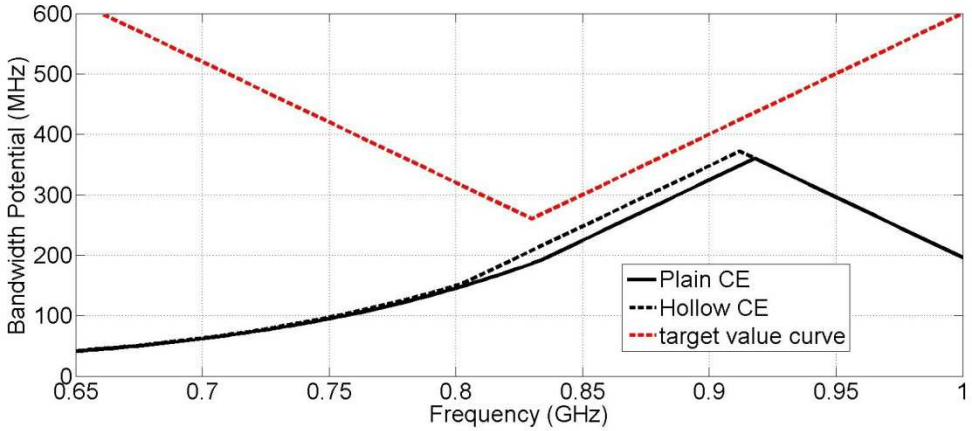

Figure 82 Comparison of Bandwidth Potentials for Plain and Hollow Printed CE

As seen in Figure 83, the real part of the impedance increases and the magnitude of the imaginary part decreases when the CE is made hollow. The e-field distribution between the hollow CE and the ground plane at 750MHz is plotted in Figure 84. The fields are the strongest close to the corners of the hollow CE and decreases as we move away from the CE.

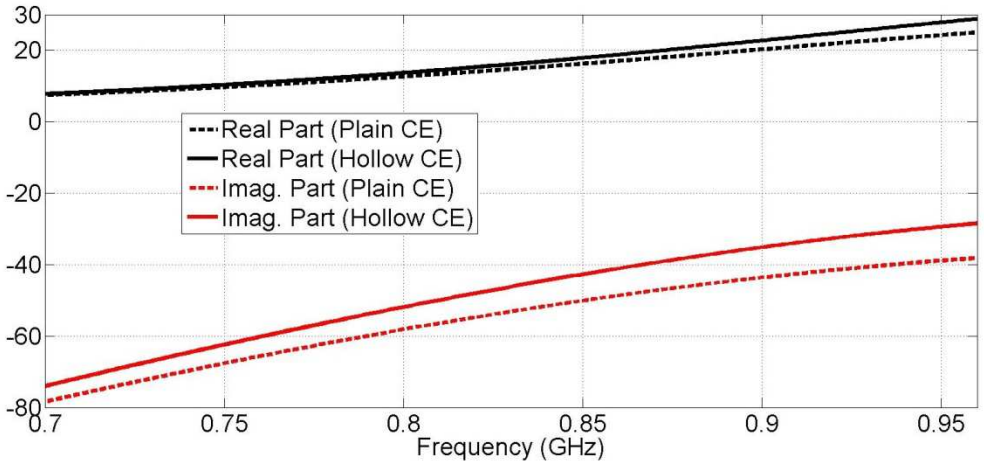

Figure 83 Comparison of Input Impedance for Plain and Hollow Printed CE

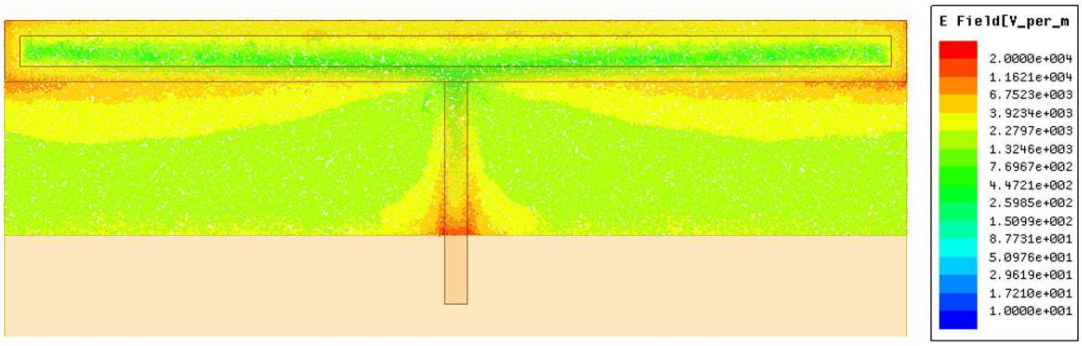

Figure 84 E-Field Distribution at 750MHz for Hollow Printed CE

The MNs for both LB and HB antenna ports were designed with Optenni Lab software (Figure 85). For the optimization of the LB antenna MN, it was intended to have a low reflection coefficient in the LB and a band-stop behavior in the HB. The same goals have been evaluated for the HB, having a stop-band in the LB. The component values were then fine-tuned with the full-wave electromagnetic simulator taking into account the linking transmission lines and vias.

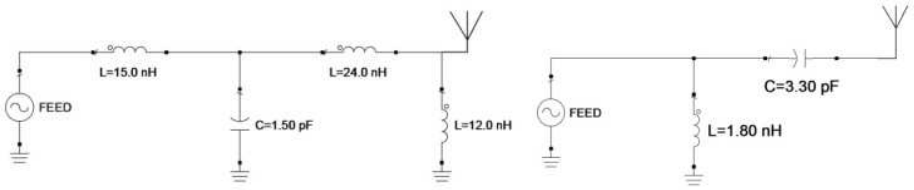

Figure 85 MN Topologies for the Printed CE Antenna (LB on left, HB on right)

The simulated input impedance of the printed CE alone can be seen in Figure 86 with and without the MN. The simulated S-parameters for the whole structure including the HB antenna can be observed in Figure 87. The target frequency bands are covered with a reflection coefficient below -6dB except the frequency interval between 700 and 720MHz. The achieved isolation level is higher than 23dB through both bands which is a consequence of both the antenna placement and the band-stop behavior of the two MN's.

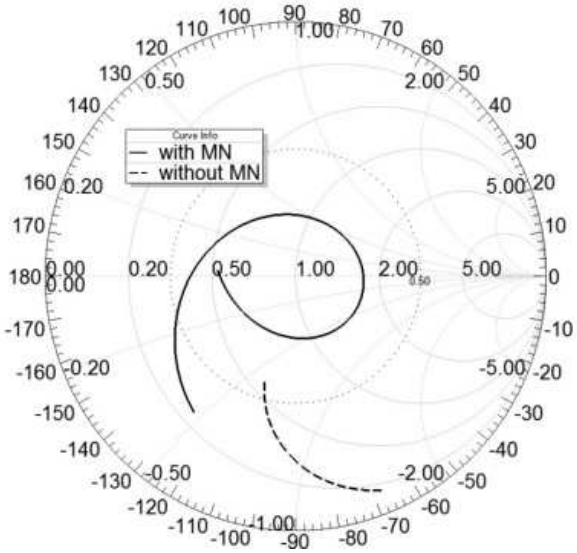

Figure 86 Simulated Input Impedance of the Printed CE Alone (with and without MN)

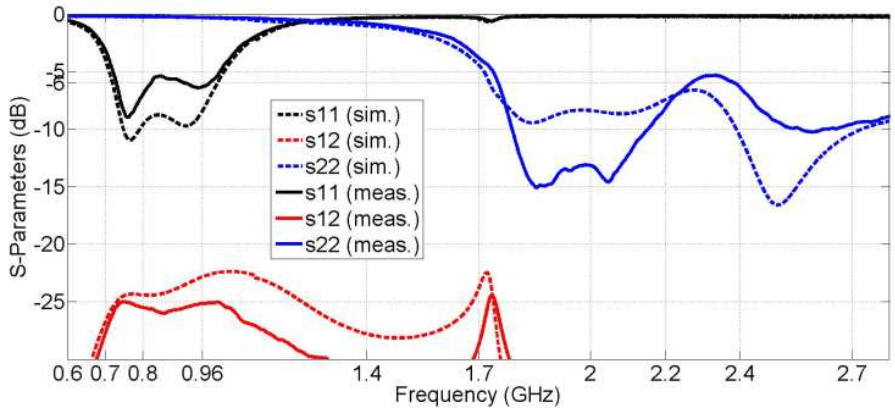

Figure 87 Simulated and Measured S-parameters of the Printed CE Antenna

To explain the wideband behavior of the HB antenna, its input impedance is plotted alone and also when the printed CE is introduced (Figure 88). Additional resonances are created from the coupling between this HB antenna and the LB CE. For instance, the HB antenna is strongly excited at 1.8GHz (Figure 89) whereas at 2.5GHz, the excitation is lower with a stronger coupling with the LB CE. Although there exists some coupling between both antennas at different frequencies, a high isolation is still maintained with the help of the band-stop characteristics of the MNs.

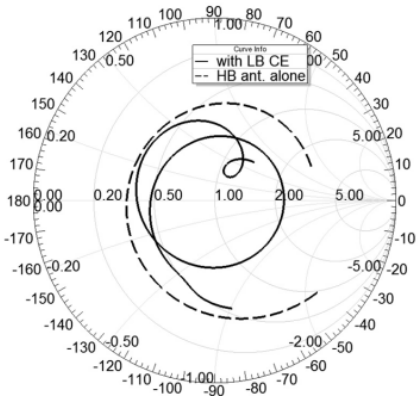

Figure 88 Simulated Input Impedance of the HB antenna alone and with the Printed CE

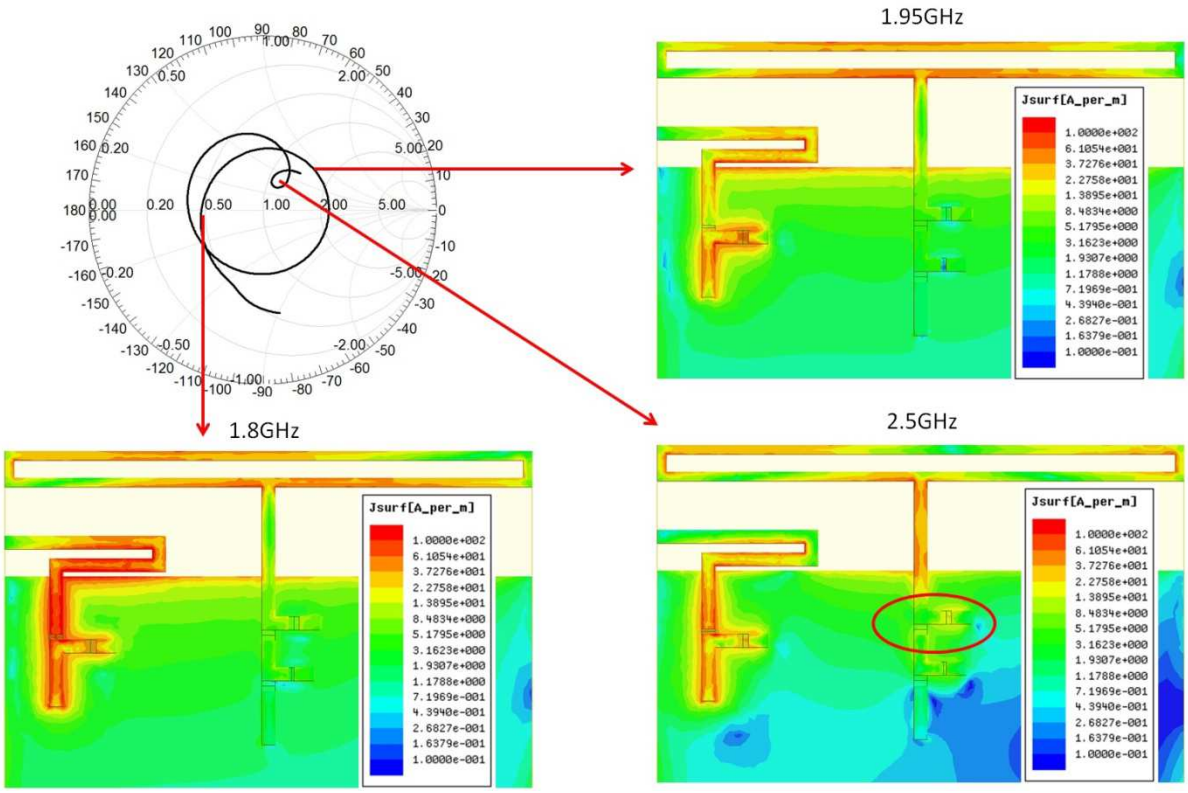

Figure 89 Current Distribution on the Printed CE when the HB Port is Excited

1.3.2. Measurement Results

The printed antenna structure has been manufactured on FR4 substrate as seen in Figure 90. The comparison of the simulated and measured S-parameters can be seen in Figure 87 and on smith chart in Figure 91. There is a fair agreement between the simulated and measured results. The proposed printed antenna can cover the target bands with a measured reflection coefficient below -6dB except the frequency interval of 700-720MHz and also a small overshoot up to -5.5dB around 850MHz.

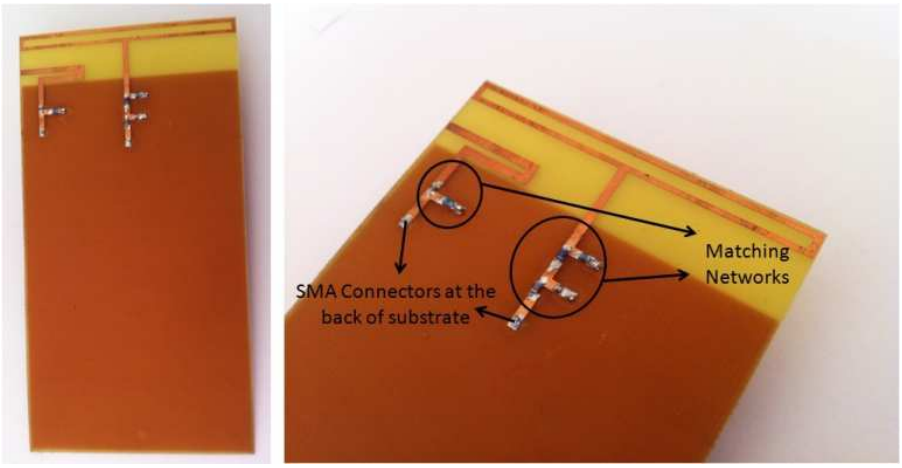

Figure 90 Manufactured Prototype of the Printed CE Antenna

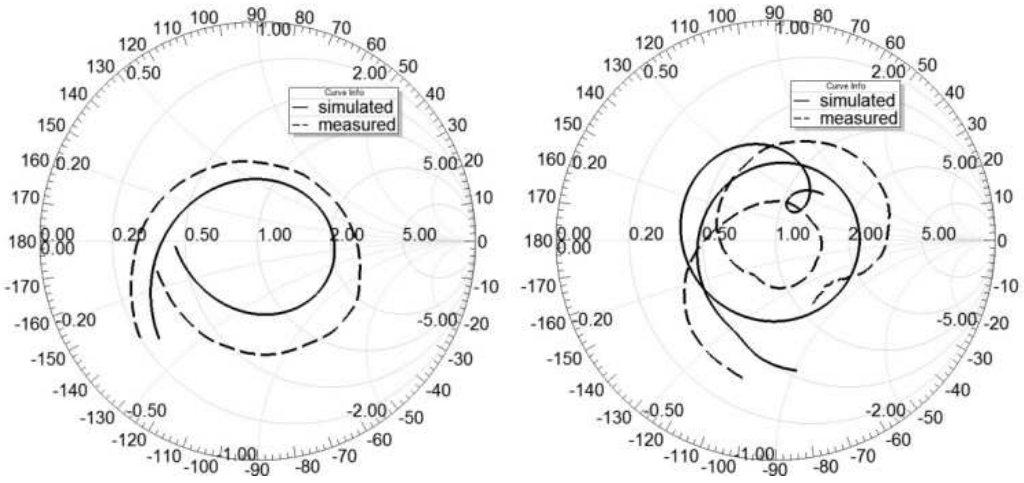

Figure 91 Simulated and Measured Input Impedance of the Printed CE Antenna (LB on left, HB on right)

The total efficiency was measured to vary from -5dB to -1.5dB in the LB and from -4dB to -1.2dB in the HB. The simulated and measured 3D gain radiation patterns are also in good agreement as seen in Figure 93.

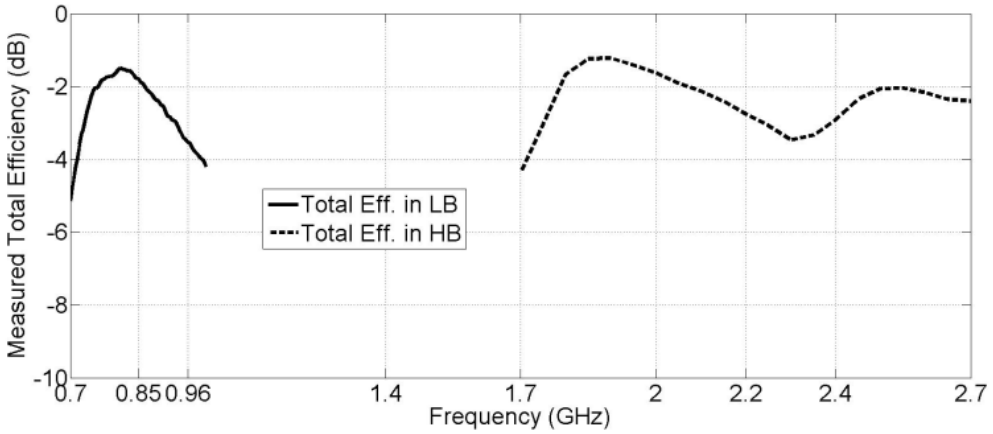

Figure 92 Measured Total Efficiency of the Printed CE Antenna

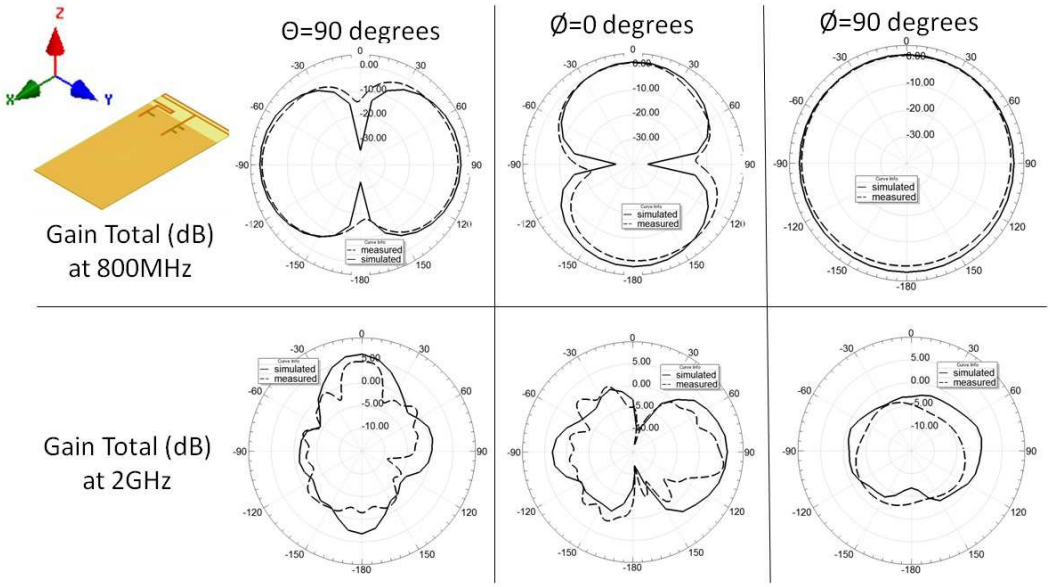

Figure 93 Simulated and Measured Total Gain Patterns for Different Cut Planes

2. TWO-ELEMENT MIMO ANTENNA USING HOLLOW COUPLING ELEMENTS

The newly proposed hollow CE was evaluated in a dual-MIMO antenna scenario as an application example. The target frequency band is 700-960MHz (for a reflection coefficient below -6dB) for both antenna structures. It is aimed to have an isolation better than 10dB between the feeds and an ECC (envelope correlation coefficient) lower than 0.5. Similar studies have been done like in [3-5] to achieve MIMO operation in mobile terminals. In [3], two meandered monopoles were placed on the short edge of a mobile terminal PCB with a hybrid coupler at the feeds to improve isolation. With this antenna, good matching bandwidth and good isolation was achieved only in a very limited bandwidth (between 705-725MHz). A similar structure having two meandered monopoles is also presented in [4], using a suspended line to increase isolation. This antenna is also narrowband, with MIMO operation only in LTE band-13 (746-787MHz). In [5], first an active antenna structure is proposed to cover 700-960MHz with four different states and then the MIMO performance is investigated with combinations of active-passive antennas.

As widely known, it is a challenging problem to obtain a MIMO antenna with low ECC (envelope correlation coefficient) and high isolation for a typical mobile terminal in whole LB (700-960MHz), where the antenna is electrically small and most of the radiation comes from the excitation of the ground plane. Due to this fact, it is hard to obtain a high level of isolation between the two antenna feeds. Although a good isolation in terms of S_{21} is obtained, it is not sufficient to get an acceptable Envelope Correlation Coefficient (ECC) since the radiation patterns should also be different for the two antennas. For this purpose, two identical hollow CEs were placed on the two corners of the short edge of the PCB as in [6]. In this way, a good ECC from the 3D pattern point of view can be expected. To increase the port-to-port isolation between the two CEs, the neutralization technique, which is explained in [7] was used.

2.1. THE LTE MIMO ANTENNA MODEL

The simulation model of the antenna can be observed in Figure 94. An FR4 substrate of 0.8mm thickness was used as the PCB. The height of the antenna is 4.2mm above the substrate. The CEs on each corner are identical, each with a MN of 4 SMD components at the antenna feeds (Figure 95). To increase the inductive effect of the neutralization line, an inductor of 100nH was used in the middle of this line.

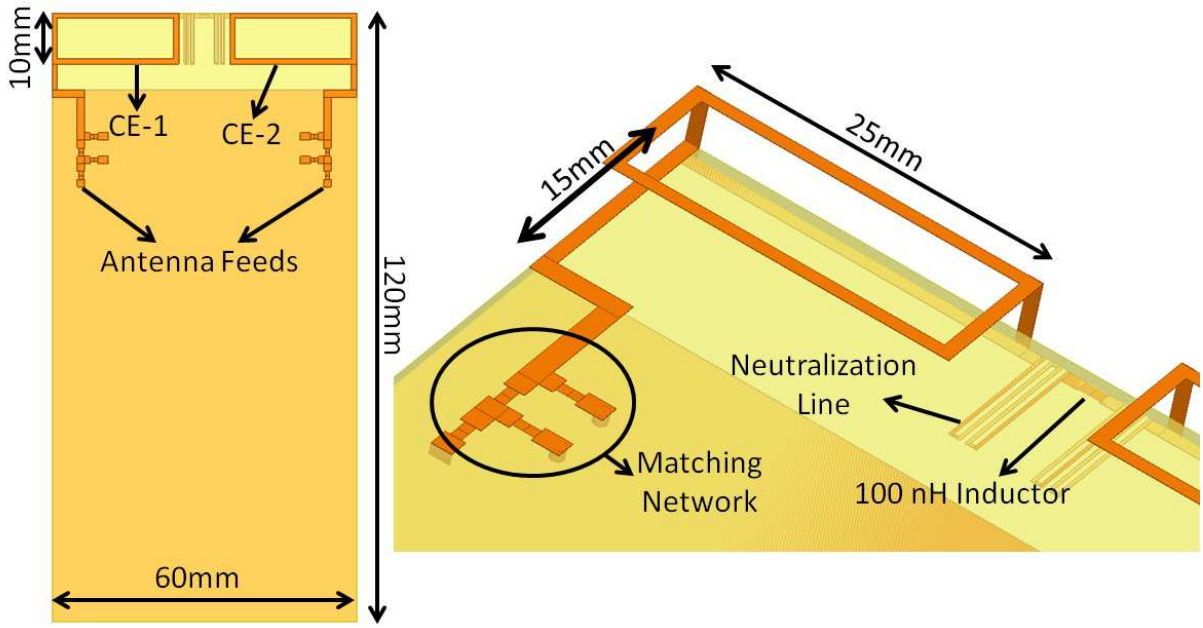

Figure 94 The LTE MIMO Antenna Simulation Model

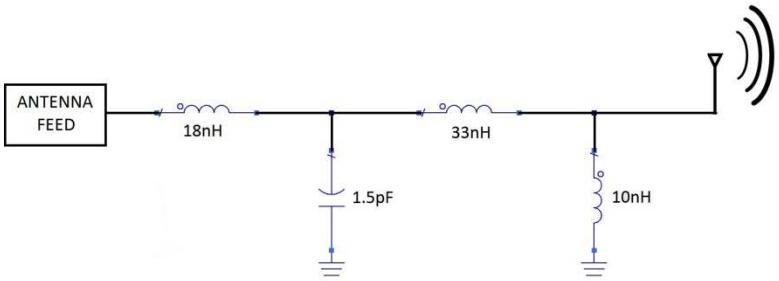

Figure 95 The MN for LTE MIMO CEs

To illustrate the effect of the MN on the input impedance, simulation results have been plotted in Figure 96, between 700-960MHz. As shown with the red curve, the single CE is far from being matched without the MN. The MN (optimized using Optenni Lab software), creates an optimally overcoupled response to obtain the highest possible matching bandwidth.

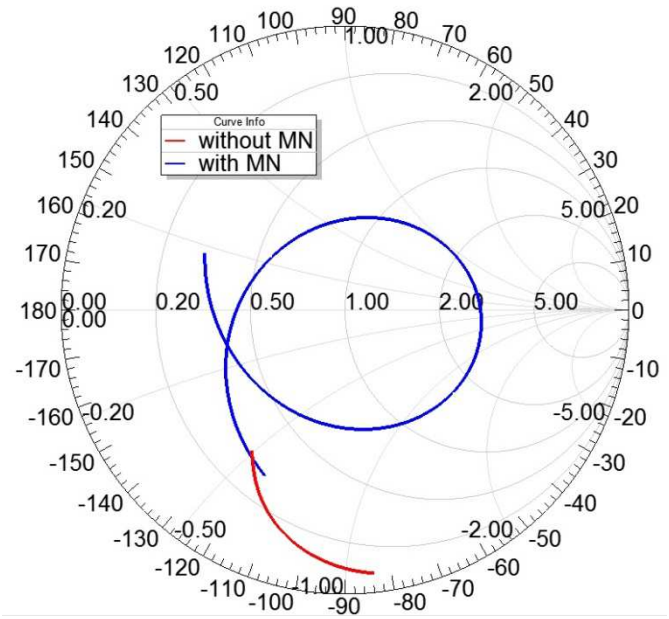

Figure 96 Input Impedance of a Single CE with/without MN

Figure 97 presents the currents on the ground plane when a single CE is placed on top left corner of the PCB. It can be seen that the main direction of current flow on the ground plane is through the long edge of the ground plane, continuing the short edge and having the lowest value close to the corner. The currents flowing on the short edge introduce an offset in the radiation pattern as seen in Figure 98 (at 800MHz). The pattern is different from regular patterns in the sense that it is slightly rotated through the diagonal direction of the PCB, which is an interesting feature to obtain a reasonable ECC value when the second CE is added.

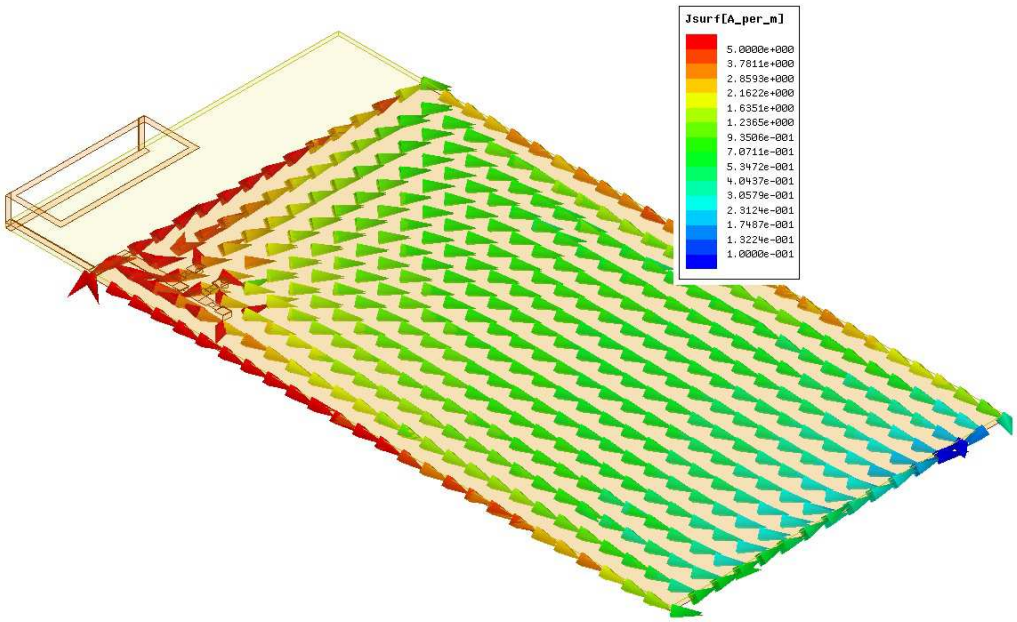

Figure 97 Current Distribution on the Ground Plane of a Single CE with MN

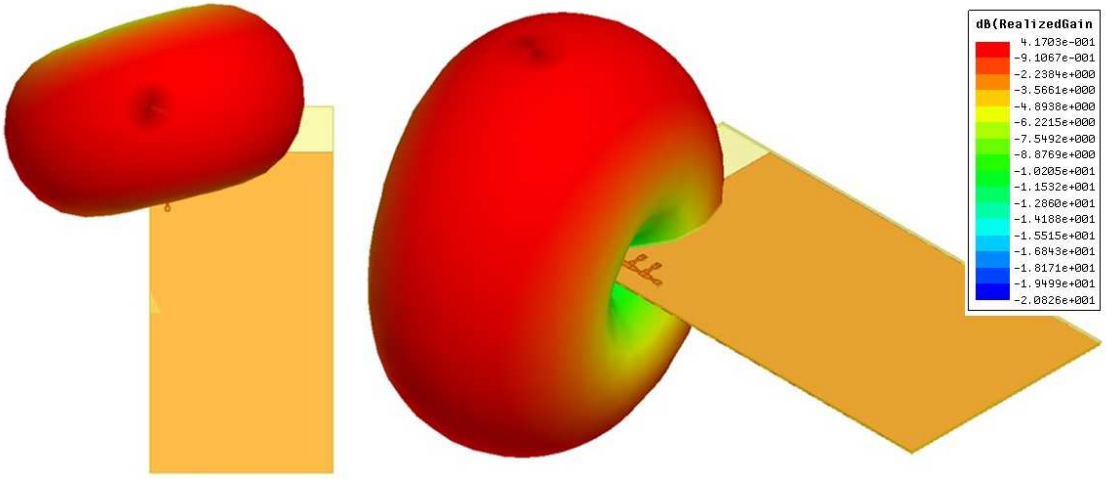

Figure 98 3D Radiation Pattern of a Single CE placed at the Top Left Side of the PCB

Another very important point for this antenna is the neutralization line added between the two CEs, connecting them inductively to increase the isolation between their feeds. The main idea behind this technique is to create an additional inductive path (to the existing capacitive coupling path). In this way, the currents between the two antennas are forced to flow somewhere else than the non-excited feed. Detailed description of the methodology is not given here for the sake of brevity. The antenna (consisting of both CEs on each corner with MNs) was simulated both with and without the neutralization line and the results are presented in Figure 99. The isolation is poor in the absence of the neutralization, falling down to 4.5dB around 720MHz. After the neutralization line is introduced, a significant improvement is seen in the isolation, being better than 10.2dB through the target band (30% bandwidth). The simulated reflection coefficient for the CEs (with MNs) is below -6dB between 740-940MHz.

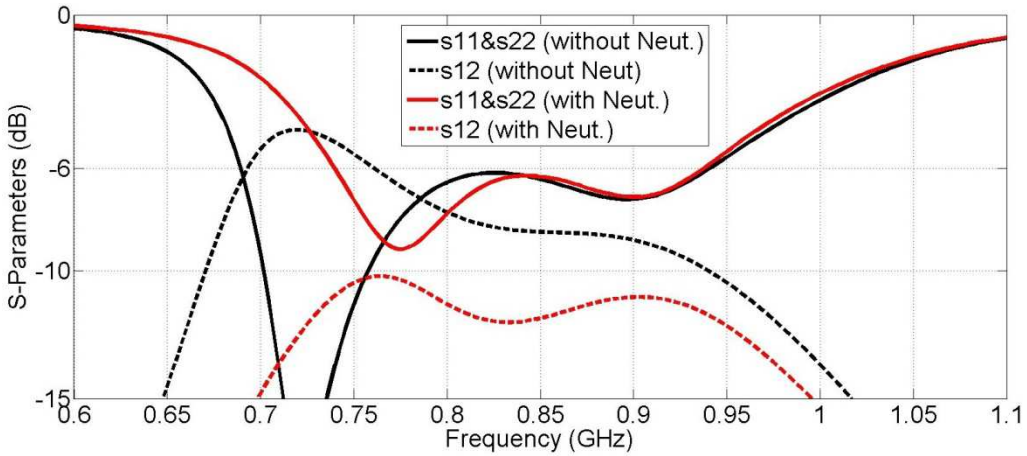

Figure 99 Effect of the Neutralization Line on Simulated S-Parameters

The simulated 3D radiation patterns for the whole antenna system (at 800MHz) can be observed in Figure 100, where the pattern for CE-1 is plotted when the other port is matched and vice versa. The rotated dipole type patterns, symmetrical along the longitudinal axis, for the two CEs verify the particular excitation of the ground plane. It produces pattern diversity which is of particular interest for low ECC.

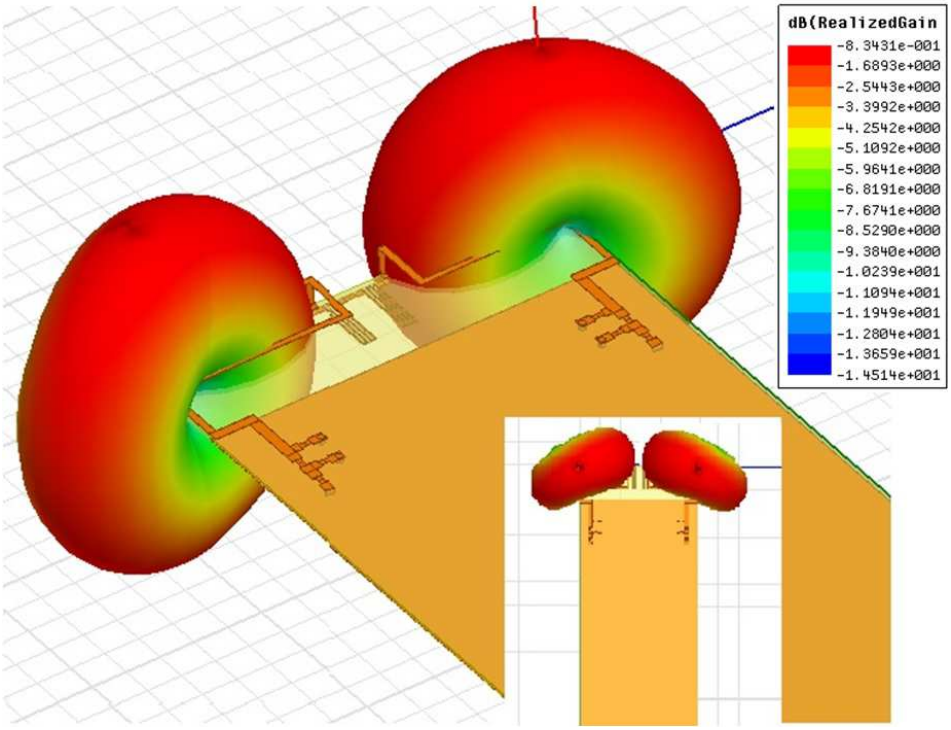

Figure 100 3D Radiation Pattern of Dual CE Antenna

2.2. MEASUREMENT RESULTS OF THE LTE MIMO ANTENNA

The proposed antenna has been manufactured on FR4 substrate (Figure 101). The S-parameter measurements have been performed, whose results are presented in Figure 102. A fair agreement can be observed between simulation and measurements. The frequency region between 740-950MHz can be covered with a reflection coefficient below -6dB and the isolation between the two ports is always higher than 11dB in the measurements. From the best knowledge of the authors, this isolation level was not achieved over such a broad band for LTE mobile phones.

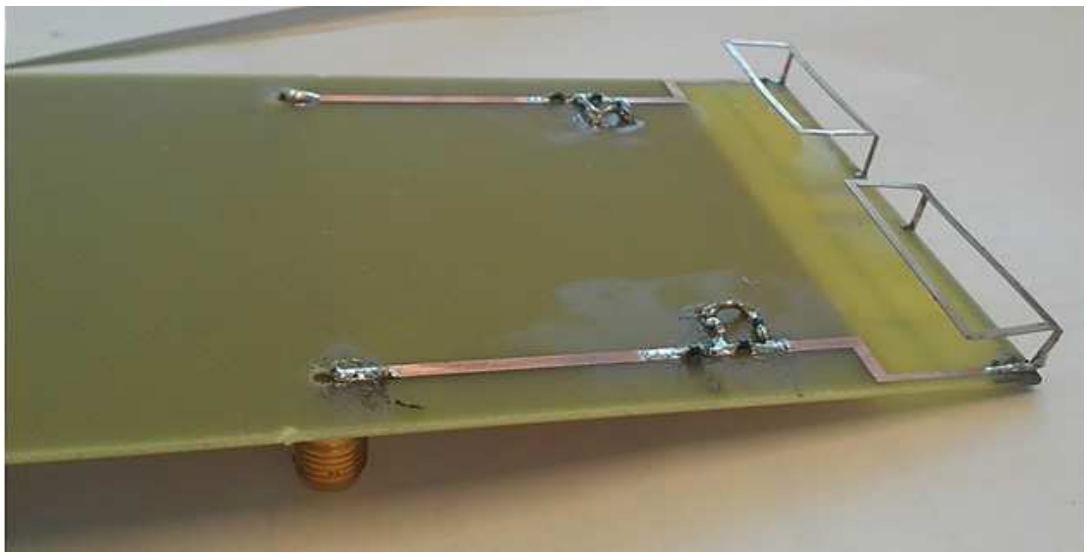

Figure 101 Manufactured MIMO Antenna Prototype

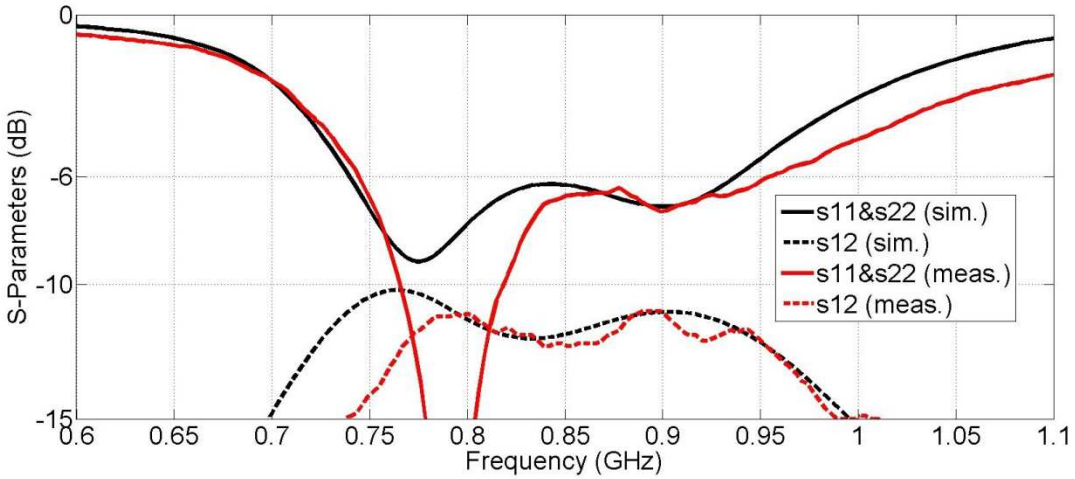

Figure 102 Simulated and Measured S-Parameters of the MIMO Antenna

The total efficiency of the MIMO antenna system was measured in a Satimo Starlab station, where the unmeasured antenna port is terminated with a matched load. The two CEs give similar performance in terms of efficiency so the result of only one CE is presented in Figure 103. The antenna has a measured total efficiency between -6dB and -4dB in the coverage band.

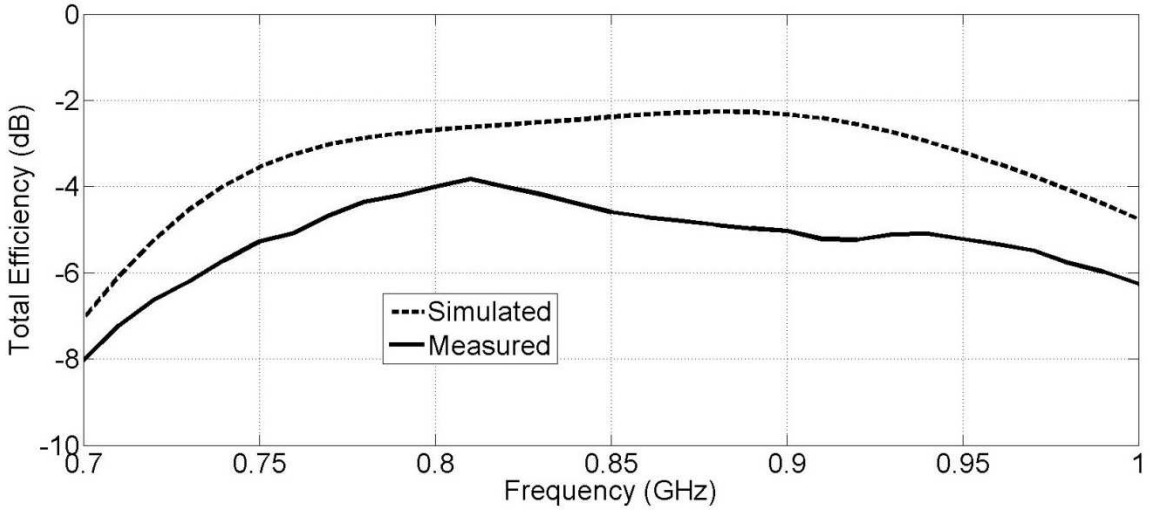

Figure 103 Simulated and Measured Total Efficiency of the MIMO Antenna

As widely known, there are two formulas used for the calculation of the envelope correlation coefficient of MIMO antenna systems. The first one presented in equation-1 uses the S-parameters of the two antennas whereas the second one (equation-2) uses the 3D complex radiation pattern. Although much simpler to calculate, Equation-1 is not suitable in this study since it may give misleading results due to the lossy antennas. For this reason, equation-2 (for an isotropic propagation environment) was used to calculate the ECC.

$$\rho_e = \frac{|s_{11}^{*}.s_{12}+s_{21}^{*}.s_{22}|^2}{(1-|s_{11}|^2-|s_{21}|^2)(1-|s_{22}|^2-|s_{12}|^2)} \qquad \text{Equation-1}$$

$$\rho_e = \frac{\left|\iint_{4\pi} F_1(\theta,\phi)^*.F_2(\theta,\phi)d\Omega\right|^2}{\left(\iint_{4\pi}|F_1(\theta,\phi)|^2 d\Omega\right).\left(\iint_{4\pi}|F_2(\theta,\phi)|^2 d\Omega\right)}$$ Equation-2

The comparison of the simulated and measured ECC using the radiation patterns is given in Figure 104. The agreement between simulation and measurement (complex radiation patterns have been recorded with the SATIMO station) seems very good. The measured ECC turned out to be below 0.5 (a generally accepted value for mobile terminals) between 765MHz and 950MHz which contains most of the coverage band. The MIMO antenna system is suitable for MIMO applications in mobile terminals, keeping in mind that other metrics like diversity gain and mean effective gain should also be measured.

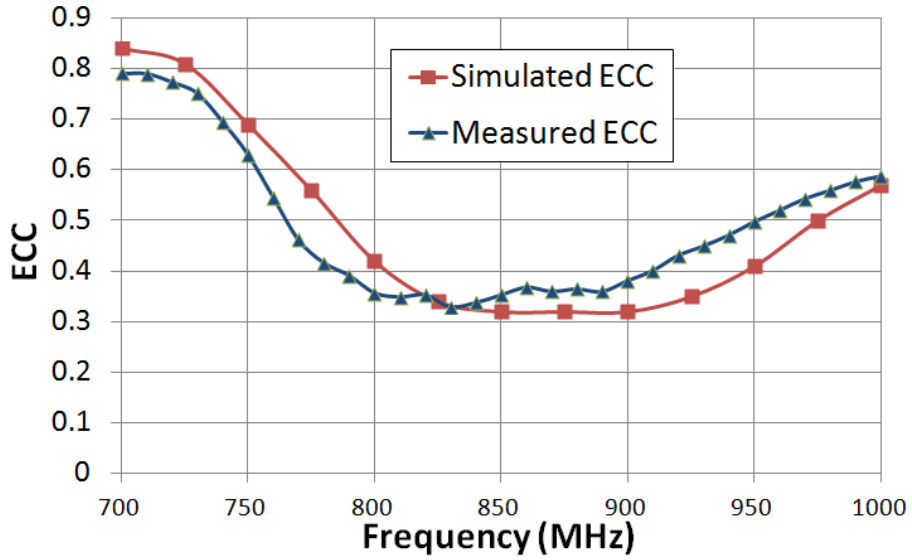

Figure 104 Simulated and Measured ECC of the MIMO Antenna

3. CONCLUSION

A novel approach using CEs for 700-960MHz and 1.7-2.7GHz coverage in mobile terminals was presented in this chapter. The approach consists of making the plain CE hollow by removing the metal plate inside and leaving a metal strip of around 1mm. In this way, a space efficient layout is obtained with weaker E-fields inside the hollow region. This space is then used for inserting a HB antenna separately fed with a high isolation between the feeds. A comparison between plain CE and hollow CE was first presented showing the negligible difference in terms of bandwidth potential performance.

The approach was then evaluated with a CE of 3mm height to cover the 700-960MHz frequency band. A monopole antenna was inserted inside this hollow CE on the substrate and it was shown that the whole target band can be covered with this dual feed structure. Another antenna was proposed in section 1.3, using again a dual-feed topology but this time the CE was also printed directly on the substrate.

Finally, in section 2, the CE idea was applied to obtain MIMO performance in the LB, using two CEs situated on the two corners of the PCB. With this layout, specific currents of the ground plane were excited for both CEs, enabling a level of default isolation. To further improve the isolation, the

neutralization line technique was applied to the CEs. The S-parameter and ECC measurements were performed and presented for the MIMO antenna.

It was shown in this chapter that it is possible to obtain the coverage of 4G communication standards in a mobile terminal with coupling element antennas. The disadvantage of the prototypes presented here can be the 3D structure without any supporting materials. This might lead to some manufacturing errors in different prototypes of the same antenna, due to tolerances. For this reason, antenna structures with a different manufacturing technology will be addressed in the next chapter, which will be capable of supporting 3D shapes for antennas.

CHAPTER IV
SINGLE FEED ANTENNAS ON LDS TECHNOLOGY

This chapter presents two antenna designs which are realized on plastic material using the Laser Direct Structuring (LDS) technology. Both of these antennas utilize the parasitic strip approach (presented in Chapter II) for bandwidth enhancement. The first antenna to be presented covers the low-LTE and UMTS frequency bands of 700-960MHz and 1.7-2.2GHz, while the second antenna can cover the same bands also including the WLAN2400 and LTE2500 bands (i.e. 700-960MHz and 1.7-2.7GHz in total).

A novel point here is the realization of the antennas using Laser Direct Structuring (LDS) technology which offers more freedom in terms of antenna layout and also enables the utilisation of the available space more efficiently. As also described in [1], this process uses a thermoplastic material which has already been doped with a metal-plastic additive(Figure 105-a). A laser beam then tracks the surface of the material, according to the shape of the traces intended on it(Figure 105-b). In this way, a microscopically rough surface is created, forming the nuclei for the metallization step(Figure 105-c). Finally, the metal traces are formed by putting the laser activated material in the electroless copper baths(Figure 105-d). Using this technology, a high degree of freedom is obtained in terms of the metallization shape.

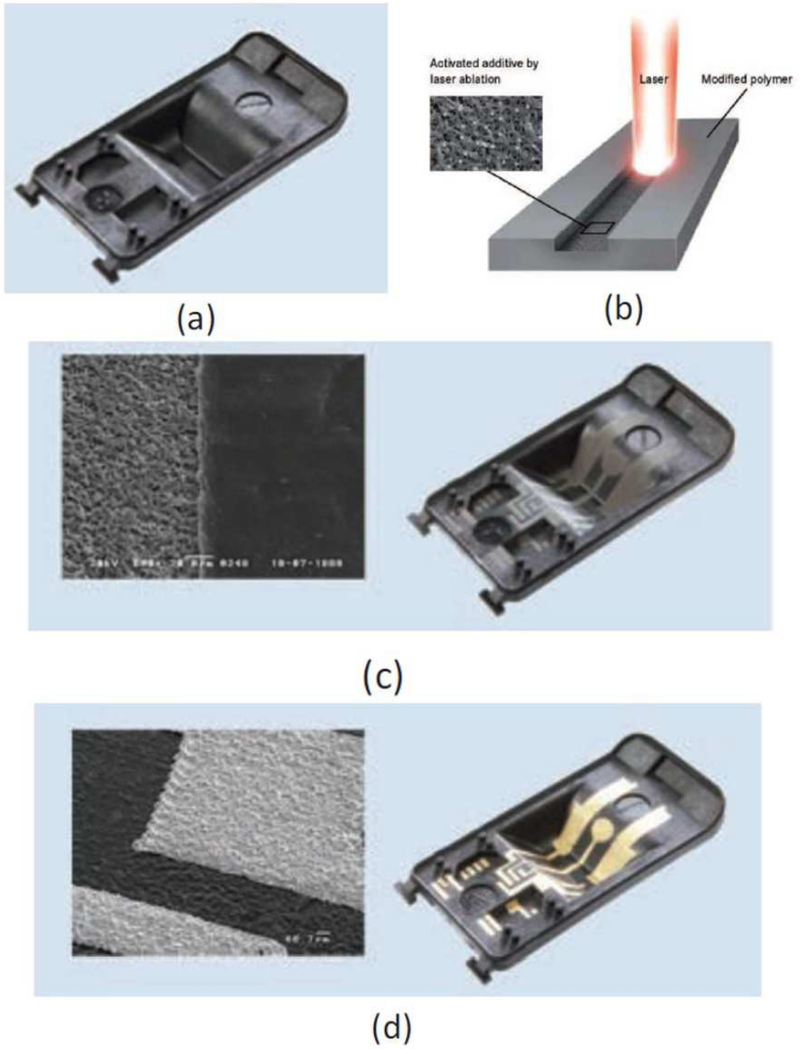

Figure 105 LDS Manufacturing Process

As also mentioned in the Introduction part, many antennas using parasitic elements for LTE/4G frequency bands have been proposed[2-5]. The common property of these antennas is their

relatively complex geometry, which might make the antenna performance sensitive to manufacturing tolerances. Here, the main target is to simplify the geometry of the antenna as much as possible by introducing a matching network having few number (targeted as less than 4) of SMD components.

1. LOW-LTE AND UMTS ANTENNA

1.1. ANTENNA MODEL

The antenna model can be observed in Figure 106. For the plastic piece, DP-T-7140 material [6] was chosen since it is appropriate for reflow soldering, considering the possible usage of lumped components on the plastic piece. This plastic piece is shown in grey colour in Figure 106 and it has a relative permittivity of 4.1 and a loss tangent of 0.0138, given by the manufacturer for 1MHz. The dimensions of the plastic mold are 57mm X 18mm with a height of 5mm. The plastic mold rests on a PCB of FR4 substrate with the dimensions 114mm X 59mm X 0.8mm. There is a ground plane of 75mm X 50mm under the PCB. The main reason of choosing 75mm for the length of the ground plane is to simulate a worst case scenario, where the antenna relies only on the 3.5 inch touch screen of a smart phone, as the ground plane. This is a generic scenario for today's smart phones so the antennas designed are able to be integrated in any smart phone. One point to consider is the additional components (which will have ground connection) in the vicinity of the touch screen so the total ground plane length might be subject to an increase. This increase in the ground plane length will shift its resonance frequency down, enabling easier coverage of the LB. For example, increasing the length of the ground plane from 75mm to 100mm will shift the fundamental wavemode frequency from 1.45GHz to 1.18GHz.

The connection between the metallizations on the plastic mold and the traces on the PCB are achieved by using two pogo pins having 3mm height, under the plastic mold. The antenna basically consists of a driven strip (shown in orange), which capacitively excites a parasitic strip (shown in red) connected to ground on one end. The design methodology when optimizing the final form of the antenna was to tune the length of the parasitic strip, in combination with the driven strip, until obtaining sufficient bandwidth potential for dual-band operation. A meander was introduced to the parasitic element for this reason in the final antenna form. Concerning the input impedance of the antenna, a matching network consisting of four lumped components was decided to be used at the antenna feed.

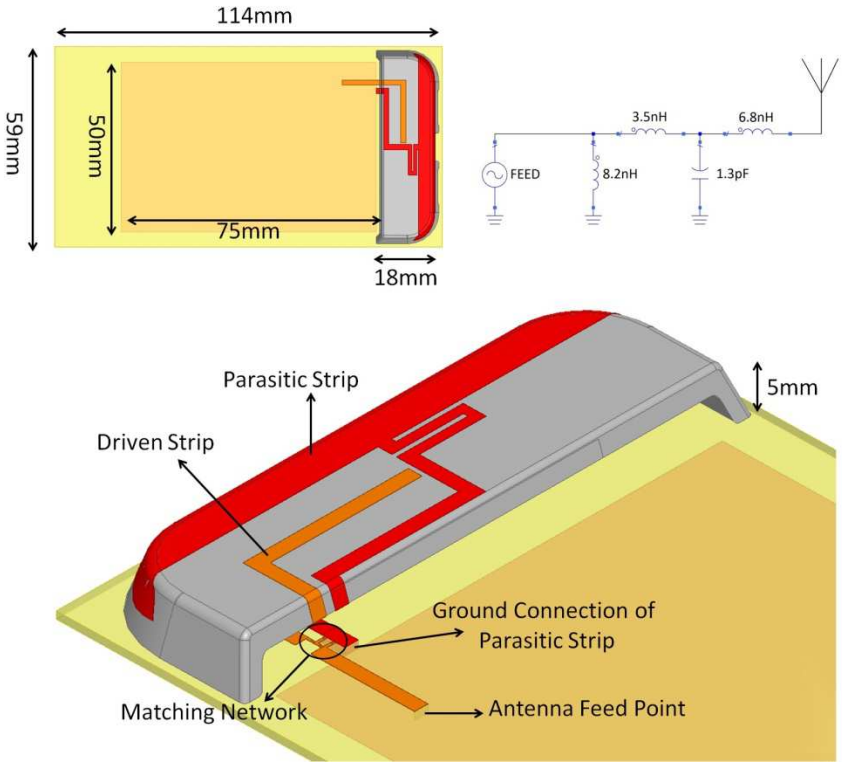

Figure 106 UMTS Antenna Model

To show the effect of the parasitic element on the input impedance of the antenna, simulations were performed in the case of "driven strip only" and "whole structure without MN". These simulation results can be observed in Figure 107, where the LB impedance is plotted between 700-960MHz and HB response plotted between 1.7-2.2GHz. It can be seen from the figure that introducing the parasitic strip creates a resonance in the LB, increasing the real part of the input impedance considerably. This behaviour enables an increase in the bandwidth potential of the antenna especially in the LB (Figure 108).

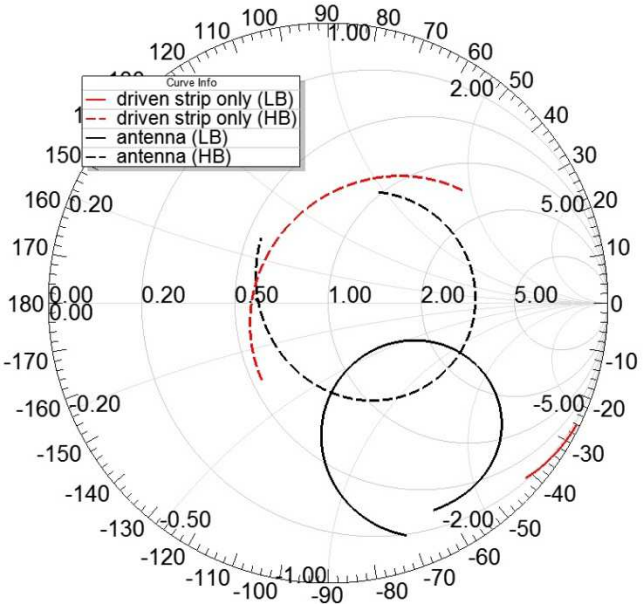

Figure 107 Simulated Input Impedance of the UMTS Antenna, with/without Parasitic Strip

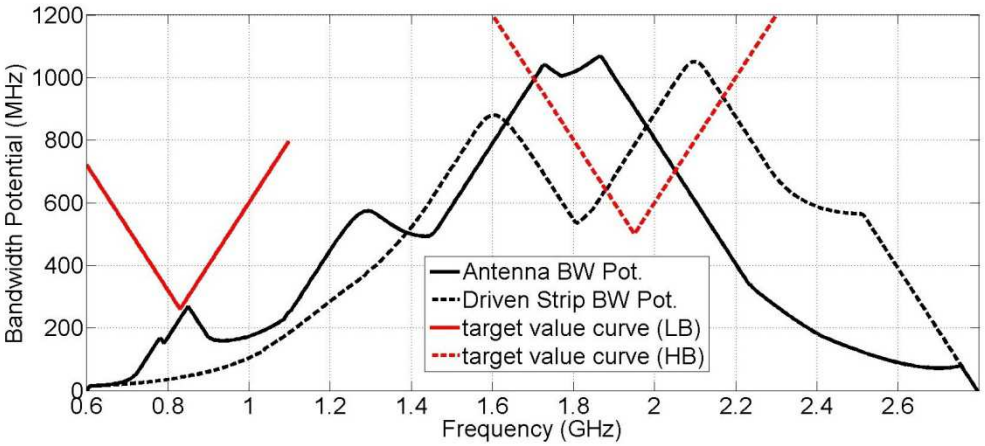

Figure 108 Bandwidth Potential of the UMTS Antenna, with/without Parasitic Strip

The effect of the parasitic element can be also seen looking at the surface current distribution in Figure 109. At 750MHz, a strong excitation of the parasitic element is observed, while its excitation is weaker at 900MHz. It can also be seen that, at both frequencies, the currents on the ground plane are excited almost at the same strength, which enables the exploitation of the low-Q property of the thick ground plane.

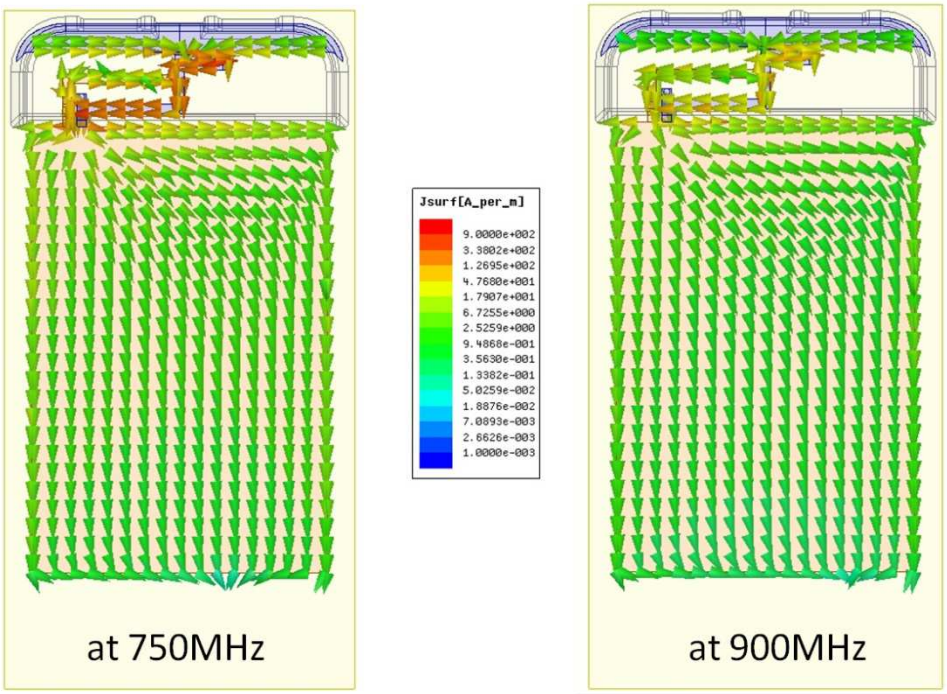

Figure 109 Current Distributions on the UMTS Antenna and Ground Plane

The simulated antenna impedance with and without MN can be observed on smith chart in Figure 110. The corresponding reflection coefficient can also be observed in Figure 111. The antenna can cover the target bands of 700-960MHz and 1.7-2.2GHz, although a small overshoot in reflection coefficient is observed around 780MHz rising up to -5dB (in simulations).

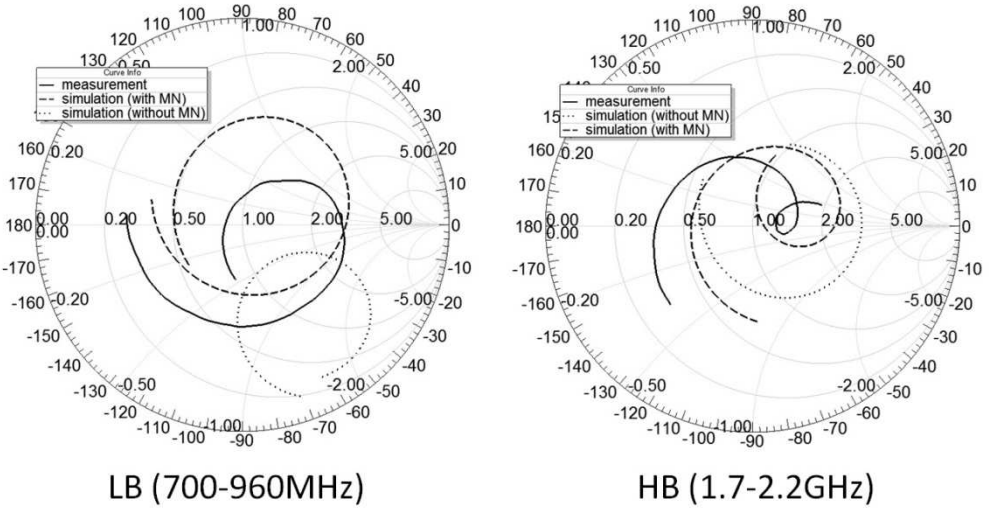

Figure 110 Simulated and Measured Input Impedance for UMTS Antenna, with/without MN

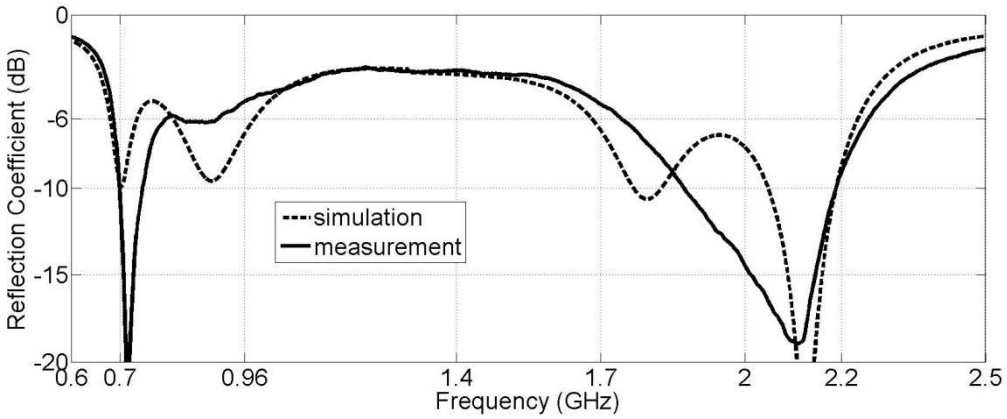

Figure 111 Simulated and Measured Reflection Coefficient for the UMTS Antenna

1.2. MEASUREMENT RESULTS

The manufactured antenna (using LDS technology) can be seen in Figure 112. For the antenna feed, an SMA connector was placed on the PCB as shown in left in Figure 112. To validate the simulation results, s-parameter measurements were performed with the manufactured prototype and are presented in Figure 110 and Figure 111. A fair agreement can be observed between simulated and measured reflection coefficients. The antenna has a measured reflection coefficient below -6dB in the LB and HB with small overshoots around 950MHz and 1.7GHz.

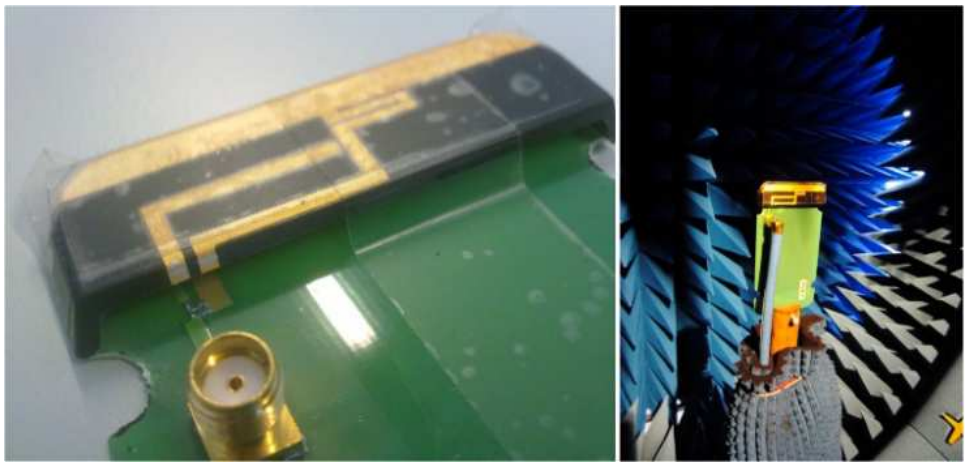

Figure 112 Manufactured UMTS Antenna Prototype and Efficiency Measurement Environment

The total efficiency measurements were also performed in a Satimo Starlab station. Two configurations were measured with this prototype, consisting of short (75mm) and long (90mm) ground plane dimensions. For the long ground plane configuration, the ground plane was extended to 90mm from 75mm by using copper tapes under the PCB. The comparison of the measured reflection coefficient for short and long GND plane configurations is seen Figure 113. Extending the ground plane to 90mm helps for slightly better coverage in the LB (around 950MHz) since most of the radiation is coming from the ground plane around this frequency and the chassis resonance is coming more towards the band of interest by increasing the length (1.28GHz instead of 1.46GHz). The effect is not significant in the HB for this antenna & MN combination.

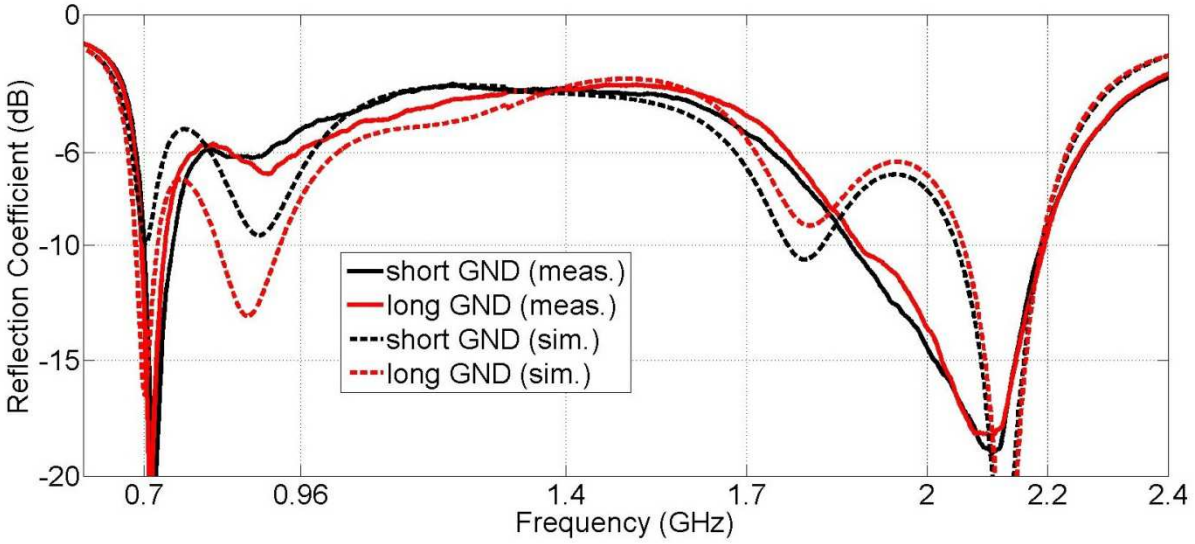

Figure 113 Measured/Simulated Reflection Coefficient of UMTS Antenna with Short/Long Ground Plane

The measured total efficiency for the two configurations can be observed in Figure 114. With the 75mm ground plane, the measured total efficiency is between -7.5dB and -3dB in the LB and between -4dB and -2dB in the HB. Increasing the ground plane length to 90mm has a considerable effect on the total efficiency in the LB, increasing the efficiency by approximately 1.5dB on average. The efficiency in the LB is now between -4dB and -2dB. The efficiency in the HB is not affected by the change, since a major part of the radiation comes from the antenna itself at this frequency range.

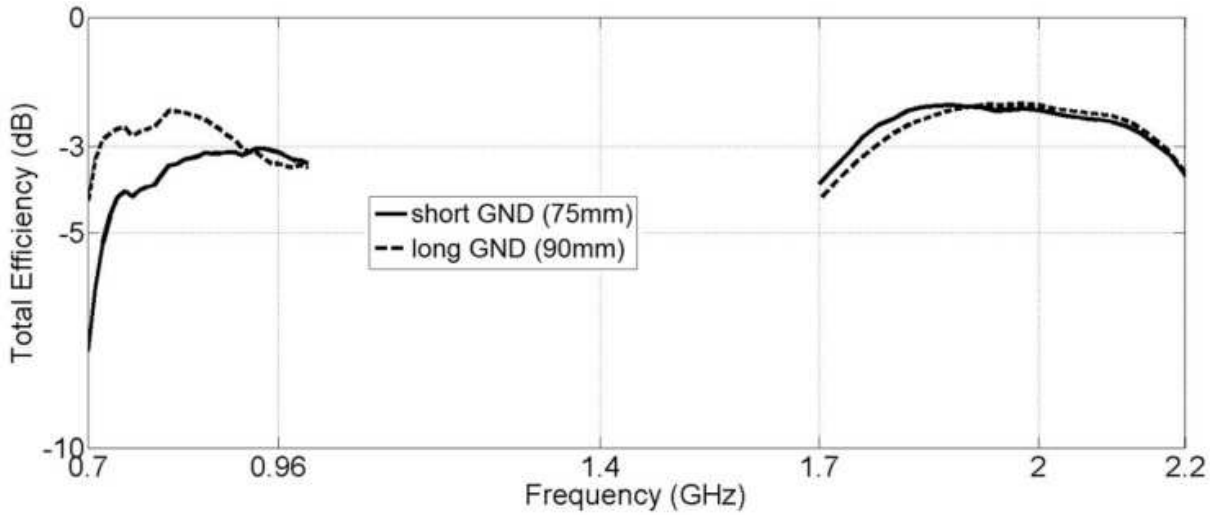

Figure 114 Measured Total Efficiency of UMTS Antenna with Short/Long Ground Plane

2. LTE ANTENNA

2.1. ANTENNA MODEL

A quite similar antenna was designed using the same dimensions for the plastic piece, the ground and the FR4 substrate. The orientation of the driven strip was changed, facing the open end to the corner of the ground plane, to exploit better the low-Q property of the ground plane especially in the HB. The parasitic strip is again excited by this driven strip via capacitive coupling, creating a resonance in the LB, increasing the bandwidth potential. Considering the bandwidth potential of the antenna, a matching network consisting of only two SMD components (a shunt inductor and a series capacitor) was evaluated at the antenna feed but due to the series resonance frequency (SRF) issue, the shunt inductor was split into two inductors, increasing the number of SMD components to three. Pogo-pins were again used under the plastic mold, for the connection of the antenna elements and PCB traces.

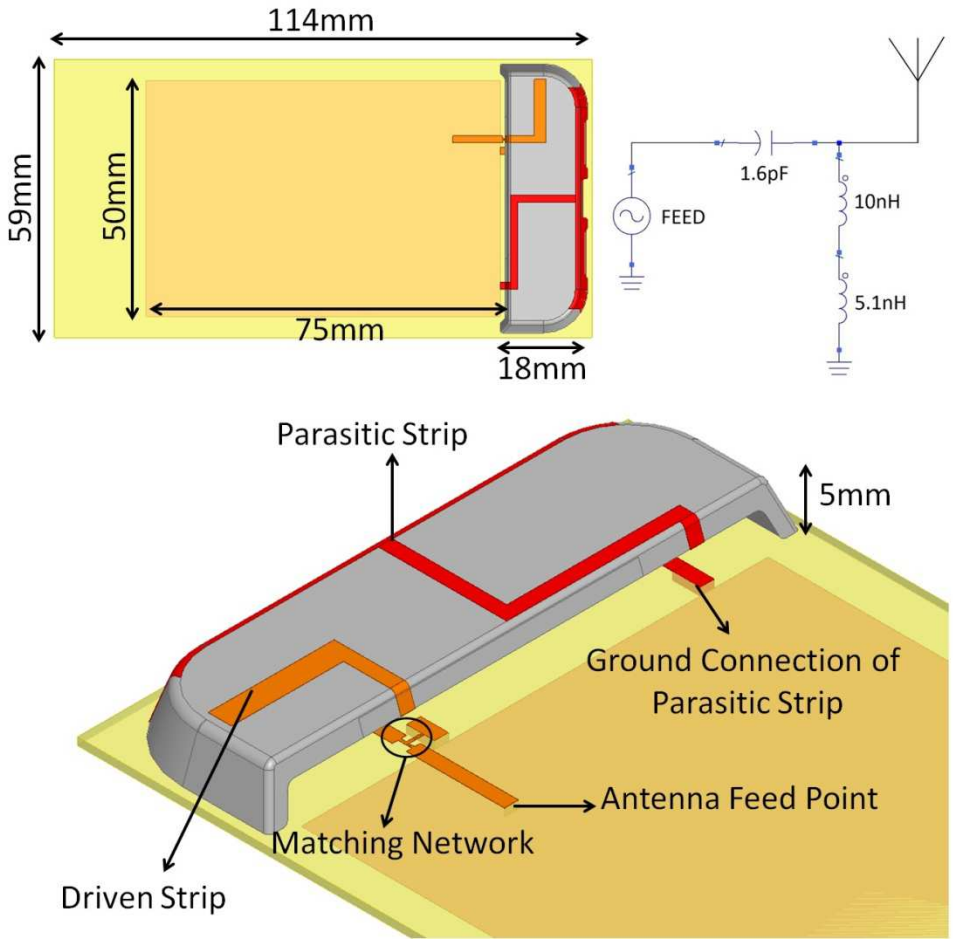

Figure 115 LTE Antenna Model

The simulations were performed for the antenna with and without the parasitic strip (driven strip only). They are presented in smith chart in Figure 116, without any MN at the feed. The introduction of the parasitic element creates a resonance in the LB, increasing the real part of the input impedance. This enables higher bandwidth potential especially in the LB (Figure 117). For the HB response, an additional resonance can also be observed after the introduction of the parasitic element, which occurs approximately around 2GHz (loop in the smith chart).

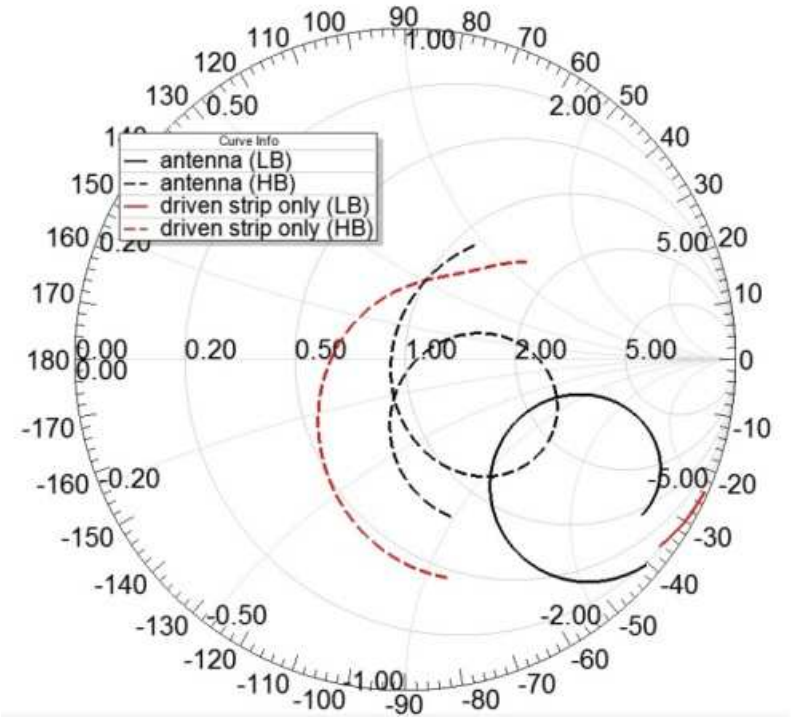

Figure 116 Simulated Input Impedance of the LTE Antenna, with/without Parasitic Strip

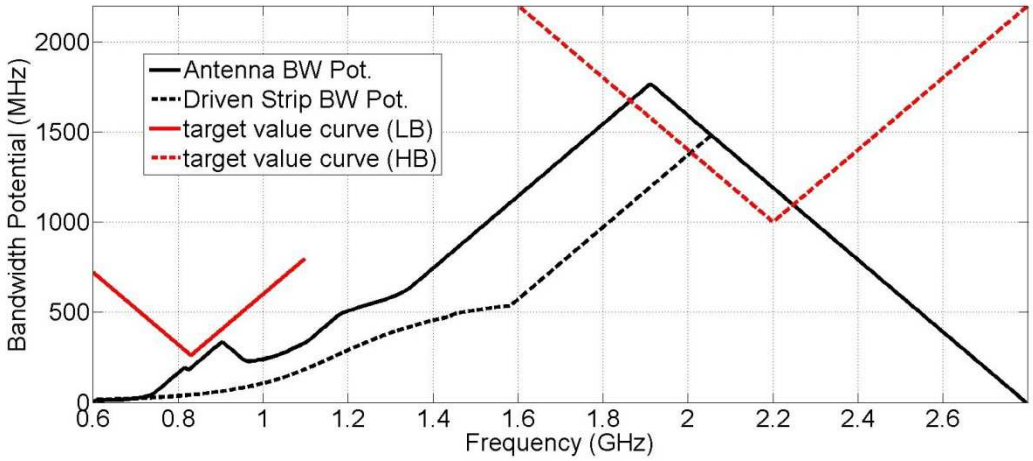

Figure 117 Bandwidth Potential of the LTE Antenna, with/without Parasitic Strip

In order to explain better the role of the parasitic strip in the HB, the input impedance of the antenna structure without MN is given again in Figure 118, with current distributions over the antenna and the ground plane at two different frequency points. There is a loop in the smith chart at 2GHz and when the corresponding surface current is observed, a strong excitation of the parasitic element can be seen. At another frequency point (2.5GHz), the excitation of the parasitic element is weak whereas the driven strip is strongly excited. This suggests that the role of the parasitic element is not confined only within the LB, it also enables higher bandwidth in the HB by creating additional resonance.

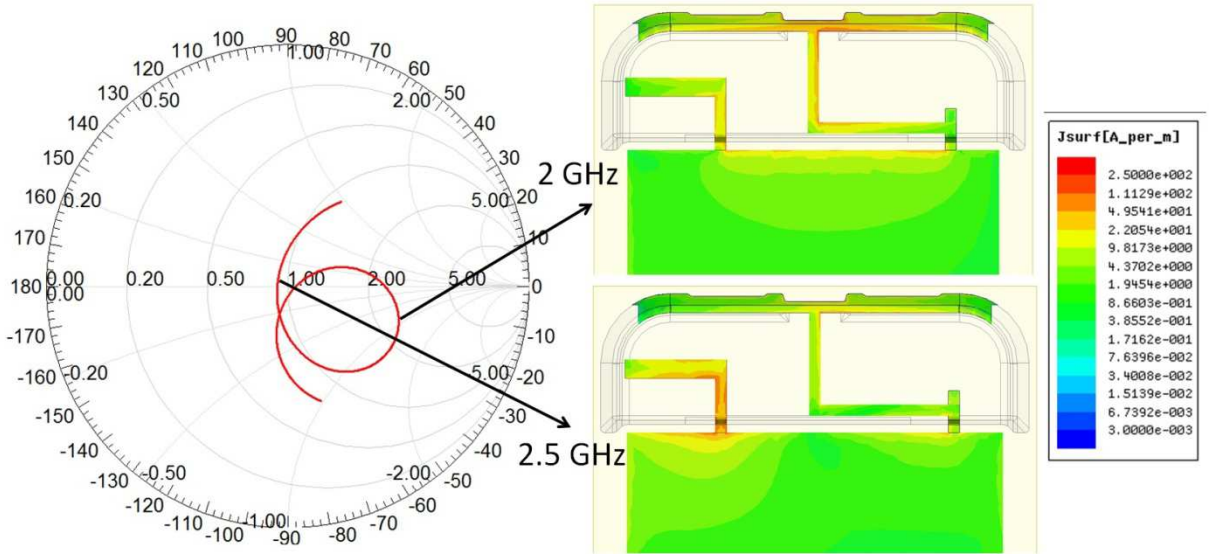

Figure 118 Surface Current Distribution of the LTE Antenna

The simulated input impedance and reflection coefficient of the antenna (with and without MN) are presented in Figure 119 and Figure 120. The antenna can cover the whole target band except some overshoots around 950MHz, 1.7GHz and 2.2GHz.

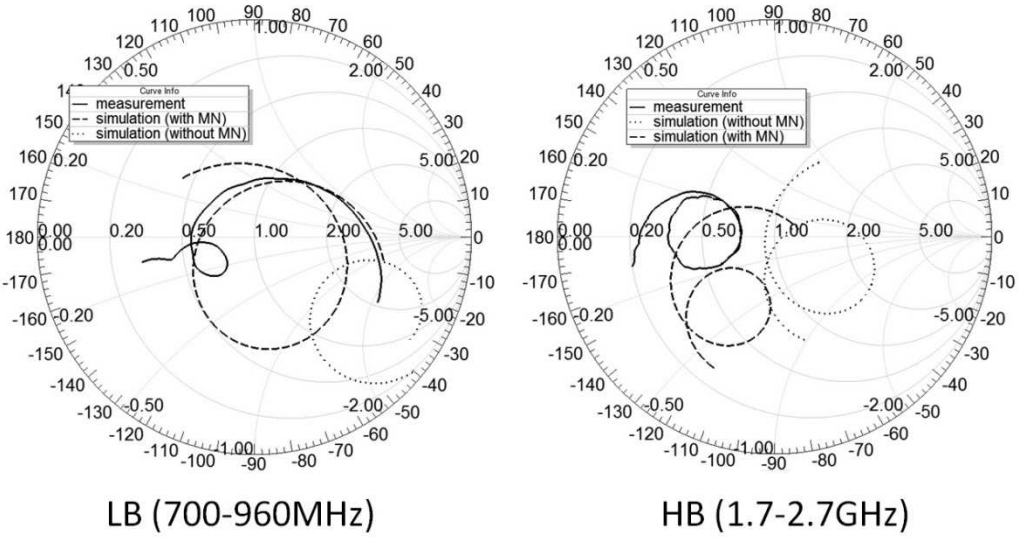

Figure 119 Simulated and Measured Input Impedance for LTE Antenna, with/without MN

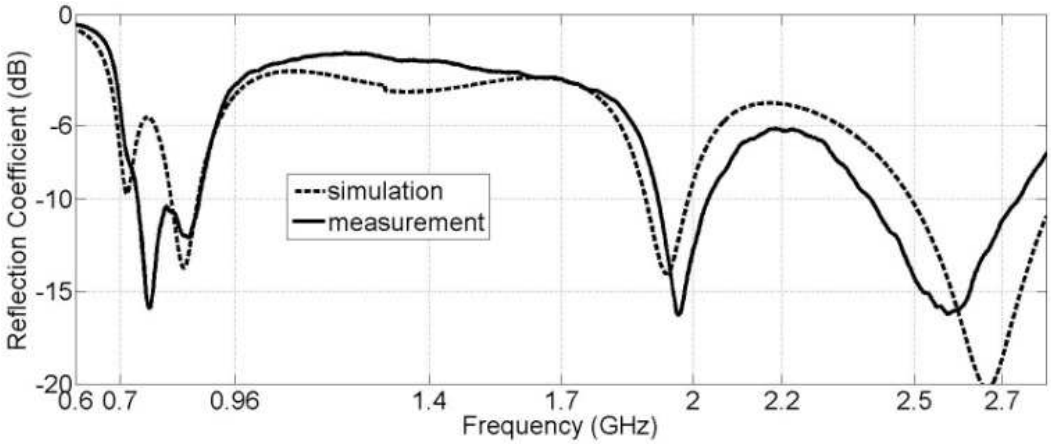

Figure 120 Simulated and Measured Reflection Coefficient of the LTE Antenna

2.2. MEASUREMENT RESULTS

The manufactured antenna prototype can be seen in Figure 121. The antenna is fed through an SMA connector placed on the PCB. The comparison of the measured and simulated reflection coefficient can be seen in Figure 119 and Figure 120. A fair agreement is observed between simulation and measurement results. The agreement is less obvious for LB in smith chart, which may be coming from the misalignment of the plastic piece on the PCB. In the HB, the difference in the input impedance is only a phase difference, coming from the possible differences on the feed line between simulation and measurement.

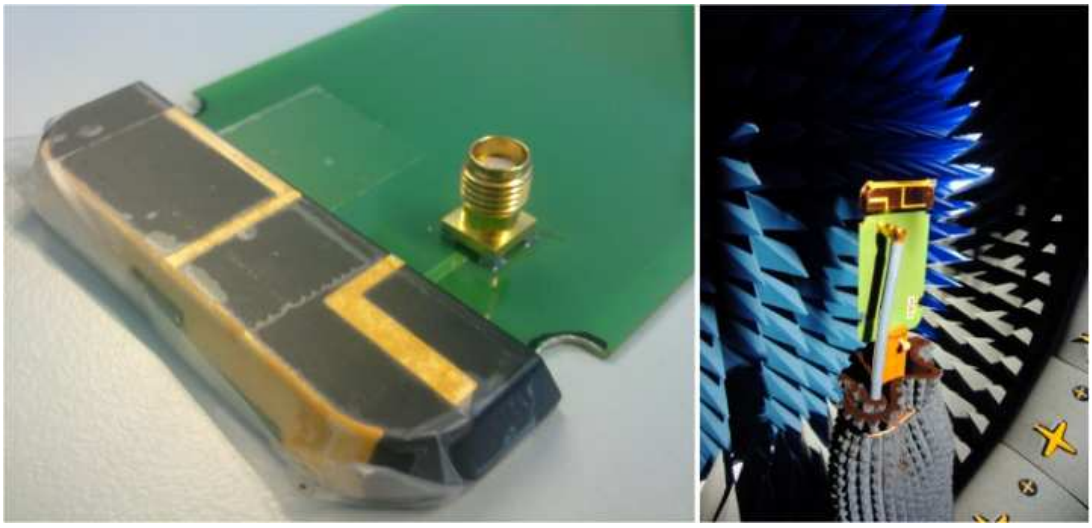

Figure 121 Manufactured LTE Antenna Prototype and Efficiency Measurement Environment

The s-parameter measurements for this antenna were performed also with the longer ground plane (90mm) configuration, whose results are presented in Figure 122. In Figure 123, an efficiency between approximately -7dB and -3dB is seen in the LB with short GND plane. However the efficiency drops further to -10dB for a narrow bandwidth, around 700MHz. When the ground plane length is increased to 90mm, an improvement is observed as expected, efficiency being between -5dB and -2.4dB. The measured efficiency is below -5dB between 700-800MHz for short ground plane and between 700-730MHz for long ground plane. The HB efficiency is not affected by the change in the length of the ground plane and is between -5dB and -1.8dB for both cases.

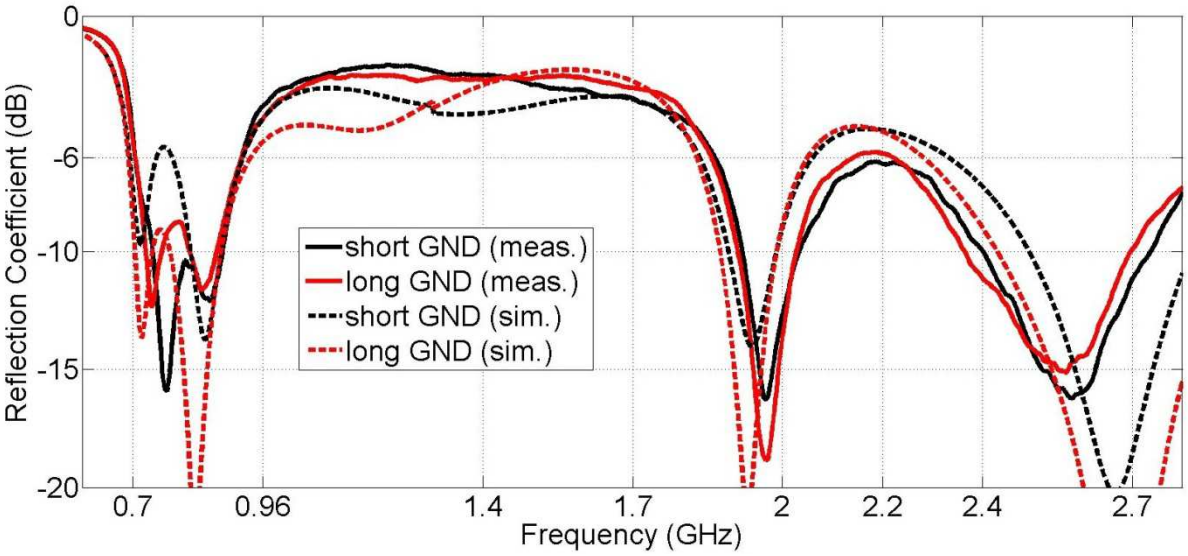

Figure 122 Measured/Simulated Reflection Coefficient of LTE Antenna with Short/Long Ground Plane

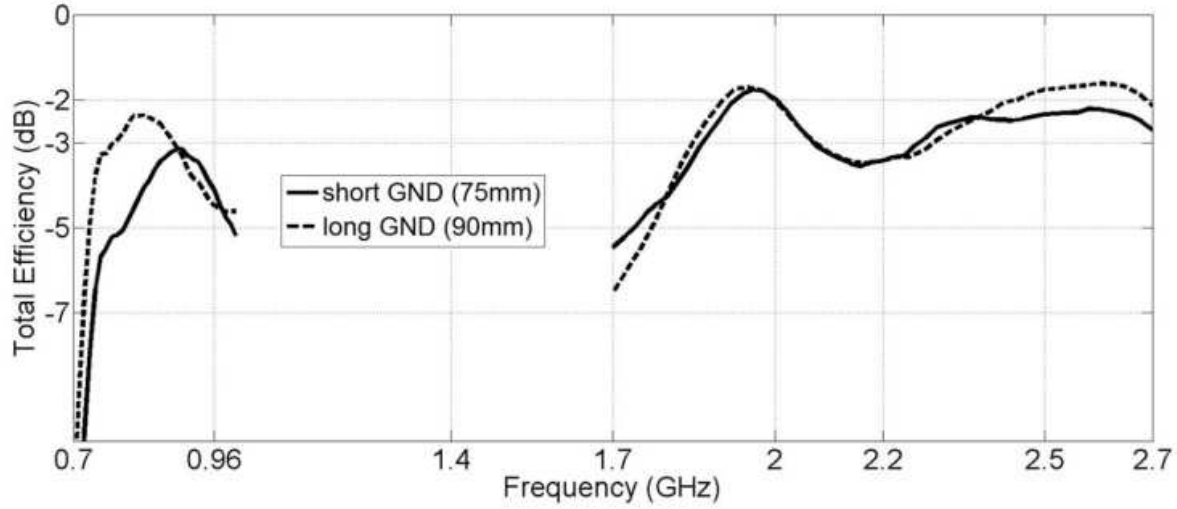

Figure 123 Measured Total Efficiency of LTE Antenna with Short/Long Ground Plane

To investigate the reason of the very low radiation efficiency at 700MHz, surface currents were plotted at 700MHz, 750MHz and 900MHz (Figure 124). The parasitic element is strongly excited at 700MHz and the current circulates following the path of: antenna feed-driven strip-parasitic strip-ground plane-back to the antenna feed. For this reason, the currents on the ground plane (especially on long edges of the PCB) are weak, when compared to the more uniform excitation (in the longitudinal direction) of the ground plane at 750MHz and 900MHz. Since most of the radiation comes from the first chassis wavemode at the lower frequencies, the low radiation efficiency can be explained by the currents circulating between the driven strip and parasitic strip and not forming the first wavemode.

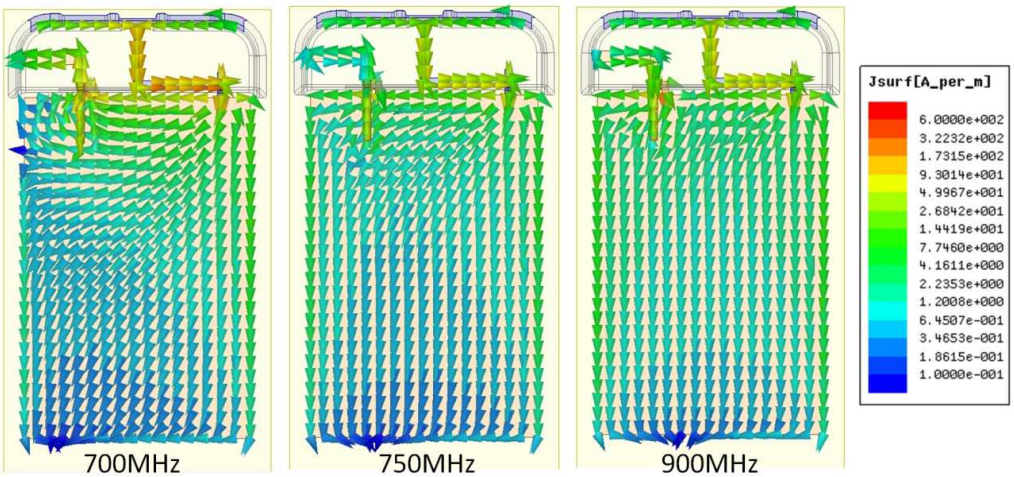

Figure 124 Surface Current Distribution of the LTE Antenna in the LB

3. INVESTIGATION OF THE USER EFFECT

The effect of the user's hand and head on the efficiency and matching of the antenna was investigated through measurements using the two antenna prototypes which were designed for free space. It is worthwhile to note that the antennas were not designed on purpose to be resistant to detuning and the main aim of the study was to form a basis for future studies.

As widely known, the user's hand and head affects the antenna performance in two ways. The first effect is the change in the reflection coefficient due to dielectric loading. The second effect is the reduced total efficiency, due to the lossy characteristics of different body tissues in the near field of the radiating elements and this last effect is difficult to avoid as a lot of power will be lost in those lossy tissues.

To investigate both these effects, s-parameter and total efficiency measurements were performed, using CTIA hand and head phantoms (Figure 125 on left taken from [7]). In order to perform a more realistic measurement, a dielectric casing made of ABS P430 material was used (white structure in Figure 125 on right). The relative permittivity of the ABS material is 2.4 and the loss tangent is 0.0053.

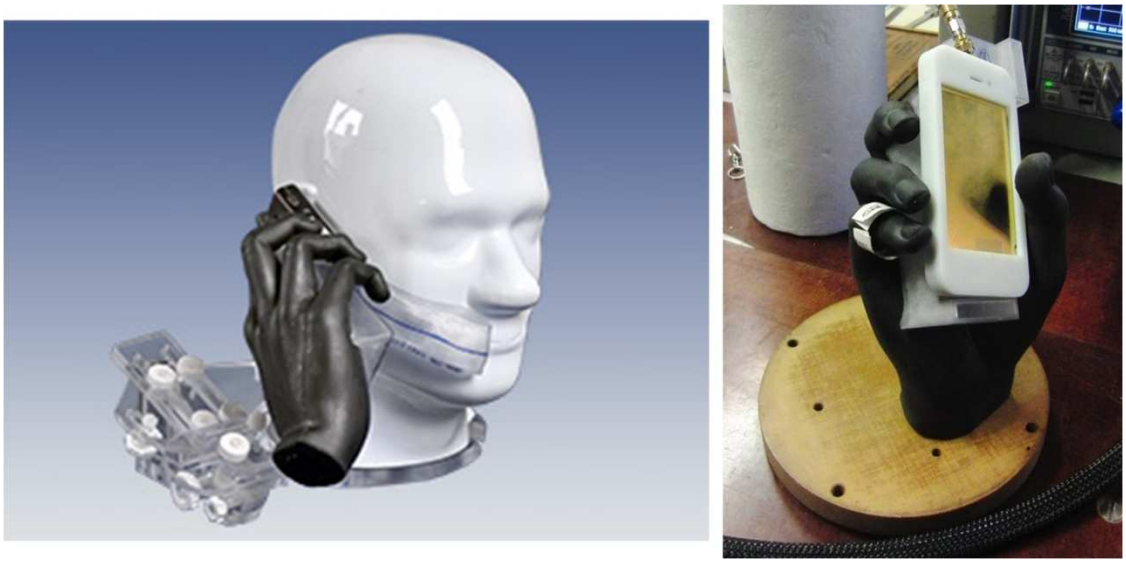

Figure 125 CTIA Hand and Head Phantoms and Dielectric Casing

Figure 126 Efficiency Measurement Setup Taking into Account the User's Head and Hand

The s-parameter measurements of the UMTS antenna in four different cases are presented in Figure 127. These four cases are defined as:

- Free Space
- Casing: The antenna placed inside the dielectric casing
- Hand: The antenna placed in the CTIA hand with the casing
- Head + Hand : The antenna with casing, placed between the CTIA hand and head phantom

It is necessary to note that the antenna was placed on the bottom of the PCB (facing the palm) in the measurements with hand, to stand for the real use case in today's mobile phones.

It is a well known fact that introducing the user's hand to an antenna will shift its operating frequency down, due to dielectric loading. This behaviour can be seen Figure 127 for the UMTS antenna. With the introduction of the hand and head into the s-parameter measurements, a shift in the frequency of minimum $|s_{11}|$ can be seen towards the lower frequencies. The detuning in the matching of the antenna is more dominant in the LB. The measured total efficiency for the four cases (free space, with casing, with casing and hand, with casing and hand and head) can be seen in Figure 128. It is observed that introducing the casing into the antenna had a positive effect on the efficiency through dielectric loading. The resonance created by the parasitic strip around 700MHz (which has lower efficiency than other frequencies since the currents are concentrated mainly on the parasitic strip so that chassis wavemode is excited weakly) is shifted down, which increases the radiation efficiency (and thus total efficiency) in the band of interest. When the hand phantom is taken into account, there is a decrease in the total efficiency of approximately 5dB in the LB, decreasing the efficiency to the levels below -8dB, due to both detuning effects and loss mechanisms. The same behaviour can also be seen in the HB, where the efficiency drops to the levels around -5dB due to losses in the hand. When the head is also taken into account with the hand, the antenna detuning gets more severe (in the LB) and further decrease is observed in the measured efficiency. The efficiency level is between -17dB and -14dB in the LB and between -13dB and -10dB in the HB.

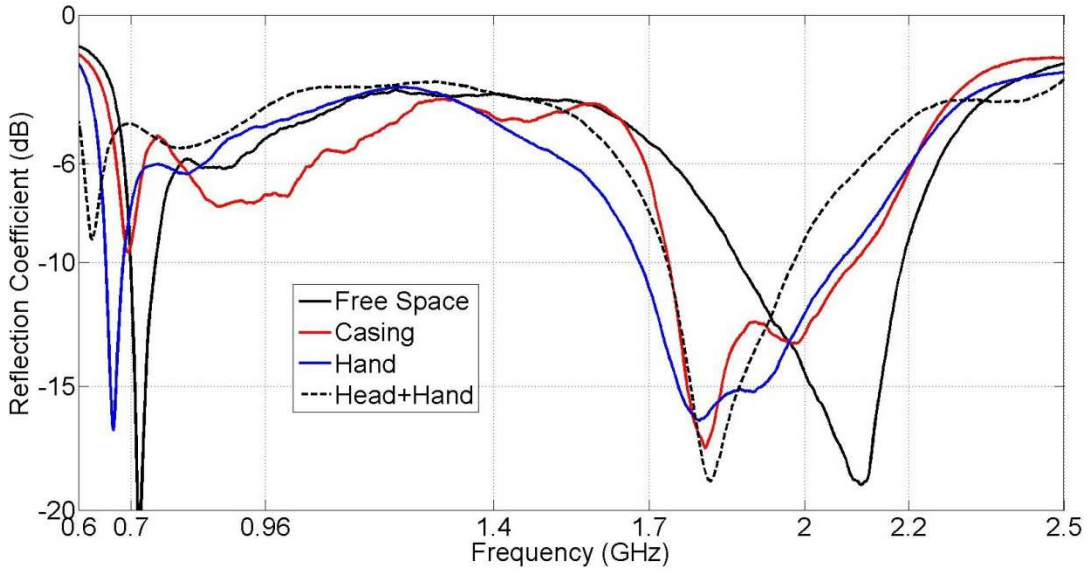

Figure 127 S-Parameter Measurements of the UMTS Antenna with User Effect

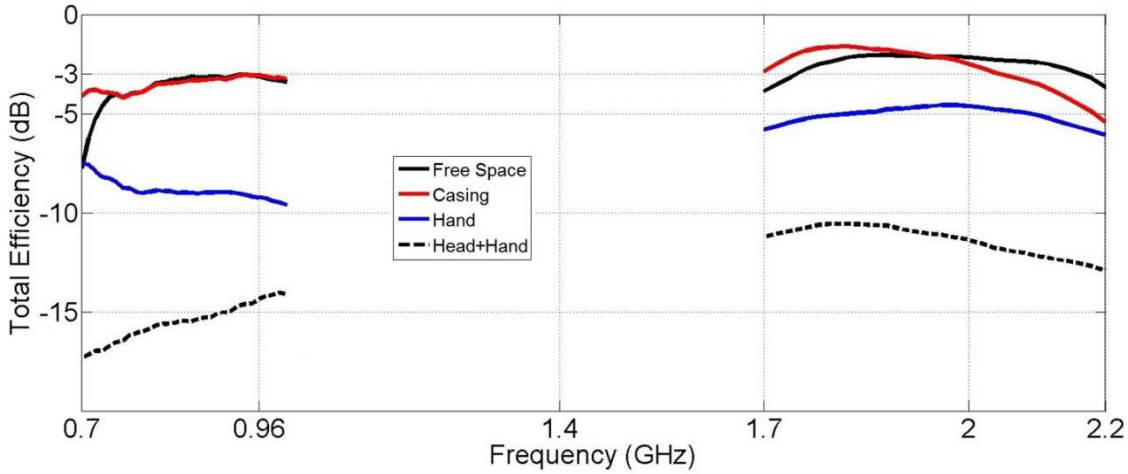

Figure 128 Total Efficiency Measurement of the UMTS Antenna with User Effect

The same comments are applicable also to the measurement results of the LTE antenna. The s-parameter and total efficiency measurement results for this antenna can be seen in Figure 129 and Figure 130 respectively. About the detuning, the antenna stays more or less tuned in the LB in "casing" and "hand" configuration except some narrow overshoots. The mismatch is severe when the head is introduced. The effect is less in the HB and the antenna is matched despite the user effect, although some overshoot is seen with the casing. For the efficiency, when the hand is taken into account, it drops to the levels between -10dB and -7.5dB in the LB and between -10dB and -3.5dB in the HB. When the head is also introduced, efficiency levels between -19dB and -17dB in the LB and between -13dB and -9dB in the HB are observed.

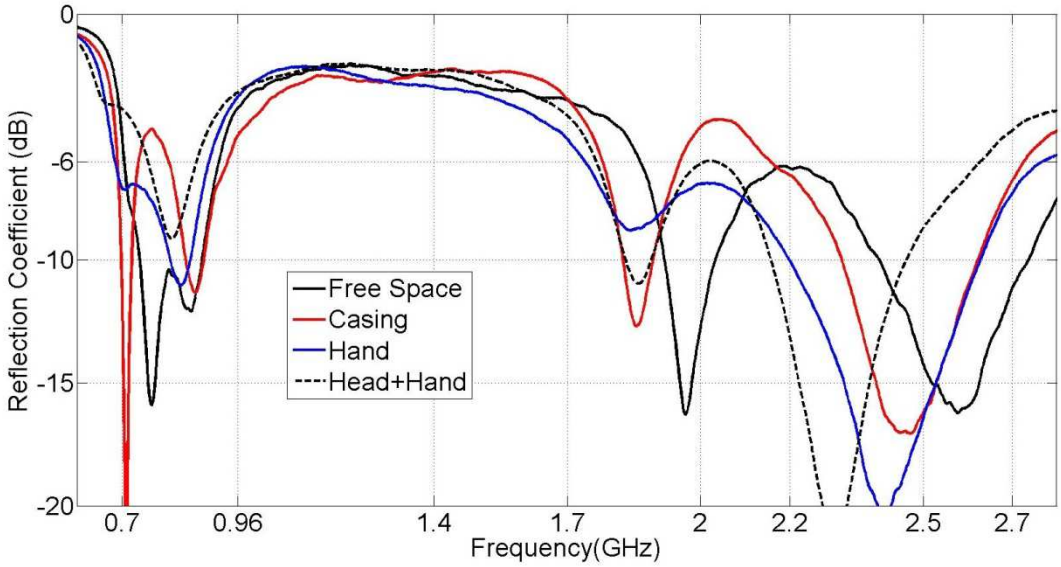

Figure 129 S-Parameter Measurement of the LTE Antenna with User Effect

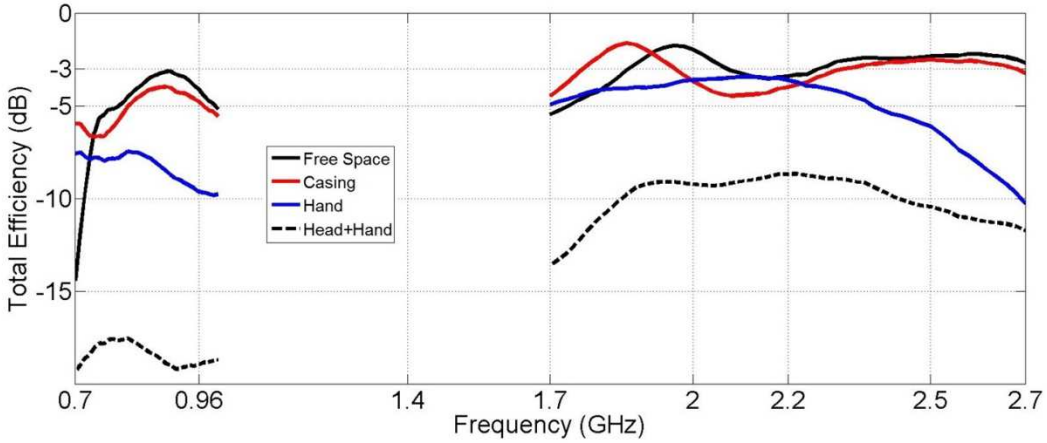

Figure 130 Total Efficiency Measurement of the LTE Antenna with User Effect

4. CONCLUSION

In this chapter, two different antenna designs were presented targeting the 4G communication frequency bands. Both antennas proposed are single feed antennas realized on plastic material using Laser Direct Structuring (LDS) technology. The major design challenge is the relatively short ground plane of 75mm, to rely only on the 3.5" touchscreen of a smart phone as the ground plane.

The first antenna consists of a driven strip, which capacitively excites a parasitic strip connected to the ground plane. With this topology, a high bandwidth potential can be achieved in the LB (700-960MHz) where the antenna is electrically small. With a four element MN introduced to the antenna feed, the low LTE (700-960MHz) and UMTS (1.7-2.2GHz) frequency range can be covered with a single feed design with a reflection coefficient below -6dB. The simulation results have been verified through measurements and total efficiency results for the antenna have been presented.

A similar topology was used for a second design where the driven strip capacitively excites a parasitic element but the orientation of the driven strip was changed. In this way, the additional coverage of the WLAN and high-LTE bands was also made possible.

Finally, an investigation about the effect of the user's hand and head was done using the two antennas. Measurements were performed with a dielectric casing, CTIA hand and head phantom to see the effect on both the s-parameters and total efficiency. Table 5 summarizes the measured total efficiency values in the presence of user hand and head. for the two prototypes. There is also a number of studies, investigating the effect of the user on antennas for mobile terminals like in [8-11]. For example in [4], a CE antenna with a shielding structure was proposed for GSM/UMTS bands. The shielding structure was used to reduce the interaction between the user and the antenna. In the "antenna on top" configuration, the measured efficiency was -10dB at 900MHz and -7.5dB in HB with hand and head. It is worthwhile to state that antenna on top configuration (when the antenna faces only the index finger) is more advantageous than "antenna on bottom" configuration used in this study since the detuning is less effective and absorption losses are less. In [9], a CE with multiband MN was used to cover low LTE/GSM/UMTS bands, with special attention to mitigate detuning in the design phase. The main target was to minimize the detuning especially in the LB when the antenna is placed on top of the PCB. The measurements were performed with the hand only in both on top and on bottom placements. An efficiency drop of approximately 7dB was seen in efficiency measurements with hand when compared to free space. In [10], a dual feed antenna structure was proposed on Rogers 4003 substrate. The LB coverage (700-960MHz) was achieved thanks to a CE and the HB coverage (1.7-2.7GHz) was done using a portion of the CE by offset feeding. This antenna was also designed on purpose to be resistant to detuning when the antenna is on top of the PCB. The measured efficiency drop (compared to free space) with the hand (when antenna is on bottom) was -6.5dB in LB and -7dB in HB. Finally in [11], the user effect was investigated on a narrowband PIFA antenna covering GSM900/DCS1800 frequency bands. An efficiency drop of 11dB at 900MHz and 8.5dB at 1800MHz was measured with hand and head when the antenna is placed on bottom of the PCB.

When the data in Table 5 are compared with corresponding results from these studies, it can be concluded that the efficiency levels obtained by the two antennas presented here are competitive in terms of total efficiency. It should also be noted that no specific effort was spent considering the user effect in the design phase, and a ground plane of only 75mm was used in this study. It was previously shown that an additional increase of 0.5dB can be obtained making the ground plane length 90mm.

Table 5 Summary of the Measured Efficiency Taking into Account the User Effects

		UMTS Antenna	LTE Antenna
With Hand	Eff. in LB	Between -7dB & -9dB	Between -8dB & -10dB
	Eff. Drop from FS (LB)	4dB	3dB
	Eff. in HB	Between -4dB & -6dB	Between -10dB & -3dB
	Eff. Drop from FS (HB)	3dB	2dB
With Hand+Head	Eff. in LB	Between -17dB & -14dB	Between -19dB & -17dB
	Eff. Drop from FS (LB)	11dB	14dB
	Eff. in HB	Between -10dB & -13dB	Between -13dB & -9dB
	Eff. Drop from FS (HB)	9dB	7dB

5. PERSPECTIVES

It was mentioned previously that the results obtained from user effect study will be used for future studies on this subject. As also mentioned in Conclusion part, there has been a number of studies to design mobile terminal antennas resistant to detuning (mismatching) when the antenna is located on the top of the PCB. This configuration is less problematic when compared to "antenna on bottom" configuration, since the antenna only faces the index finger (instead of the whole palm) which results in less severe detuning compared to bottom location. It is also worthwhile to note that the antenna is generally located at the bottom of today's smart phones. For these reasons, it would be better to focus the future studies on an antenna resistant to detuning due to user's hand and head, when the antenna is placed on the bottom of the PCB.

In addition to the antennas presented in this chapter, some more measurements were also performed on the hollow CE antennas (presented in chapter III) with the CTIA hand. The main target was first to obtain the general behaviour of the impedance change of an optimally-overcoupled antenna(placed on the bottom of PCB) in presence of the user's hand. The measured input impedances of the two different hollow CE antennas are given in Figure 131 for free space (FS) and with hand configurations.

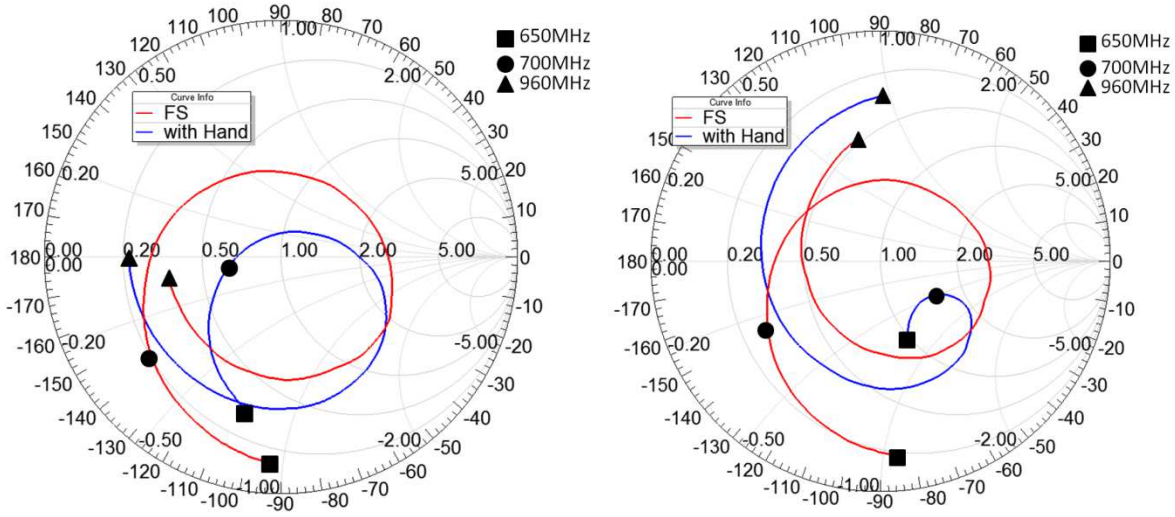

Figure 131 Measured Input Impedance of Hollow CE Antennas in FS and with Hand

Evaluating these results about the input impedance in a geometrical way in smith chart, it can be told that the impedance loop in FS condition is subject to shrinking when the user's hand is introduced. Due to the dielectric loading, the lower frequency point of the loop is pulled through the middle, where the higher frequency points are pushed out of the loop (Figure 132).

This can be verified by turning back to the results in Figure 131. For the antenna on left, the 700MHz point (shown with a circle) is initially quite outside of the starting region of the loop (in FS). When the hand is introduced, this point goes inside the loop and as a consequence the starting frequency of the loop falls to frequencies like 650MHz. The 960MHz point (shown with a triangle) which is close to the end point of the loop in FS, is pushed out of it when the hand in introduced. A similar behaviour can also be seen for the results in the smith chart on right.

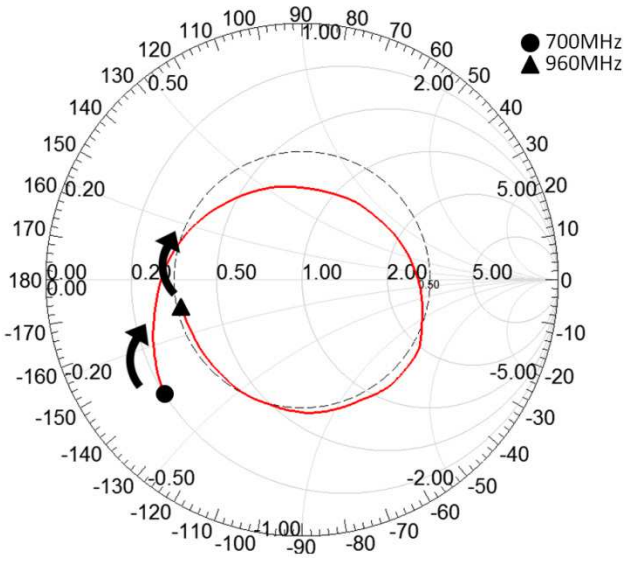

Figure 132 Geometrical Analysis of the Impedance Change with User's Hand
